PREPARATION OF THIS DOCUMENT

The study of ichthyoplankton is crucial in understanding the dynamics of fish populations. The knowledge of the distribution and abundance of fish eggs and larvae, obtained through plankton surveys can, among other things, help scientists improve the understanding of the spatial distribution of fisheries resources and the processes affecting the fluctuations in recruitment; two important underpinnings of fish stocks assessment and management. The FAO Regional Project “CopeMed Phase II”: Coordination to Support Fisheries Management in the Western and Central Mediterranean” has among its priorities the strengthening of research capabilities in its member countries in support of sustainable management of fishery resources. In February 2016, the Project organized a course on ichthyoplankton identification at the Spanish Institute of Oceanography, in Fuengirola (Málaga). For this course, the lecturer and co-author of this guide, J.M. Rodríguez, prepared a collection of technical sheets for several larval fish species with their corresponding description and illustrations. During the course, the scarcity of identification guides for the Mediterranean Sea was noticed. Participants asked the organizers to expand the number of sheets of the species used at the course and requested that CopeMed II publish a FAO Guide including the most common species occurring in the Mediterranean Sea. The present guide is the outcome of this process. It presents the egg and larval descriptions of 100 species of fishes belonging to 55 families, which are most likely to be present in the plankton samples collected in the continental shelf and oceanic waters of the Western Mediterranean Sea. The document is not meant to be a complete guide for ichthyoplankton of the Western Mediterranean Sea but a comprehensive tool with which to support students and researchers new to the field of ichthyoplankton identification.

ABSTRACT

This guide presents the egg and larval descriptions of 100 species of fishes belonging to 55 families, which are most likely to be present in plankton samples collected in the continental shelf and oceanic waters of the Western Mediterranean Sea. The guide is structured in two parts. The first introductory part describes the different applications of ichthyoplankton studies in fisheries research, the main sampling strategies, methods and gears, the early life history of fishes and how to identify them. A brief historical account of ichthyoplankton identification studies in the Mediterranean Sea is also provided. The second part of the guide contains the identification sheets of the species. Each species sheet includes the following information: illustration of the adult fish and information on its habitat and spawning season; description of the main features useful towards identifying the egg, yolk sac and larval stage of each fish species; illustrations and (when available) photos of the different life stages.

ACKNOWLEDGEMENTS

This guide was prepared in support of the training courses for identification of early life stages of fish implemented by the FAO through the Mediterranean Regional Project “CopeMed II” (Coordination to Support Fisheries Management in the Western and Central Mediterranean). CopeMed II is funded by the Government of Spain, represented by the Secretaría General de Pesca (Mº de Agricultura, Pesca, Alimentación y Medio Ambiente, MAPAMA), and the European Union, represented by the European Commission (EC).

The authors would like to thank Pilar Hernández, CopeMed II Fishery Expert, who supervised the whole elaboration process and Marcelo Vasconcellos, FAO Fishery Resources Officer, who provided overall support and feedback. Many thanks to the two anonymous reviewers who, with their precious suggestions and comments, have significantly contributed to the improvement of the original manuscript.

The authors also wish to express their gratitude to the publishers and authors that gave their permission to use figures from their publication, such as:

- American Fisheries Society
- American Society of Ichthyologists and Herpetologists
- Dr. Bill Richards
- Fishery Bulletin
- Ichthyological Bulletin of the J.L.B. Smith Institute of Ichthyology
- International Council for the Exploration of the Sea (ICES) · Conseil International pour l'Exploration de la Mer (CIEM)
- Investigación Pesquera
- Investigaciones Marinas Valparaiso
- Journal of Northwest Atlantic Fisheries Science
- Journal of Plankton Research
- Journal of the Marine Biological Association of the United Kingdom
- Scientia Marina
- South African Journal of Aquatic Science

All photos included in the introduction and species sheets were provided by the authors.

Finally, J.M. Rodríguez would like to thank his wife Rosa Vázquez for revising the manual, correcting many typographical errors and spelling mistakes, and improving the quality of several illustrations.
1. INTRODUCTION

1.1 What is ichthyoplankton?

The early life stages (eggs and larvae) of marine fishes are referred to as ichthyoplankton (Fig. 1). Some species of marine fishes produce demersal eggs that lay on the sea bottom, or are even deposited in nests. Demersal eggs of a number of species are under parental care, extended in some exceptional cases, such as in sea horses, to the larval stage. However, most marine fish species spawn pelagic eggs. Larvae hatched from pelagic and from most demersal eggs are pelagic. Due to their null (eggs) or limited (larvae) swimming abilities, they are both integrated within the plankton community as part of the meroplankton (organisms that only spend part of their life cycle within the plankton community). Ichthyoplankton is mainly found in the upper layers (from 200 m depth to the surface) of the water column, where it is subject to spatial dispersion, mainly by marine currents. The planktonic stage of fishes usually lasts from a couple of weeks to a few months (Victor, 1986; Brothers et al., 1983).

During the larval stage, larvae develop specializations for the planktonic life and other important changes occur. For example, most fishes increase their weight by five orders of magnitude throughout their life and three of them occur during the planktonic stage (Werner and Gilliam, 1984; Houde, 1987; Miller et al., 1988). The end of the larval stage is marked by a metamorphosis or transformation process, more or less abrupt depending on the species, during which the larva becomes a juvenile that is morphologically similar to the adult and has the meristic characters of the species. Juveniles of pelagic species are integrated in the nekton community and those of most demersal species migrate directly to the bottom, after the metamorphosis. However, in several demersal species, where the transformation is prolonged, there is an intermediate stage (called the pre–juvenile stage) where the fish develops specializations that are distinct from both larvae and juveniles. These pelagic pre–juveniles eventually transform into demersal juveniles (Kendall et al., 1984). Pelagic pre–juveniles of demersal species and the early juveniles of the pelagic ones maintain an intense relationship, mainly trophic, with the plankton community, but because of their behaviour and swimming abilities, they cannot be considered ichthyoplankton, they become part of the micronekton.
1.2 Why study ichthyoplankton?

There are several reasons for studying ichthyoplankton. For example, information regarding the distribution and abundance of fish eggs and larvae can provide clues to spawning locations and environmental requirements of important fish species. Moreover, the knowledge of ichthyoplankton is necessary because, as one of the components of the pelagic food web (Raymont, 1983), it can represent an important link between smaller planktonic and larger nektonic organisms. In addition, as most fishes inhabit the upper water column during their early life history and have limited avoidance capability, ichthyoplankton surveys provide a relatively low–cost efficient means to monitor marine fish populations and communities (Koslow and Wright, 2016). Finally, survival of fish larvae may directly influence future abundances of adult fish stocks. The latter has been and it still is the most important reason for studying ichthyoplankton, as most processes determining the recruitment strength and the spatial distribution of fish populations occur during the planktonic stage of fishes, resulting in important interannual fluctuations in fish stock biomasses. Such fluctuations have been known for centuries, but they started to worry scientists and fishery managers only at the end of the nineteenth century (Petersen, 1894; Garstang, 1900). Initially, it was thought that fishing pressure itself or fish migrations were responsible for such fluctuations, but at the beginning of the twentieth century, Hjort (1914, 1926), after analysing the causes of the successful herring year–class of 1904, suggested that the variability in “year–class success” was determined during the early life stages of fishes. He proposed two hypotheses to explain those fish stock fluctuations resulting from interannual recruitment variability, the Critical Period Hypothesis and the Aberrant Drift Hypothesis, or larval transport to unfavourable areas (due to interannual variability in ocean circulation), from which juveniles could not recruit to the exploited stock.

According to the Critical Period Hypothesis, the strength of a year–class is determined shortly after yolk–sac absorption, at the beginning of exogenous feeding, when larvae must find suitable prey and in sufficient amounts (Fig. 2). Failing to find adequate feeding conditions would lead to massive larval mortality, in a short period of time. Hjort’s hypotheses laid the groundwork for future research on recruitment variability, mainly focused on the Critical Period Hypothesis (Cowan and Shaw, 2002; Houde, 2008), fostering the development of “recruitment fisheries oceanography” as a multidisciplinary science to investigate the spectrum of oceanographic processes controlling recruitment (Kendall and Duker, 1998).
food limitation at any time of the larval period, rather than mortality being concentrated at a specific larval stage, could be a major contributor to the recruitment variability. In addition, abiotic factors that regulate water–column mixing and the timing and intensity of seasonal production cycles may be involved.

Lasker (1981), in the Stable Ocean Hypothesis, proposed that the occurrence and frequency of calm periods in upwelling ecosystems (named Lasker events) lead to stratification of the water column and, hence, the aggregation of fish larvae and their prey, supporting high larval feeding, survival and recruitment. A further extension of Lasker’s Stable Ocean Hypothesis was the Optimal Environmental Window (OEW) Hypothesis by Cury and Roy (1989). These authors hypothesized that, in upwelling ecosystems, the relationship between annual recruitment of small pelagic fish species (sardines and anchovies) and upwelling intensity is dome shaped, confirming the existence of an optimal environmental window for recruitment, with recruitment most successful under moderate (roughly 5–6 m*s–1) wind stress that controls both ichthyoplankton advective losses and food availability for fish larvae. On the contrary, weak winds, if prolonged, disrupt the upwelling process and the renewal of nutrients in the surface layer, inducing nutrient limitation, which reduces primary productivity (Huntsman and Barber, 1977) and food availability for fish larvae. Finally, strong winds generate strong turbulence that also limits primary productivity (Huntsman and Barber, 1977) and increases the offshore transport of fish egg and larvae (Bakun and Parrish, 1982).

Based on the Hjort’s Aberrant Drift Hypothesis, Iles and Sinclair (1982) and Sinclair (1988) proposed the Larval Retention or Member/Vagrant Hypothesis. In this hypothesis, larval retention, not levels of available prey, is critical in the recruitment process.

For tropical reef fish species, Sale (1978, 1991) proposed the Lottery Hypothesis, which states that recruitment in tropical reef fishes is strongly dependent on delivery potential to the reef of settlers and that post–settlement processes could control recruitment levels. However, nowadays, both pre– and post–settlements processes are acknowledged to influence recruitment (Jones, 1991; Doherty, 2002).

The above hypotheses consider starvation and physical processes as the main drivers of recruitment variability; however, there is strong evidence that predation is the main source of ichthyoplankton mortality and, consequently, the main factor influencing recruitment (Hunter, 1981; Bailey and Houde, 1989). Mortality from nutritional deficiencies and predation may not act independently. Slow–growing and small fish larvae remain relatively vulnerable to predation for longer periods of time. This is the foundation of the Stage–Duration Hypothesis, which implies that large size (“bigger is better”) and fast growth improves survival potential (Houde, 1987; Anderson, 1988; Houde, 2008).

![Figure 3. Schematic diagram of different processes acting on the early stages of a marine fish (eggs, yolk–sac larvae, larvae and juveniles). From Houde (1987).](image-url)
In summary, although Hjort focused on starvation of first-feeding larvae as the main driver of larval mortality, he already envisaged that recruitment variability was the result of complex, interacting factors, stating that “the simultaneous investigation of meteorology, hydrography and biology seems the only way to a deeper understanding of the conditions in which the destiny of the spawned ova is being decided” (Hjort, 1926). In this line, nowadays it is widely agreed that recruitment variability is the outcome of complex trophodynamic and physical processes, operating on different temporal and spatial scales and throughout the pre-recruit life stages of fishes (Fig. 3). That is to say, recruitment success is not determined during a particular ontogenetic stage and it depends on the species, populations and environmental conditions (Houde, 2008). In this way, the knowledge of the ecology of the early life stages of fishes is crucial to understanding the population dynamics of fish stocks, but also, the functioning of marine ecosystems.

New discoveries, technological advances and new analytical techniques, developed in the last decades, have allowed for significant advances in the knowledge of the causes of mortality of the early life fish stages. One of the major findings was the discovery by Pannella (1971) that growth rings in fish otoliths are deposited daily. Brothers et al. (1976) confirmed the presence of daily growth rings in otoliths of fish larvae (Fig. 4). This finding allowed for the estimation of growth and mortality rates during the larval stage, and for the cohort contributions to recruitment (Methot, 1983; Miller et al., 1988; Houde, 1997). The analysis of the otolith’s microstructure also allows for assessing the environmental influence on larval survival, dating, with high precision, early life events and relating them to environmental conditions.

Other indicators useful for determining the nutritional status and recent growth rate in fish larvae are the RNA/DNA ratio (Buckley, 1979, 1980, 1984) and the nitrogen (N) and carbon (C) stable isotope analysis (SIA). The latter is used to assess the trophic position and C flow to consumers in food webs (Minagawa and Wada, 1984, Peterson and Fry 1987, Post, 2002). Specifically, 15N provides an estimate of the trophic level, and 13C can be used to assess the sources of C for an organism when the isotopic nature of the sources is different, since C isotope ratios undergo small changes within the food web (Peterson and Fry, 1987, France and Peters, 1997). The SIA analysis has also been used recently to assess the trophic ecology of fish larvae (e.g. Laiz–Carrión et al., 2013, Laiz–Carrión et al., 2015). Finally, advances in telemetry have allowed synoptic sampling of environmental variables over large areas and advances in computer power the development of biophysical models, simulating larval drift and survival under real or hypothetical environmental scenarios.

1.3 Applications of ichthyoplankton studies in fisheries research

One of the main objectives of ichthyoplankton field studies is the direct assessment of the number or biomass of exploitable populations (Heath, 1992). This is based on the fact that for some fish

![Figure 4. Otolith of a sardine (Sardina pilchardus) larva](image)
populations there may be a relationship between the number of eggs and/or larvae in a given area and the number or biomass of spawning adult fish, and this can be used to estimate the size of the adult population (Heath, 1992). There are six direct methods that use ichthyoplankton production for estimating the abundance of fish stocks, three based on eggs and three on larvae, with the latter used for demersal spawners (Stratoudakis et al., 2006). The underlying principle of the ichthyoplankton–based methods is that the abundance of an early life stage of a fish species can be used to estimate the reproductive outcome of the population over a time period (Stratoudakis et al., 2006).

Of the three methods based on eggs production, the Daily Egg Production Method (DEPM), the most widely used, was developed for small pelagic fishes (such as anchovies and sardines) that exhibit indeterminate fecundity (Lasker, 1985; Parker, 1980). Fecundity is indeterminate when the potential annual fecundity of a female is not fixed prior to the onset of spawning and unyolked oocytes continue to be matured and spawned during the spawning season (Hunter et al., 1992). The advantage of the DEPM is that it only requires a single survey to estimate the daily egg production at sea and the daily specific fecundity at the peak of the spawning period (Parker, 1980). In addition, the application of this method provides information about the reproductive biology and reproductive behaviour of a population and about the distribution, mortality and development of the early life fish stages, which are of particular importance for studying the underlying mechanisms of recruitment (Murua et al., 2010). The other two methods based on eggs, the Annual Egg Production Method (AEPM) (Lockwood et al., 1981) and the Daily Fecundity Reduction Method (DFRM) (Lo et al., 1992) were developed for species with determinate fecundity, for which the potential annual fecundity becomes fixed prior to the onset of spawning (Hunter et al., 1992). Where egg production methods are impractical, a larval census has been employed to obtain a relative index of the spawning biomass (Heath, 1992).

Larval survey data can be used to obtain estimates of recruitment. The estimation or forecasting of recruitment strength, under variable environmental scenarios, is essential for the proper management of fish stocks, particularly in a context of relatively rapid climate change. Moreover, the implementation of the Ecosystem Approach to Fisheries (EAF), where fisheries management recognizes the full range of interactions within a marine ecosystem (Katsanevakis et al., 2011), has led to an increase of studies aimed at understanding recruitment and its underlying processes. In addition, a holistic understanding of ecosystems, of the environmental influence on fish population, especially on their highly vulnerable early life stages, is required to implement the EAF. This knowledge is also essential towards implementing the Ecosystem–Based Management of Fisheries (EBMF), in which the order of management priorities is inverse to the customary norm, addressing the status of ecosystems, rather than that of the fishery resources (Pikitch et al., 2004; Cogan et al., 2009).

Furthermore, ichthyoplankton studies can provide a lot of information on the ecology and structure of fish populations, in a cheaper and simpler way than information obtained studying juvenile or adult populations. Thus, a single collection of plankton hauls can give information about most fish species spawning in a given area, both pelagic and demersal, whereas sampling of adults would require larger vessels and a variety of sampling gears and methodologies. Ichthyoplankton surveys can also be used for the prospection of new resources, determining the timing and location of spawning areas and their variations or estimating the relative abundance of different stocks and monitoring their abundance trends over time.

1.4 Ichthyoplankton sampling strategies, methods and gears

Any study on ichthyoplankton communities is based on two pillars: an adequate sampling strategy for the specific objectives to be achieved and a correct taxonomic identification of the target taxa. There is a great variety of sampling strategies, from large–scale surveys to intensive sampling of a single patch of larvae tracked by means of a Lagrangian buoy (a free–floating buoy that moves with a parcel of water). The sampling methodology to be followed and the sampling gear to be used will depend on the objectives of the study, on the target species and/or the early life stages to be sampled.
It is out of the scope of this guide to explain in detail all possible sampling strategies or describe the different types of ichthyoplankton sampling devices and sampling methods. However, it is worth illustrating those that are most frequently used and the potential sources of bias affecting sample representativeness.

As already explained, many ichthyoplankton studies are aimed at estimating the biomass of adult fish stocks, either by using eggs or larvae. When using eggs for e.g. applying the *Daily Egg Production Method* (DEPM), the gear employed is the CalVET net in vertical hauls, and the sampling strategy consists of sampling stations arranged in a regular grid, with a short distance between stations, covering the whole spawning area of the fish stock to be studied. When the objective is to estimate the biomass of an adult fish stock using larvae, to study the horizontal distribution of fish eggs and larvae of specific species or, in general, the ichthyoplankton community of an area, the most adequate sampling gear to be used is the Bongo net (Fig. 5). Hauls are oblique and the sampling strategy consists of sampling a regular grid of stations. Ichthyoplankton hauls must cover the depth distribution range of the target species or, if the goal is to sample the entire ichthyoplankton community, at least the upper 200 m of the water column, where most fish eggs and larvae are concentrated.

When the aim of ichthyoplankton studies is to investigate the vertical distribution of fish eggs and larvae and/or the vertical (diel and/or ontogenetic) migrations of fish larvae, a multiple net system, capable of sampling successive water layers during the same tow, is required (Fig. 6). Hauls are also oblique.

---

*Figure 5.* Left, CalVET net and right, Bongo net

*Figure 6.* Multiple net systems. Left, MultiNet sampler and right, MOCNESS net
Neuston nets are used to sample the very most surface water layer (Fig. 7). Large micronekton nets, fitted with meshes of the size of 1 mm or larger, may also be necessary for effectively sampling larger larvae. Light traps are used for capturing advanced post-larvae in pre-settlement stages.

Ichthyoplankton samples can also be obtained with continuous sampling systems, such as the Continuous Underway Fish Egg Sampler (CUFES), capable of collecting plankton as the research vessel is sailing. It consists essentially of a pump that draws seawater at a given depth and sends it through a plankton collector, where plankton is retained (Fig. 8). The collector is changed and plankton collected after a fixed period of time. While CUFES is running, a data logger records the date, time, and position of each sample, as well as other environmental data from the ship’s sensors.

In the last decades, new and more sophisticated sampling systems are being implemented. In situ ichthyoplankton imaging systems or plankton acoustics, despite not providing biological samples for other types of analyses, can produce impressive amounts of data on larval abundance or biomass, over large areas in relatively short periods of time (Cowen and Guigand, 2008; Garcia–Seoane et al., 2016).

Any sampling aimed at obtaining quantitative data on ichthyoplankton requires knowing the exact volume of water filtered by the net during each haul. This is done by using flowmeters attached to the mouth of the net. Flowmeters measure the length of the haul path, which, multiplied by the surface

---

**Figure 7.** Neuston net

**Figure 8.** Continuous underway fish egg sampler (CUFES) (http://cufes.ucsd.edu/text/descr.htm)
of the mouth of the net, gives the volume of water filtered by the net during the haul. This allows standardization of fish eggs and larvae captured in each haul to number of individuals per cubic meter, or densities. Ichthyoplankton counts can be also standardised to number of individuals beneath a unit of sea surface (square meter), by multiplying densities by the maximum depth of tow in meters (Smith and Richardson, 1977). Haul depth can be determined by using any device equipped with pressure sensors, such as a conductivity–temperature depth instrument (CTD) of small size or simple depth gauges, such as those used for scuba diving, attached to the sampling gear structure. If flowmeters or depth gauges are not available, the volume of water filtered can be estimated from the duration of the tow and the vessel's speed, which allows for estimating the distance covered by the net's path. Haul depth can be estimated by multiplying the maximum length of wire led out by the cosine of the wire angle at the moment when the maximum amount of wire has been let out. Finally, to get a reliable estimation of ichthyoplankton densities or abundances, it is necessary to homogeneously sample the water column over the whole haul depth range.

Once the haul is finished, plankton must be concentrated into the cod ends by gently washing the nets (Fig. 5). After that, plankton is transferred into jars and fixed for long–term preservation. The most commonly used preservatives are a 5% solution of buffered formalin and seawater, or ethanol at different concentrations. Formalin is more adequate for preserving samples to be used in taxonomic studies, since the egg and larval morphology is better preserved, but presents the problem that formalin is carcinogenic. Ethanol dehydrates both eggs and larvae. Eggs lose their shape, and larvae tend to curl making them difficult to measure. However, it has the advantage that specimens can be used for genetic and for larval growth studies. Other fixatives are liquid nitrogen, used to preserve larvae in biochemical and daily growth analyses, and RNAlater, when it is necessary to stabilize and protect cellular RNA. For some specific studies, larvae must be quickly sorted and identified on board, prior to fixation.

1.5 Sample representativeness

There are several papers dealing with problems associated to ichthyoplankton sampling (Hempel, 1974; Smith and Richardson, 1977; Lasker, 1981; Heath, 1992). Specifically, difficulties in obtaining representative samples of ichthyoplankton communities derive from the spatial and temporal heterogeneity in ichthyoplankton distribution and from the interaction of fish eggs and larvae with sampling gears (Ahlstrom et al., 1973). Fish eggs and larvae are not distributed randomly, but they tend to be concentrated in patches that become part of the plankton during specific periods of the year. This is the result of the distribution of adult fishes, their spawning strategies, hydrodynamic processes, egg and larval density, and larval behaviour, which varies throughout ontogeny. The only way to deal with non-random distribution of ichthyoplankton is through an adequate sampling design.

The main sources of sampling bias, related to the direct interactions between fish eggs and larvae with the plankton nets, are escapement and avoidance. Escapement is the passage of smaller ichthyoplankton organisms through the meshes of the net. It may be active or passive and it is a function of the size, shape and behaviour of the organisms in relation to mesh size (Vannucci, 1968). Active escapement is the process by which fish larvae caught in the net may squeeze through the meshes. This involves behavioural patterns that vary with species and with the developmental stage (Vannucci, 1968). Passive escapement or extrusion is the forced passage of eggs or larvae through the net's meshes. When the organisms are larger than the meshes, extrusion is aided by the compressibility of the organisms and the flexibility of the meshes (Saville, 1958). This source of sampling bias is easily overcome by using net meshes of size adequate to retain smaller fish eggs and larvae. Considering the fact that most fish eggs have a diameter of over 0.5 mm and that most newly hatched larvae are more than 2.0 mm long, the adequate mesh size for sampling ichthyoplankton is between 300 and 500 microns. However, mesh size should not be too small for avoiding, or at least reducing, mesh clogging produced by plankton. Net clogging reduces the filtration efficiency of the net.
Avoidance is the process by which larger fish larvae avoid capture, swimming out of the path of the approaching net or migrating below the net’s maximum sampling depth (Morse, 1989). This is probably the most important source of sampling bias (Clutter and Ankaru, 1968). Evidence of this phenomenon is the observed difference in larval fish abundances between night and day samples (Russell, 1976; Bridger, 1956; Ahlstrom, 1954, 1959). However, it seems that avoidance occurs both day and night (Murphy and Clutter, 1972). Larvae are not only able to see the approaching nets (visual avoidance), but they are capable of detecting the water vibrations produced by the towing wires and also the wave pressure produced by the net ahead of it (Smith and Clutter, 1965; Mahnken and Jossi, 1967; Tranter and Smith, 1968). Thus, to reduce or minimize net avoidance, it is useful to use nets without bridles in front of the net mouth, such as Bongo type nets (McGowan and Brown, 1966).

1.6 Ichthyoplankton sorting

For the taxonomic identification of ichthyoplankton or for other analyses, fish eggs and larvae are usually sorted from the plankton samples. The first step in ichthyoplankton sorting is to eliminate formalin from plankton samples. To do this, samples must be sieved through meshes (of smaller sizes than those used for sampling at sea), washed with seawater and placed into jars with seawater. This task must be carried out under a fume hood to avoid breathing the carcinogenic formalin vapours. Then, the sample can be placed in Petri dishes and analysed under a stereoscopic microscope, at low magnification (10x is adequate), to detect and sort fish eggs and larvae. Considering the low abundances of larvae of some species, it is recommendable, for studies on ichthyoplankton communities, to analyse the whole sample. However, for specific studies focusing on eggs or larvae of more abundant species, it is acceptable to analyse 50 or 25% of the sample or even less, depending on the abundance of the target species. Fish eggs and larvae must be handled very carefully, with soft tweezers, thin brushes or pipettes, to separate and keep them in vials with the appropriate preservative medium.

1.7 Taxonomic identification of fish eggs and larvae

The taxonomic identification of fish eggs and larvae is not an easy task. It is more difficult than identifying the juvenile and adult stages of fishes. This is due to several reasons. First, because of the small size of fish eggs and larvae, characters useful for their identification can only be visualized under a stereoscopic microscope. Then, in the case of fish larvae, the main problem is that they undergo continuous and, in some cases, dramatic morphological, meristic, morphometric and pigmentary changes throughout their development. This has prevented the building of dichotomous keys, such as those existing for adult fishes. In addition, other characters, such as pigmentation patterns, can present an important geographical and even individual variability. Despite these difficulties, partial dichotomous keys were developed for the Western Mediterranean Sea by Abossouan (1964) and Marinaro (1971). However, these keys only include some developmental stages of a relatively small number of the species present in the area. Therefore, they easily lead to identification dead ends or to misidentifications. To overcome this problem, the use of intelligent software, capable of managing extensive databases and integrating all the available information on larval stages of different fish species, including ecological information, such as the distribution of adults, reproduction season, etc. has been proposed (Froese and Papasissi, 1989). However, the design and implementation of such information systems is not easy, due to the heterogeneity of the available information, or even the lack of information on the early life stages of many marine fish species. Even in well-studied areas, eggs and larvae of many species are still unknown or, in many cases, early fish stages remain undescribed. More recently, molecular techniques are being used to identify fish eggs and larvae, or for validating previous descriptions of these, but they cannot be routinely applied. Because of all these difficulties, the “look-alike” method remains the method usually used to identify fish eggs and larvae. It consists of comparing the individuals with descriptions made by other authors. This elimination process ultimately results in “assigning” an individual to a species. This is also the method followed in this guide.
However, to properly use the “look-alike” method, it is first necessary to compile and analyse all the available information about the ichthyofauna of the study area. That is to say, faunistic lists and all the available information on the spawning strategies, spawning seasons and known distribution of the fish species inhabiting the study area. Another prerequisite for using this method is being able to accurately determine the developmental stage of the individual under analysis and to compare it with the corresponding developmental stage described in the literature.

The nomenclature of the different early developmental stages of fishes varies by author. In this guide, we follow the nomenclature suggested by Kendall et al. (1984) (Fig. 9), one of the most widely accepted. They divided the early life–history of fishes into three stages: egg, from spawning to hatching; larva, from hatching to attainment of complete fin–ray counts and beginning of squamation (juvenile); and juvenile, young fish, fundamentally like the adult in the meristic characters (excluding squamation) but smaller and reproductively inactive. Kendall et al. (1984) also divided the larval stage into four sub–stages: yolk–sac larva, from hatching to exhausting of yolk reserves; preflexion larva, from yolk exhausting to the beginning of upward flexion of the notochord; flexion larva, that ends when the urostyle is in its final position, at approximately 45° from the notochord axis and post–flexion larva, that ends when metamorphosis begins. Transformation, or metamorphosis is a transitional stage between larva and juvenile during which the young fish loses larval characters and acquires those of the adult (Kendall et al., 1984; Moser, 1996).

Figure 9. Early life history stages of *Trachurus symmetricus* from Kendall et al. (1984)
Most marine fish eggs encountered in plankton samples are spherical and transparent, with a diameter of about 1.0 mm. Eggs are enclosed by a thin membrane or chorion. There is a space between the chorion and the yolk sac, the perivitelline space. Most fish eggs have oil globules (Fig. 10). The main anatomical, morphological and morphometric features used in fish egg identification are: egg shape (spherical or elliptic); egg size (ranges from 0.5 to more than 5.5 mm in diameter); type of surface membrane (smooth, sculptured, with a single protuberance or filaments); presence of a second internal membrane; type of yolk (homogeneous or segmented); size of the perivitelline space; absence/presence, number, position and colour (for live individuals) of oil globules. When the embryo is well developed, embryonic characters, such as morphological features, pigment patterns and special structures are also used to identify fish eggs (Russell, 1976; Matarese and Sandknop, 1984; Ahlstrom and Moser, 1980). Scanning electron microscopy has proved to be a good tool for the taxonomic identification of fish eggs, but cannot be used in routine analysis (Boehlert, 1984). The identification of fish eggs is usually a more difficult task than larval fish identification. This is reflected by the fact that the number of fish species with the egg stage described is much lower than those with the larval stage described. In the Mediterranean Sea, it is worth mentioning the pioneer identification guide to fish eggs developed by Marinaro (1971), which has been recently revised and extended by Crec’hriou et al. (2015).

In most fish species with pelagic eggs, the newly hatched larvae are in general less than 4 mm long (Russell, 1976). The size and state of development at hatching is generally related to yolk–sac diameter. Typically, the body length at hatching is 2.5 to 3.0 times the diameter of the yolk sac (Moser, 1996). In general, yolk–sac larvae hatched from eggs less than 1.5 mm in diameter have an unformed mouth, unpigmented eyes and pectoral–fin buds, while yolk–sac larvae hatched from larger eggs are comparatively well developed, with the mouth formed, eyes pigmented and pectoral fins developed (Moser, 1996). In both cases, the locomotion is aided by a prominent fin–fold that extends from the top of the head, around the caudal region, and ventrally forward to the posterior margin of the yolk sac (Fig. 11).

The identification of yolk–sac larvae is very difficult because some structures, such as fins and most of the specialized larval characters, resulting from the evolutionary adaptation to the plankton realm, are not yet well developed. Consequently, yolk–sac larvae of different species are very similar. The yolk–sac stage is characterized by the migration, coalescence and rearrangement of pigment cells or melanophores (Moser, 1996). Melanophores are amoeboid and capable of migrating from their point of origin in the neural crest to various sites in the larva, to establish the species–specific larval pigmentation pattern, at the end of the yolk–sac stage. Useful characters for the identification of yolk–sac larvae are the shape and relative size of the yolk sac, the presence and the relative position of oil globules in the yolk sac, the position of the anus in relation to the yolk sac and, in some, the species–specific pigmentation pattern.
The complete utilization of the yolk marks the end of the yolk–sac stage. By this time, most of the organs and the sensory system required to capture prey are functional. The mouth and gut are formed, the anus is open at the margin of the ventral fin–fold, the eyes are pigmented, and the primordial pectoral fins are present. It is now an early larva and during the larval development, the fish gradually acquires the characters of the adult, thus facilitating its identification (Moser, 1996; Russell, 1976).

At first, the body is still surrounded by the primordial fin, the urostyle is straight and rudiments of the hypural elements are visible in its ventral side. As the larva grows, the urostyle bends upwards, the hypural elements become defined, caudal rays develop, and the first signs of the formation of the dorsal and anal fins appear as interspinous areas. At this stage, both the meristic characters and pigmentation pattern that are characteristic of the adult of the species, have usually appeared (Russell, 1976). The main anatomical features of a larva are shown in figure 12.

The main characters used in larval fish identification are the body form, the pigmentation pattern and meristic and morphometric characters. The body form allows for separating larvae into several major groups (Russell, 1976). For example, larvae with narrow, elongated bodies (e.g. Families Clupeidae, Engraulidae, Stomiidae, etc.); larvae with laterally compressed bodies (includes all flatfishes, e.g. Families Bothidae, Pleuronectidae, Soleidae, etc.); bodies with the typical fish shape (includes larvae of most fish species, e.g. Families Gadidae, Triglidae, Gobiidae); bodies with aberrant shapes (e.g. Family Belonidae) or showing specialized larval characters for the plankton life, such as cranial armatures (e.g. Family Scorpaenidae), elongate fin rays (e.g. Families Carapidae, Lophiidae), stalked eyes (e.g. some Myctophidae species) or early developed and large fins (e.g. Family Trachinidae).

Meristic characters are countable structures appearing in series, such as the number of miomeres, vertebrae or fin rays. They have a high diagnostic value (at least the combination of several counts), because they are species–specific. However, they have the disadvantages that some of them, such as fin rays, are completely formed only in older larvae, which are scarce in plankton samples. Others, such as miomeres or vertebrae, are difficult to visualize, even using staining methods, or other techniques, such as X–rays (Pothoff, 1984; Tucker and Laroche, 1984).
Morphometric characters include the different measurements of a larva. The main measurements of a larva, shown in figure 13, are the total length (TL), or the distance from the tip of the snout to the caudal–fin end; the standard length (SL), or the distance between the tip of the snout and the urostyle end; the preanus length, or the distance between the tip of the snout and the anus; the head length, or the distance from the tip of the snout to the border of the cleitrum, and eye diameter, or the maximum diameter of the eye. When measuring the different body regions for identification purposes, the stage of development of the larvae must be taken into account, since larval growth is allometric.

Fish larvae show a variety of pigmentary cells or chromatophores. Those containing black or brown pigments are known as melanophores; those with yellow pigments, xanthophores and those with red pigments, erythrophores (Russell, 1976). However, in formalin–preserved specimens, only black pigmented cells or melanophores remain. For this reason, the latter are usually the only ones used in ichthyoplankton identification. Melanophores are situated in different parts of the body, defining a species-specific pigmentation pattern. This pattern is one of the chief diagnostic characters used for the identification of the larval stage of fish species. Often, the identification of species with similar larvae is made possible thanks to the presence or absence of a single melanophore or by its position (Russell, 1976). The general appearance of preserved specimens will differ very much according to the degree of expansion or contraction of the melanophores. Moreover, in specimens preserved for a long time, the pigmentation will fade, especially if kept in the light (Russell, 1976). Besides, there may be an intraspecific and geographical variability in pigmentation patterns.

1.8 The importance of a proper taxonomic identification of ichthyoplankton

The first step in any ichthyoplankton study is the proper taxonomic classification of eggs and/or larvae since, as Powles and Markle (1984) pointed out, small errors in their identification can result in important misinterpretations about the biology and ecology of fish species. Moreover, there are several examples in the literature showing that wrong identifications of fish eggs or larvae have led to biased stock evaluations and, subsequently, inadequate management measures (Daniel and Graves, 1994; Armstrong et al., 2001; Fox et al., 2005). Unfortunately, these identification errors are probably more frequent and important than desirable. For example, a recent study focusing on the ability of researchers from five different laboratories in Taiwan to identify fish larvae, determined that the average accuracy of identification was 80.1, 41.1 and 13.5 % at the family, genus and species levels, respectively (Ko et al., 2013). Recently, Puncher et al. (2015a) revealed that the Atlantic bluefin tuna (Thunnus thynnus) larvae have been misidentified in the Mediterranean Sea. These authors demonstrated, through genetic analysis, that more than half of the larvae, submitted by three Mediterranean institutions to a bluefin tuna research project, funded by the International Commission for the Conservation of Atlantic Tunas (ICCAT), were misidentified. Some of these errors are caused by the persistence in literature of wrong descriptions. However, also in species whose larvae are accurately described, the inexperience

![Figure 13. Body regions and the most important measurements of a fish larva](image-url)
or lack of training of the people in charge of the taxonomic identification of ichthyoplankton can lead to massive misidentifications (Puncher et al., 2015b). Because of this, it is of paramount importance to produce identification guides with accurate descriptions, taking advantage of molecular genetic techniques, to validate doubtful identifications, as well as to organize courses given by experienced ichthyoplanktologists and aimed at properly training new generations of technicians and researchers in charge of the taxonomic classification of fish eggs and larvae. This book, based on a course on larval fish taxonomy, supported by the FAO COPEMED regional program, intends to be a step in this direction, for the western Mediterranean region.

1.9 History of studies on ichthyoplankton identification in the Mediterranean Sea

The pioneering works on ichthyoplankton identification in the Mediterranean Sea were those of Raffaele (1888) and Marion (1894). These authors described eggs and yolk sac larvae of several fish species from the Gulf of Naples (Raffaele, 1888) and from the Gulf of Marseille (Marion, 1894). Some years later, Fage (1910) published the results of ichthyoplankton surveys carried out off the city of Nice and in the Gulf of Lion including descriptions of larvae of several fish species. Roule and Angel (1930), summarized the results of the oceanographic surveys supported by the Prince of Monaco, Albert I, carried out between 1895 and 1915. Outstanding papers on ichthyoplankton identification are the reports on the “Danish Oceanographic Expeditions in the Mediterranean and Adjacent Seas” (Dana–Reports) by e.g. Kyle (1913), Jespersen (1915), Ege (1918, 1930), Fage (1918, 1920), Schmidt (1918), Schmidt and Strubberg (1918), Täning (1918, 1923), Jespersen and Täning (1926), Guitel (1920), Ehrembaum (1924), and Schnakenbeck (1931). However, the most important publication on ichthyoplankton identification from the Mediterranean Sea is the monography “Uova, larve e stadi giovanili di Teleostei”, elaborated using material gathered by Lo Bianco and edited by Bertolini et al. (1931–1956). This monography compiles the description and illustrations of fish eggs and larvae of many species carried out by several authors. This monography, along with the Dana–Reports, are even nowadays the basic and essential references for any study on ichthyoplankton identification from the Mediterranean Sea. It is also worth mentioning the papers from Aboussouan (1964) and Lee (1966) that include useful keys for the identification of fish eggs and larvae and the paper by Marinaro (1971), which includes a useful key for the identification of fish eggs. In recent years, the PhD Theses of Sabatès (1988) and Alemany (1997) deserve special attention. These include the description and original illustrations of larvae of several fish species. Several illustrations of the Alemany’s PhD Thesis are included in this manual.
1.10 Glossary

**Anal fin**: Fin (usually single but double in some gadiforms) located on the ventral margin of the tail, behind the anus.

**Anus**: Orifice and surrounding tissue at end of the gut.

**Bathypelagic**: Pelagic zone between 1 000 and 4 000 m depth. Bathypelagic fish are those inhabiting the bathypelagic region.

**Benthic**: Referring to the sea bottom. Benthic species are those living on or in the bottom (substrate).

**Benthopelagic**: Living and feeding near the bottom as well as in midwater or even near the surface.

**Caudal fin**: Median fin situated at the posterior end of the fish.

**Caudal peduncle**: Narrow part of the tail located between the posterior end of dorsal or anal fin and the base of the caudal fin.

**Chorion/shell**: Outer membrane of a fish egg.

**Choroid tissue**: Mass of vascular tissue on the ventral side of the eye in larvae of some myctophids and other meso- and bathypelagic fishes, usually associated with elliptical eyes.

**Cleithrum**: Vertical bone in the pectoral girdle, at the junction of head and body of the larva.

**Cleithral symphysis**: Ventral junction of the cleithral bones.

**Chromatophore**: Cell containing pigment that reflects the light.

**Continental shelf**: The flattened edge of the continental land mass, between the coast and the continental slope (generally, the continental subtidal zone to a depth of about 200 m).

**Continental slope**: The sloping edge of the continental land mass, generally beginning at depth of around 200 m.

**Demersal**: Living on or near the bottom of the sea.

**Dorsal fin**: Median fin or fins located on the dorsal margin of the body.

**Early life history**: The early life stages of fishes spanning from egg to juvenile.

**Embryo**: Early stage of development, from fertilisation to hatching.

**Epipelagic**: The illuminated, uppermost layer of the ocean (from 0 to 200 m depth).

**Eye stalks**: Movable peduncles of varying length bearing the eyes.

**Finfold/primordial fin**: Median fold of skin surrounding the body of young larvae, within which the dorsal, caudal and anal fins are developed.

**Flexion**: Larval stage during which the urostyle bends dorsally.

**Gut**: Alimentary tube and associated organs.

**Gut loop**: Loop, fold, or curve found along the axis of the gut.

**Head length**: Distance from the tip of the snout to the posterior margin of the cleithrum.

**Hindgut**: Posterior part of the gut.

**Homogeneous**: Uniform composition throughout; opposite to segmented in referring to egg yolk.

**Ichthyoplankton**: Zooplankton fraction including eggs and larval stages of fishes.

**Isthmus**: Ventral region of the head separating the gill openings of a fish.

**Juvenile**: A young fish, fundamentally resembling the adult in meristic characters (excluding squamation) but smaller and reproductively inactive.

**Larva**: Early life–history stage of fishes between the egg and juvenile stages.

**Leptocephalus**: The flat, transparent, and often large larvae of fishes in the orders Anguilliformes, Elopiformes and Notacanthiformes, characterized by small heads and prominent teeth.

**Melanophore**: A cell containing melanin; a black or brown pigment cell.
Meristic characters: Countable structures occurring in series (e.g. myomeres, vertebrae, fin rays).

Mesopelagic: Occurring in the open ocean at middle depths, usually between 200 and 1 000 m.

Metamorphosis: A marked change in form or structure at the end of the larval stage involving acquisition of adult characters and loss of larval characters; synonymous of transformation.

Myomeres: Muscle segments occurring in series, the number is approximately equal to the number of vertebrae in adults.

Myosepta: Connecting tissue between adjacent myomeres.

Nekton: Motile, marine organisms living in the water column and capable of swimming against currents.

Neritic: Pelagic coastal zone extending from the low tide mark to the edge of the continental shelf.

Neural crest: Region of the neural ridge of the developing embryo that differentiates into many kinds of tissue and cells, including melanophores.

Neustonic: Occurring close to the surface of the ocean.

Notochord: Longitudinal flexible cartilaginous rod of cells forming the supporting axis of the body.

Notochord length (NL): The distance from the tip of the snout to the posterior tip of the notochord.

Occipital crest: A median, bony ridge, usually serrated, located on top of the head, posteriorly.

Oceanic: Open sea region beyond the edge of the continental shelf.

Oil globule: Spheres of fatty material within the yolk of some fish eggs.

Opercular: Relative to the operculum.

Opercular or Opercle: The bony plate of the gill cover.

Ovoviviparous: Producing eggs that develop within the maternal body.

Pectoral fin: Paired lateral (sometimes ventralateral) fins located behind the head.

Peduncle: A narrow part or stalk that connects a structure to the body (e.g. caudal peduncle connecting the caudal fin to body).

Pelagia: Free living in the water column, away from the sea bottom.

Pelvic fins: Paired fins, usually located on the ventral edge of the body, in the abdominal region.

Peritoneal: Region of the body associated with the gut or the membrane of the peritoneum.

Peritoneum: The membrane and associated tissue lining the gut cavity.

Perivitelline space: Fluid–filled space between the embryo and chorion or shell of an egg.

Photophores: Luminous organs on some marine (mostly deep–sea) fish larvae.

Plankton: Small free–living organisms, passively floating or weakly swimming that drift with currents.

Pigmentation: Deposition of pigment in body tissues.

Planktonic: Passively floating, drifting, or weakly swimming with prevailing currents.

Postanal: posterior to the anus.

Postflexion stage: A stage in the development of larvae after the completion of flexion.

Preanal/preanus: Located anterior to the anus; preanal length (synonymous of snout–anus distance) measured from the tip of the snout to the posterior margin of the anus.

Preflexion stage: Larval stage before the beginning of the process of flexion.

Preopercle: Upper anterior bone of the gill cover.

Preopercular: Relative to the preopercle.

Recruitment: The amount of fish added to the exploitable stock each year due to growth and/or migration into the fishing area.

Sculptured: Egg chorion with ornamentations or surface features of different shapes and textures.
**Segmented**: Particulate or divided; opposite of homogeneous in referring to egg yolk.

**Shell**: The membrane that encloses an egg; generally, equivalent to chorion.

**Shrinkage**: The act or fact of shrinking, to contract or lessen in size.

**Swimbladder**: Sac filled with air or other gases located in the abdominal region, beneath the backbone.

**Snout**: Forward part of the head, anterior to the eye.

**Stalked eye**: Eye situated on a stalk or peduncle.

**Standard length (SL)**: The distance from the tip of the snout to the tip of urostyle.

**Stellate melanophore**: Star–like pigment spot.

**Stock (Fish)**: A group of individuals in a species occupying a well–defined spatial range independent of other stocks of the same species.

**Supraorbital spine**: Occurring above the eye.

**Tail**: The portion of the body posterior to the anus, the postanal region.

**Telescopic eye**: Elongate, cylindrical eye that protrudes forward or upward within an envelope of skin.

**Tentacle**: Any of various slender, flexible appendages in larvae.

**Total length (TL)**: Measurement from the tip of the snout to the most posterior part of a larva, including the caudal finfold or caudal fin.

**Transformation**: The process (synonymous of metamorphosis) at the end of the larval stage, characterized by a marked change in form or structure and involving the acquisition of juvenile or adult characters and the loss of larval characters.

**Trunk**: Portion of the body between the head and the anus.

**Urostyle**: The last vertebral elements in fishes, formed by fusion or loss of several vertebrae.

**Year class**: All of the fish in a stock that were spawned in a particular year, such as all those spawned in 1990. Also referred to as a “cohort”.

**Yolk**: Nutritive material of the egg forming a sac–like mass (yolk sac) below the abdominal region of a newly hatched larva.

**Yolk–sac larva**: Newly hatched larva with yolk sac.

2. IDENTIFICATION SHEETS
**OPHICHTHIDAE**  
*Dalophis imberbis* (Delaroche, 1809)

**En:** Armless snake eel

**Habitat:** Benthic, littoral, burrowing in sand or mud bottoms, between 20 and 100 m depth

**Spawning season:** Between August and September

---

**EGGS**

**Habitat:** pelagic  
**Shape:** spherical  
**Diameter:** 2.10–2.40 mm  
**Chorion:** smooth  
**Oil globules:** 1–17  
**Perivitelline space:** large  
**Yolk:** segmented

**YOLK–SAC LARVAE**

**Hatch size:** about 5.0 mm SL  
**Distinctive characters:** body elongate and slender; no teeth on jaws  
**Number of myomeres:** 159; 77 ahead of anus  
**Pigmentation:** body unpigmented

**LARVAE**

**Distinctive characters:** leptocephalus; body elongate, transparent, laterally compressed; in young larvae, 8 long teeth on each jaw; 5 or 6 gut loops  
**Preanus length:** decreases with development  
**Number of myomeres:** 152–155; 68–76 preanal  
**Pigmentation:** in small larvae, 12 ventral spots, 9 over gut and 3 postanl; lower jaw and urostyle pigmented; larger larvae with up to 5 lateral melanophores located under the notochord  
**Length at transformation:** unknown

#### EGGS

- **Habitat:** pelagic
- **Shape:** spherical
- **Diameter:** 1.60–1.72 mm
- **Chorion:** with ‘pustules’ on inner surface
- **Oil globules:** single, 0.48–0.52 mm in diameter
- **Perivitelline space:** small
- **Yolk:** segmented

#### YOLK–SAC LARVAE

Undescribed

#### LARVAE

**Distinctive characters:** body moderately elongate and laterally compressed in early larvae, becomes rounded in older larvae; gut locally swollen and detached from body at its end

- **Preamus length:** about 75% TL
- **Pigmentation:** some melanophores on snout; continuous row of melanophores running along ventral side of body, from posterior margin of eye to caudal fin; row of ventral melanophores from pectoral fins to caudal peduncle; short series of spots under developing dorsal fin, becomes longer in older larvae

**Length at flexion:** flexion occurs between 7.0 and 11.0 mm

**Distinctive characters:** body shape typical of a gadid species, relatively short with a relatively large head and deep abdominal region; body depth decreases gradually with development starting from a size of 3.5–4.0 mm; anus does not reach finfold edge in early larvae; 2 prominent cephalic spines on each side of head; large pelvic fins with 4 rays, located on sides of gut

**Preanus length:** less than 60% SL in early larvae, decreases slightly with development

**Pigmentation:** dorsal side of peritoneum strongly pigmented; melanophores on top of head and on lateral surface of trunk, these latter increase in number and widen joining those on head and forming a continuous bar; upper and lower jaw tips pigmented; pelvic fins heavily pigmented; postanal region unpigmented, in young larvae

**Length at flexion:** unknown

LOPHIIDAE  

*Lophius piscatorius* Linnaeus, 1758

**En:** Angler (=Monk) – **Fr:** Baudroie commune – **Sp:** Rape

**Habitat:** Benthic, from shallow, inshore waters down to 500 m depth

**Spawning season:** Between February and July

**EGGS**

**Habitat:** pelagic

**Shape:** slightly oval, embedded in a gelatinous ribbon

**Size:** 2.3–3.1 mm wide, 0.62–0.70 mm high

**Chorion:** smooth

**Oil globules:** 1–9 oil globules, the largest 0.51–0.88 mm in diameter

**Yolk:** unsegmented

**YOLK–SAC LARVAE**

**Hatch size:** may be about 4.5 mm

**Distinctive characters:** yolk sac very large and globular; rudiments of pelvic fins apparent; at end of yolk sac stage, dorsal fin shows 3 rays and pelvic fins, formed by a single ray, are strongly developed

**Pigmentation:** large and branched melanophores on head and shoulder region, on gut, yolk sac and oil globules; pelvic fins heavily pigmented; postanal region unpigmented

**LARVAE**

**Distinctive characters:** body head and trunk globose; dorsal fin formed by 5 rays and pelvic fin formed by 4 rays, strongly developed

**Preanus length:** about 50% SL

**Pigmentation:** early larvae similar to yolk–sac larvae; larvae of more than 11.0–12.0 mm in length develop two postanal bars of melanophores

**Length at flexion:** unknown

**SERRANIDAE**

*Anthias anthias* (Linnaeus, 1758)

**En:** Swallowtail seaperch – **Sp:** Tres colas

**Habitat:** Benthic, on the continental shelf and upper slope, down to 200 m depth

**Spawning season:** Between March and August

---

**EGGS**

Undescribed

**YOLK–SAC LARVAE**

Undescribed

**LARVAE**

**Distinctive characters:** body, head and trunk height increases with development; a supraorbital crest, two series (inner and outer) of preopercular and a series of opercular spines are present; a spine of both the outer preopercular and opercular series is quite large; second ray of dorsal fin and first and second rays of pelvic fins are quite large

**Preanus length:** more than 50% SL

**Pigmentation:** some peritoneal melanophores; a relatively large spot over hindgut and another one opposite it in dorsal region; a series of melanophores between anus and caudal fin that decrease in number to 3 in late larval stages; a melanophore on caudal–fin base

**Length at flexion:** 3.3–6.0 mm SL

---

SERRANIDAE

**Serranus cabrilla** (Linnaeus, 1758)

**En:** Comber  
**Fr:** Serran–chèvre  
**Sp:** Cabrilla

**Habitat:** Benthic, on the continental shelf and upper slope, down to 200 m depth

**Spawning season:** Between April and July

---

**EGGS**

**Habitat:** pelagic

**Shape:** spherical

**Diameter:** 0.90–0.97 mm

**Chorion:** smooth

**Oil globules:** single, 0.14–0.15 mm in diameter

**Perivitelline space:** small

**Yolk:** unsegmented

**Fig. A**

**YOLK–SAC LARVAE**

**Hatch size:** 1.84–2.3 mm SL

**Pigmentation:** row of dorsal melanophores extending from head to level of anus; a large melanophore on hindgut and another opposite it in dorsal region; a dorsal and ventral melanophore situated at about midpoint of the postanal region

**Fig. B**

**LARVAE**

**Distinctive characters:** body height increases with development; three series of preopercular spines, one of which goes beyond the edge of the operculum in older larvae; an opercular spine in upper part of operculum; pelvic fins and third spiny ray of dorsal fin very elongate

**Preanus length:** more than 50% SL

**Pigmentation:** ventral abdominal region pigmented in young larvae and several postanal ventral melanophores may be present; pair of opposing melanophores, one dorsal and another ventral, located at midway along postanal region; caudal–fin base pigmented; spot on hindgut and another opposite it in dorsal region in young larvae; pelvic fins pigmented

**Length at flexion:** flexion begins at about 4.8 mm SL and is completed at 9.7 mm SL

## MULLIDAE

*Mullus barbatus* Linnaeus, 1758

**En:** Red mullet – **Fr:** Rouget de vase – **Sp:** Salmonete de fango

### Habitat
Benthic, on muddy bottoms of the continental shelf, between 10 and 500 m depth

### Spawning season
Between April and August

### EGGS
Undescribed

### YOLK–SAC LARVAE
Undescribed

### LARVAE

**Distinctive characters:** body relatively elongate

**Preanus length:** about 37% SL

**Pigmentation:** increases with development; early larvae show an occipital melanophore, peritoneum strongly pigmented, a row of postanal ventral melanophores, from anus to about two-thirds of tail region, a short series of mid-lateral melanophores and a single melanophore under urostyle; later larvae with several melanophores over head and on dorsal region of trunk; entire surface of gut, except its ventral side, pigmented

**Length at flexion:** flexion occurs between about 3.5 and 5.2 mm SL

### PHOTOS

MULLIDAE

*Mullus barbatus* Linnaeus, 1758

A. 2.6 mm SL

No dorsal melanophores in tail region

B. 2.9 mm SL

Short series of mid–lateral melanophores

C. 3.7 mm SL

Postanal row of ventral melanophores

D. 4.7 mm SL

E. 5.2 mm SL

MULLIDAE

*Mullus surmuletus* Linnaeus, 1758

**En:** Surmullet  
**Fr:** Rouget de roche  
**Sp:** Salmonete de roca

**Habitat:** Benthic, over rocky bottoms, down to 400 m depth

**Spawning season:** Between May and July

### EGGS

**Habitat:** pelagic  
**Shape:** spherical  
**Diameter:** 0.81–0.91 mm  
**Chorion:** smooth  
**Oil globules:** single, 0.23–0.25 mm in diameter  
**Perivitelline space:** small  
**Yolk:** segmented

### YOLK–SAC LARVAE

**Hatch size:** about 2.83 mm  
**Distinctive characters:** yolk sac projected beyond snout; oil globule located at anterior edge of yolk sac; anus situated close behind to posterior edge of yolk sac  
**Pigmentation:** melanophores scattered over body; oil globule strongly pigmented

### LARVAE

**Distinctive characters:** body relatively elongate  
**Preanus length:** about 30% SL  
**Pigmentation:** at about 4.0 mm SL shows a ventral row of 10–12 postanal melanophores extending from anus to about two-thirds of tail region; 2 or 3 melanophores over and below urostyle; mid–lateral line of melanophores; peritoneum pigmented; later larvae develop dorsal and dorsolateral rows of melanophores  
**Length at flexion:** it occurs between less than 4.0 and 7.6 mm SL

### PHOTOS

**CEPOLIDAE**

*Cepola macrophthalma* (Linnaeus, 1758)

**En:** Cardinal fish  
**Fr:** Coq  
**Sp:** Salmonete real

**Habitat:** Benthic, down to 320 m depth

**Spawning season:** Spring to autumn

---

**EGGS**

**Habitat:** pelagic

**Shape:** quasi spherical

**Diameter:** 0.77 mm

**Chorion:** with filaments

**Oil globules:** single, 0.23 mm in diameter

**Yolk:** segmented

---

**YOLK–SAC LARVAE**

Undescribed

---

**LARVAE**

**Distinctive characters:** body relatively short and high; a series of preopercular spines in larvae more than 2.4 mm SL; at 6.5 mm, larvae have a long preopercular spine, 3 shorter opercular spines and a small supraorbital crest; swimbladder apparent

**Preanus length:** 50% SL

**Pigmentation:** ventral side of trunk pigmented, from pectoral–fin base to mid–tail region; group of dorsal melanophores in caudal region; two melanophores over head and some melanophores under gut; pigmentation diminishes with development

**Length at flexion:** flexion begins at 3.0 mm SL

---

Supraorbital crest

Prominent head armature

Denticles

Tail region unpigmented in older larvae

MUGILIDAE

*Mugil cephalus* Linnaeus, 1758

**En:** Flathead grey mullet – **Fr:** Mulet à grosse tête – **Sp:** Pardete

**Habitat:** Pelagic, inshore, entering lagoons and estuaries

**Spawning season:** Between July and October

### EGGS

**Habitat:** pelagic

**Shape:** spherical

**Diameter:** 0.72 mm

**Chorion:** smooth, fine raised striations

**Oil globules:** single, 0.28 mm in diameter

**Perivitelline space:** small

**Yolk:** unsegmented

### YOLK–SAC LARVAE

**Hatch size:** about 2.5 mm

**Pigmentation:** heavily pigmented, except caudal region; a dorsal and another ventral row of about 4 dotted melanophores each at caudal region; oil globule strongly pigmented

### LARVAE

**Distinctive characters:** body relatively stubby with a large, bulky gut, moderate head and small mouth; no swimbladder

**Preanus length:** up to 70% SL

**Pigmentation:** strongly pigmented, except lateral sides of head and caudal region where dotted melanophores persist; pigment is heaviest on dorsum, dorsal surface of gut and on postanal ventral region; apparent mid–lateral row of melanophores

**Length at flexion:** 4.0–5.0 mm SL

**POMACENTRIDAE**

*Chromis chromis* (Linnaeus, 1758)

**En:** Damselfish

**Habitat:** Littoral, mainly in rocky areas, between 3 and 35 m depth

**Spawning season:** Between May and August

---

**EGGS**

**Habitat:** demersal

**Shape:** ovoid, attached to substrate with filaments

**Size:** 0.85–0.90 x 0.70–0.72 mm

**Oil globules:** single, 0.20 mm in diameter

**Perivitelline space:** small

**Yolk:** segmented

---

**YOLK–SAC LARVAE**

**Hatch size:** 2.6 mm SL

**Distinctive characters:** body relatively slender; oil globule situated ventrally in yolk sac

**Preanus length:** about 33% SL

**Pigmentation:** yolk sac pigmented; row of postanal ventral melanophores; occipital melanophores; melanophores dorsal and ventral to urostyle

---

**LARVAE**

**Distinctive characters:** body of early larvae similar to that of yolk–sac larvae, becoming short and robust with development; gut triangular–shaped

**Preanus length:** slightly less than 50% SL

**Pigmentation:** similar to yolk–sac larvae in earlier larvae; with development, postanal pigmentation reduces to a transversal band located around mid–tail region; posteriorly, melanophores appear on mid–lateral line and on dorsum, at same level of ventral group; peritoneum pigmented; melanophores on head

**Length at flexion:** begins at 3.60 mm and is completed at 4.75 mm SL

**LABRIDA**

*Coris julis* (Linnaeus, 1758)

**En:** Rainbow wrasse – **Fr:** Girelle – **Sp:** Julia

**Habitat:** Benthic, littoral, over rocky bottoms or eelgrass beds, down to 120 m depth

**Spawning season:** Between April and August

---

**EGGS**

- **Habitat:** pelagic
- **Shape:** spherical
- **Diameter:** 0.60–0.67 mm
- **Chorion:** smooth
- **Oil globules:** single, 0.12–0.16 mm in diameter
- **Perivitelline space:** small
- **Yolk:** unsegmented

---

**YOLK–SAC LARVAE**

- **Hatch size:** about 2.2 mm
- **Distinctive characters:** oil globule situated at anterior edge of yolk sac
- **Pigmentation:** several dorsal melanophores decrease in number to 2 and migrate to finfold with development; row of ventral melanophores along ventral side of trunk and tail, ending in a large melanophore

---

**LARVAE**

- **Distinctive characters:** body elongate; gut with a prominent loop
- **Preanus length:** about 50% SL
- **Pigmentation:** in young larvae, 2 dorsal melanophores on finfold which, in older larvae, remain on dorsal fin; two large ventral melanophores, one over gut, close to gut loop and another in caudal region
- **Length at flexion:** completed at 9.8 mm

---

LABRIDAE  

*Ctenolabrus rupestris* (Linnaeus, 1758)

**En:** Goldsinny-wrasse  
**Fr:** Rouquié  
**Sp:** Tabernero

**Habitat:** Benthic, on rocky, weed-covered shores, from 1 to 50 m depth

**Spawning season:** Between January and July

---

### EGGS

**Habitat:** pelagic  
**Shape:** spherical  
**Diameter:** 0.72–1.01 mm  
**Chorion:** smooth  
**Oil globules:** none  
**Perivitelline space:** small  
**Yolk:** unsegmented

---

### YOLK–SAC LARVAE

**Hatch size:** 1.95–2.19 mm SL  
**Distinctive characters:** anus located some distance behind yolk sac  
**Pigmentation:** in newly hatched larvae, melanophores scattered over most of the body; during yolk–sac larval development, all melanophores from dorsal side of body disappear, while on ventral side, only 4 melanophores remain: over gut, hindgut, mid–tail and caudal region

---

### LARVAE

**Distinctive characters:** body relatively elongate and slender, becoming more robust with development  
**Preanus length:** about 50% SL  
**Pigmentation:** similar to yolk–sac larvae in earlier larvae; later, two melanophores appear under gut increasing in number with development; peritoneal pigment also develops  
**Length at flexion:** at less than 4.82 mm SL

---

**En:** Corkwing wrasse – **Fr:** Crénilabre mélops – **Sp:** Porredana

**Habitat:** Benthic, littoral, near rocks and eelgrass beds, from 1 to 50 m depth

**Spawning season:** Between March and May (possibly June)

### EGGS

**Habitat:** demersal, attached to weed in nests  
**Shape:** spherical  
**Diameter:** 0.75–0.80 mm  
**Oil globules:** none  
**Yolk:** unsegmented

### YOLK–SAC LARVAE

**Hatch size:** 2.4–2.85 mm SL  
**Distinctive characters:** body relatively elongate  
**Preanus length:** about 50% SL  
**Pigmentation:** two rows of dorsal melanophores from behind eye to about midway along tail region; three postanal ventral melanophores

### LARVAE

**Distinctive characters:** body relatively elongate and slender, becoming more robust with development  
**Preanus length:** about 50% SL  
**Pigmentation:** a small number of melanophores on head; two parallel rows of dorsal melanophores; lower jaw pigmented; lateral sides of body, except caudal region, and anal fin pigmented; 3 or 4 melanophores between caudal and anal fins; melanophore on caudal–fin base  
**Length at flexion:** probably begins at about 4.0 mm SL

TRACHINIDAE

*Echiichthys vipera* (Cuvier, 1829)

**En:** Lesser weever

**Habitat:** Littoral and benthic, on sandy, muddy or gravelly bottoms, from a few meters to about 150 m depth

**Spawning season:** No information

---

**EGGS**

**Habitat:** pelagic
**Shape:** spherical
**Diameter:** 1.0–1.37 mm
**Chorion:** smooth
**Oil globules:** multiple, 6–30
**Perivitelline space:** small
**Yolk:** unsegmented

---

**YOLK–SAC LARVAE**

**Hatch size:** about 3.3 mm

**Distinctive characters:** body relatively elongate; anus situated close behind yolk sac; oil globules situated ventrally in yolk sac; pelvic fins well developed

**Pigmentation:** dorsal and ventral rows of melanophores extending posteriorly a little beyond mid–tail region in newly hatched larvae; pigmentation soon becomes characteristic with melanophores on snout, head, peritoneum and two bars of pigment, one in the anal region and another midway along postanal region

---

**LARVAE**

**Distinctive characters:** body relatively elongate and slender, becoming stout and deep with development; a series of preopercular and opercular spines; pelvic fins well developed from young larvae on

**Preanus length:** about 45% SL

**Pigmentation:** anal bars of pigment disappear in larvae of about 4.5 mm SL, with only a group of melanophores remaining; melanophores on head and on shoulder; pelvic fins and peritoneum strongly pigmented

**Length at flexion:** flexion begins at about 6 mm SL

---

A. 3.3 mm

B. Oil globules situated ventrally in yolk sac

C. 3.5 mm

D. 5.2 mm

E. 9.2 mm

F. 13.5 mm

- Oil globules situated ventrally in yolk sac
- Pelvic fins well developed
- Peritoneum strongly pigmented
- Only a group of melanophores in tail region in older larvae

A–C: Padoa (1956a); D–F: Russell (1976)
TRACHINIDAE

*Trachinus draco* Linnaeus, 1758

**En:** Greater weever – **Fr:** Grande vive – **Sp:** Escorpión

**Habitat:** Benthic, littoral, over muddy, sandy or gravel bottoms, down to 150 m depth

**Spawning season:** No information

### EGGS

**Habitat:** pelagic

**Shape:** spherical

**Diameter:** 0.96–1.11 mm

**Chorion:** smooth

**Oil globules:** single, 0.19–0.23 mm in diameter

**Perivitelline space:** small

**Yolk:** unsegmented

### YOLK–SAC LARVAE

**Hatch size:** about 3.2 mm

**Distinctive characters:** oil globule and anus situated at anterior and posterior edges of yolk sac, respectively; primordial fin globose reaching the snout

**Pigmentation:** melanophores on snout, two behind eye, on dorsal anterior part of body, and near anus; row of melanophores on postanal ventral region with a postanal bar at midway between anus and tail end

### LARVAE

**Distinctive characters:** body relatively elongate and slender, becoming more robust with development; pelvic fins appear at about 4 mm SL; young larvae, with primordial fin globose, reaching the snout; older larvae have 5 preopercular spines

**Preanus length:** about 40% SL

**Pigmentation:** early stages similar to yolk–sac larvae; with development, the origin of ventral postanal row of melanophores moves backwards and melanophores decrease in number; postanal bar of melanophores disappears and peritoneal pigment increases; pelvic fins strongly pigmented

**Length at flexion:** almost completed at 5.1 mm

En: Ringneck blenny

Habitat: Benthic, littoral

Spawning season: No information

EGGS

Undescribed

YOLK–SAC LARVAE

Undescribed

LARVAE

Distinctive characters: body elongate; pectoral fins fairly large; preopercular spines appear at 4.0 mm SL

Preanus length: 36% of SL in young larvae, diminishes to 32% in older larvae

Pigmentation: young larvae with only one stellate melanophore on head (many in older larvae); dorsal surface of gut heavily pigmented, pigmentation of abdominal region increases with development; a single melanophore ventrally over hindgut; ventral row of melanophores from anus to notochord tip; older larvae show a melanophore on caudal–fin base; dorsal pigmentation in tail region appears in larvae larger than 13 mm SL

Length at flexion: between 5 and 6 mm SL

### Yolk–Sac Larvae

**Hatch size:** 4.9 mm

**Pigmentation:** Dorsal side of gut pigmented, from behind eye to anus; a few melanophores on snout and top of head; apparently, no postanal ventral row of melanophores; pectoral fin unpigmented

### Larvae

**Distinctive characters:** Body elongate; pectoral fin fairly large; preanus length short

**Preanus length:** About one third of SL

**Pigmentation:** No melanophore on hindgut; black peritoneal pigment covering dorsal side of gut, to almost anus; postanal ventral row of 19–21 regularly spaced melanophores begins some distance behind anus and extends to caudal peduncle; melanophores on head and snout and some caudal melanophores; apparent paired dorsal bands of melanophores across dorsal fin in larvae larger than 18 mm; lateral row of melanophores above notochord

**Length at flexion:** Unknown

A. 6.0 mm

B. 10.0 mm

C. 13.0 mm

D. 18.5 mm

A–D: Ford (1922)
CALLIONYMIDAE

In the Western Mediterranean Sea there are 6 species of the genus *Callionymus*. Younger larvae (< 3 mm SL) of this genus are indistinguishable. The identification at the species level is only possible in larvae larger than 3 mm, when preopercular spines develop, and pelvic fins and pigmentation patterns become species-specific.

**Habitat:** Benthic, over sandy bottoms down to 650 m depth

**Spawning season:** Between January and August (varying by species)

### EGGS

**Habitat:** pelagic

**Shape:** spherical

**Diameter:** 0.55–0.97 mm

**Chorion:** in some species it shows hexagonal sculptures

**Oil globules:** none

**Yolk:** segmented

### YOLK–SAC LARVAE

**Hatch size:** about 2 mm (*Callionymus lyra*); yolk appears fully absorbed at 2.3 mm SL

### LARVAE

**Distinctive characters:** body short with thick head and abdomen; it shows a bifurcated preopercular spine; urostyle strongly developed and curved up at its end

**Preanus length:** about 50% SL

**Pigmentation:** strongly pigmented except for urostyle region

**Length at flexion:** no information

**GOBIIDAE**

*Crystallogobius linearis* (Düben, 1845)

**En:** Crystal goby

**Habitat:** Pelagic, in coastal to offshore waters, down to over 400 m depth. Males live on the bottom during the breeding season.

**Spawning season:** Between May and August in the NE Atlantic.

**EGGS**

Undescribed

**YOLK–SAC LARVAE**

Undescribed

**LARVAE**

**Distinctive characters:** body elongate and slender; first dorsal fin absent in females and showing two rays in males.

**Preanus length:** less than 50% SL.

**Pigmentation:** larvae up to 5 mm length, strongly pigmented with melanophores on head, in front of eye, at lower jaw tip and oocyst region; 5 large evenly spaced melanophores along dorsal contour of body; dorsal and ventral sides of gut and swimbladder pigmented; postanal ventral row of melanophores; pigmentation diminishes with development, so that larvae of ca. 11.0 mm SL have a row of postanal ventral melanophores and a series of melanophores on anterior ventral side of gut; swimbladder pigmented.

**Length at flexion:** unknown.

GOBIIDAE

*Gobius paganellus* Linnaeus, 1758

**En**: Rock goby – **Fr**: Gobie paganel – **Sp**: Bobí

**Habitat**: Benthic, in inshore and intertidal waters over rocky bottoms with weed cover

**Spawning season**: Between January and June

### EGGS

**Habitat**: demersal

**Shape**: fusiform, with a rounded, pointed apex

**Size**: 2.24 x 0.84 mm

### YOLK–SAC LARVAE

**Hatch size**: about 4.76 mm with mouth open and swimbladder apparent

**Pigmentation**: branched melanophores on ventral profile of abdomen; large, opposing dorsal and ventral melanophores at about mid–postanal region; swimbladder pigmented; a melanophore on hindgut; no melanophores on head

### LARVAE

**Distinctive characters**: body relatively elongate and slender

**Pre anus length**: about 50% SL

**Pigmentation**: early larvae similar to yolk–sac larvae; larvae larger than 7.0 mm with melanophores on head and a row of postanal ventral melanophores, while postanal dorsal melanophore disappears in postflexion larvae

**Length at flexion**: unknown

### PHOTOS

**GOBIIDAE**  
*Pomatoschistus microps* (Krøyer, 1838)

**En:** Common goby - **Fr:** Gobie commun

**Habitat:** Benthic, coastal, frequently in estuaries and intertidal pools

**Spawning season:** Spring and summer

---

### EGGS

**Habitat:** demersal  
**Shape:** pear-shaped, with a rounded apex  
**Size:** 1.0–0.7 x 0.65–0.8 mm  
**Oil globules:** several, maximum size 0.08 mm in diameter  
**Yolk:** unsegmented

---

### YOLK–SAC LARVAE

**Hatch size:** about 3.0 mm  
**Pigmentation:** row of melanophores along ventral side of trunk and tail; yolk sac and ventral side of gut strongly pigmented; large branched melanophore on dorsal mid–tail region

---

### LARVAE

**Distinctive characters:** body relatively elongate and slender  
**Preanus length:** about 50% SL  
**Pigmentation:** melanophores on head and lower jaw; an almost continuous row of ventral melanophores from throat, along trunk and tail region, one of which is highly ramified; highly ramified melanophore on mid dorsal tail region, opposite to ventral one  
**Length at flexion:** unknown

---

TRICHIURIDAE

*Lepidopus caudatus* (Euphrasen, 1788)

**En:** Silver scabbardfish – **Fr:** Sabre argenté – **Sp:** Pez cinto

**Habitat:** Bentopelagic, on the continental shelf and along its edge, down to 400 m depth; usually over sandy and muddy bottoms between 100 and 250 m depth

**Spawning season:** Between June and November in the Adriatic Sea

### EGGS

**Habitat:** pelagic  
**Shape:** spherical  
**Diameter:** 1.6–1.7 mm  
**Chorion:** smooth  
**Oil globules:** single, 0.40 mm in diameter  
**Perivitelline space:** small  
**Yolk:** unsegmented

### YOLK–SAC LARVAE

**Hatch size:** about 6.0 mm  
**Distinctive characters:** oil globule and anus situated at posterior edge of yolk sac; high number of myomeres  
**Preanus length:** about 25% SL  
**Pigmentation:** two dorsal and two ventral melanophores on tail region, one at level of caudal peduncle; some melanophores on head

### LARVAE

**Distinctive characters:** body very elongate and slender; long cephalic appendix (first ray of dorsal fin) in younger larvae, shortens with development  
**Preanus length:** about 25% SL in young larvae increases to about 50% SL in later larvae  
**Pigmentation:** early stages, similar to yolk–sac larvae: melanophores on head, snout, and post–occipital region, tail patches move into finfold and later into dorsal fin; peritoneum and lateral sides of gut pigmented; pigment over caudal peduncle reduces to its ventral side with development; anterior dorsal pigment patch disappears and others decrease in size; melanophores on dorsal–fin base extends backwards  
**Length at flexion:** unknown

**Habitat:** Epipelagic, in inshore waters and near islands  
**Spawning season:** Between May and November

### EGGS

- **Habitat:** Pelagic  
- **Shape:** Spherical  
- **Diameter:** 0.82–1.10 mm  
- **Chorion:** Smooth  
- **Oil globules:** Single, 0.24–0.29 mm in diameter  
- **Yolk:** Unsegmented

### YOLK–SAC LARVAE

- **Hatch size:** 2.14 mm SL  
- **Pigmentation:** Melanophores on head, and a row of melanophores on postanal ventral region; gut pigmented

### LARVAE

- **Distinctive characters:** Body moderately elongate becoming deeper with development; gut compact and triangular; jaws relatively short, compared to other tuna–like species; preopercular spines well–developed  
- **Preanal length:** Increases from about 37% to 50% SL with development  
- **Pigmentation:** Early stages, similar to yolk–sac larvae; in late larvae, the origin of ventral postanal row of melanophores moves backwards and melanophores decrease in number; pigmentation of peritoneal region increases; some melanophores appear in the occipital region together with one or two dorsal melanophores, a little ahead of caudal peduncle; these latter ones extend forward with development  
- **Length at flexion:** 4.5–6.0 mm

*Sarda sarda* (Bloch, 1793)

**En:** Atlantic bonito – **Fr:** Bonite à dos rayé

**Sp:** Bonito del Atlántico

**Habitat:** Epipelagic, migratory

**Spawning season:** Between May and July

### EGGS

- **Habitat:** Pelagic
- **Shape:** Spherical
- **Diameter:** 1.2–1.32 mm
- **Chorion:** Smooth
- **Oil globules:** 1–5; 0.28–0.32 mm in diameter, when single; 0.02–0.24 mm in diameter, when multiple
- **Perivitelline space:** Small
- **Yolk:** Unsegmented

### YOLK–SAC LARVAE

- **Hatch size:** About 4.0 mm
- **Distinctive characters:** Yolk sac voluminous; oil globules situated at posterior edge of yolk sac
- **Pigmentation:** Finfold pigmented in its anterior dorsal part; small melanophores on head and along dorsal region; some isolated melanophores on lateral and ventral sides of body

### LARVAE

- **Distinctive characters:** Body moderately elongate, deepest at level of pectoral region; head large with pointed snout and jaws; prominent teeth from early larvae on; preopercular spines well developed; gut compact and triangular
- **Preanus length:** Increases from about 50% SL to 60% SL with development
- **Pigmentation:** Series of large spots along ventral tail region, move up internally between myomeres with development; top of head and peritoneal region well–pigmented; melanophores at cleithral symphysis, at lower jaw tip and caudal–fin base; patch of pigment in lateral caudal region in older larvae
- **Length at flexion:** 6.0–7.0 mm SL

**Scomber colias** Gmelin, 1789

| En | Atlantic chub mackerel | Fr | Maquereau espagnol |
| Sp | Estornino               |

**Habitat:** Epipelagic or meso-demersal, down to 250–300 m depth

**Spawning season:** Summer

#### EGGS

- **Habitat:** pelagic
- **Shape:** spherical
- **Diameter:** 1.04–1.14 mm
- **Chorion:** smooth
- **Oil globules:** single, 0.26–0.27 mm in diameter
- **Perivitelline space:** small
- **Yolk:** unsegmented

#### YOLK–SAC LARVAE

**Hatch size:** about 3.0 mm SL

**Distinctive characters:** body relatively elongate; oil globule located at posterior edge of the yolk sac

**Pigmentation:** melanophores irregularly distributed along dorsal and ventral contours of body; melanophores on snout and behind eye; yolk sac and oil globule pigmented

#### LARVAE

**Distinctive characters:** body moderately elongate, becoming stubby with development, deeper than that of larvae of comparable sizes of *Scomber scombrus*; head moderate; gut compact and triangular; jaws relatively short; no head spines; teeth prominent in larvae larger than 4.0 mm SL; the number of myomeres allows for distinguishing this species (32) from *Diplodus* species (24)

**Preanus length:** increases from about 50% SL to more than 60% SL with development

**Pigmentation:** postanal ventral rows of melanophores starting some distance from anus; larvae less than 7 mm long may only show two dorsal melanophores, situated on caudal peduncle; peritoneum pigmented; melanophores at caudal–fin base; melanophores on head; no melanophores on body sides in preflexion stages; no melanophores at cleithral symphysis and on isthmus

**Length at flexion:** about 6 mm

**En**: Four-spot megrim – **Fr**: Cardine à quatre taches  
**Sp**: Gallo de cuatro manchas

**Habitat**: Benthic, down to 800 m depth  
**Spawning season**: Between May and October

### EGGS
Undescribed

### YOLK–SAC LARVAE
Undescribed

### LARVAE  
**Figs. A–E**

**Distinctive characters**: body relatively slender at early stages; trunk and abdominal regions increase considerably in depth with development; larvae more than 5.0 mm long show preopercular spines and a spine on each side of upper posterior side of head  
**Preanus length**: less than 50% SL  
**Pigmentation**: 4 melanophores evenly arranged along dorsal side of body and 3 postanal ventral melanophores; gut, head and frontal region pigmented  
**Length at flexion**: unknown  
**Remarks**: asymmetry starts when the larva is about 9.7 mm long

SCOPHTHALMIDAE

*Scophthalmus rhombus* (Linnaeus, 1758)

**En:** Brill  **- Fr:** Barbue  **- Sp:** Rémol

**Habitat:** Benthic, between 5 and 70 m depth

**Spawning season:** Between February and April (probably)

---

**EGGS**

- **Habitat:** pelagic
- **Shape:** spherical
- **Diameter:** 1.24–1.50 mm
- **Chorion:** smooth
- **Oil globules:** 0.16–0.25 mm in diameter
- **Perivitelline space:** small
- **Yolk:** unsegmented

---

**YOLK–SAC LARVAE**

- **Hatch size:** 3.8–4.0 mm
- **Pigmentation:** body (except caudal region) and yolk sac pigmented; melanophores extend onto finfold to form a wide postanal bar and a dorsal patch above gut

---

**LARVAE**

- **Distinctive characters:** body relatively elongate and slender becomes laterally compressed and ovoid with development; a spiny ridge above eye and opercular spines
- **Preanus length:** about 50% SL
- **Pigmentation:** body covered with melanophores (caudal region free of pigment in early larvae); body pigment extends onto dorsal and anal fins forming almost regular bands in older larvae
- **Length at flexion:** unknown

---

BOTHIDAE

*Arnoglossus laterna* (Walbaum, 1792)

**En**: Mediterranean scaldfish – **Fr**: Arnoglosse de Méditerranée – **Sp**: Serrandell

Five *Arnoglossus* species are known to occur in the Mediterranean Sea. The identification of their larvae is difficult due to their similar morphology and pigmentation pattern. *A. laterna* is the only species of this genus for which all early life stages have been described and is here presented.

**Habitat**: Benthic, over muddy and sandy bottoms down to 200 m depth, occasionally to 400 m

**Spawning season**: Between April and August

### EGGS

- **Habitat**: pelagic
- **Shape**: spherical
- **Diameter**: 0.60–0.76 mm
- **Chorion**: smooth
- **Oil globules**: single, 0.11–0.15 mm in diameter
- **Perivitelline space**: small
- **Yolk**: unsegmented

### YOLK–SAC LARVAE

- **Hatch size**: about 2.5 mm
- **Pigmentation**: free of black pigment

### LARVAE

- **Distinctive characters**: body relatively elongate, increases in height and becomes laterally compressed with development; gut becomes curved; elongate tentacle over head, disappears in older larvae; swimbladder prominent; minute spines on different regions of body in larger larvae
- **Preanus length**: about 40% SL
- **Pigmentation**: two rows of evenly spaced ventral melanophores, extending from anus to caudal end; dorsal bar of melanophores close to caudal region; melanophores along abdominal ventral contour, on lower jaw and over hindgut; swimbladder pigmented
- **Length at flexion**: unknown

**PLEURONECTIDAE**  
*Platichthys flesus* (Linnaeus, 1758)

**En:** European flounder – **Fr:** Flet d’Europe – **Sp:** Platija europea

**Habitat:** Benthic, at shallow depths on soft bottoms

**Spawning season:** Between December and March (Black Sea)

---

**EGGS**

- **Habitat:** pelagic
- **Shape:** spherical
- **Diameter:** 0.8–1.13 mm
- **Chorion:** smooth
- **Oil globules:** none
- **Perivitelline space:** small
- **Yolk:** unsegmented

---

**YOLK–SAC LARVAE**

- **Hatch size:** about 2.3 mm
- **Pigmentation:** no pigmentation on primordial fin in earlier larvae; as development proceeds, a group of melanophores develops about mid-way along postanal region, spreading out dorsally and ventrally onto the primordial fin; other melanophores scattered on body; postanal end region unpigmented

---

**LARVAE**

- **Distinctive characters:** body elongate and slender, becoming more robust and laterally compressed with development
- **Preanus length:** less than 50% SL
- **Pigmentation:** many scattered melanophores along ventral sides of body, spreading out over anal and caudal fin where melanophores tend to be aligned with fin rays
- **Length at flexion:** unknown
- **Remarks:** asymmetry starts at about 7 mm and is completed at about 10 mm length

This guide presents the egg and larval descriptions of 100 species of fishes belonging to 55 families, which are most likely to be present in plankton samples collected in the continental shelf and oceanic waters of the Western Mediterranean Sea. The guide is structured in two parts. The first introductory part describes the different applications of ichthyoplankton studies in fisheries research, the main sampling strategies, methods and gears, the early life history of fishes and how to identify them. A brief historical account of ichthyoplankton identification studies in the Mediterranean Sea is also provided. The second part of the guide contains the identification sheets of the species. Each species sheet includes the following information: illustration of the adult fish and information on its habitat and spawning season; description of the main features useful towards identifying the egg, yolk sac and larval stage of each fish species; illustrations and (when available) photos of the different life stages.
