## FOREWORD

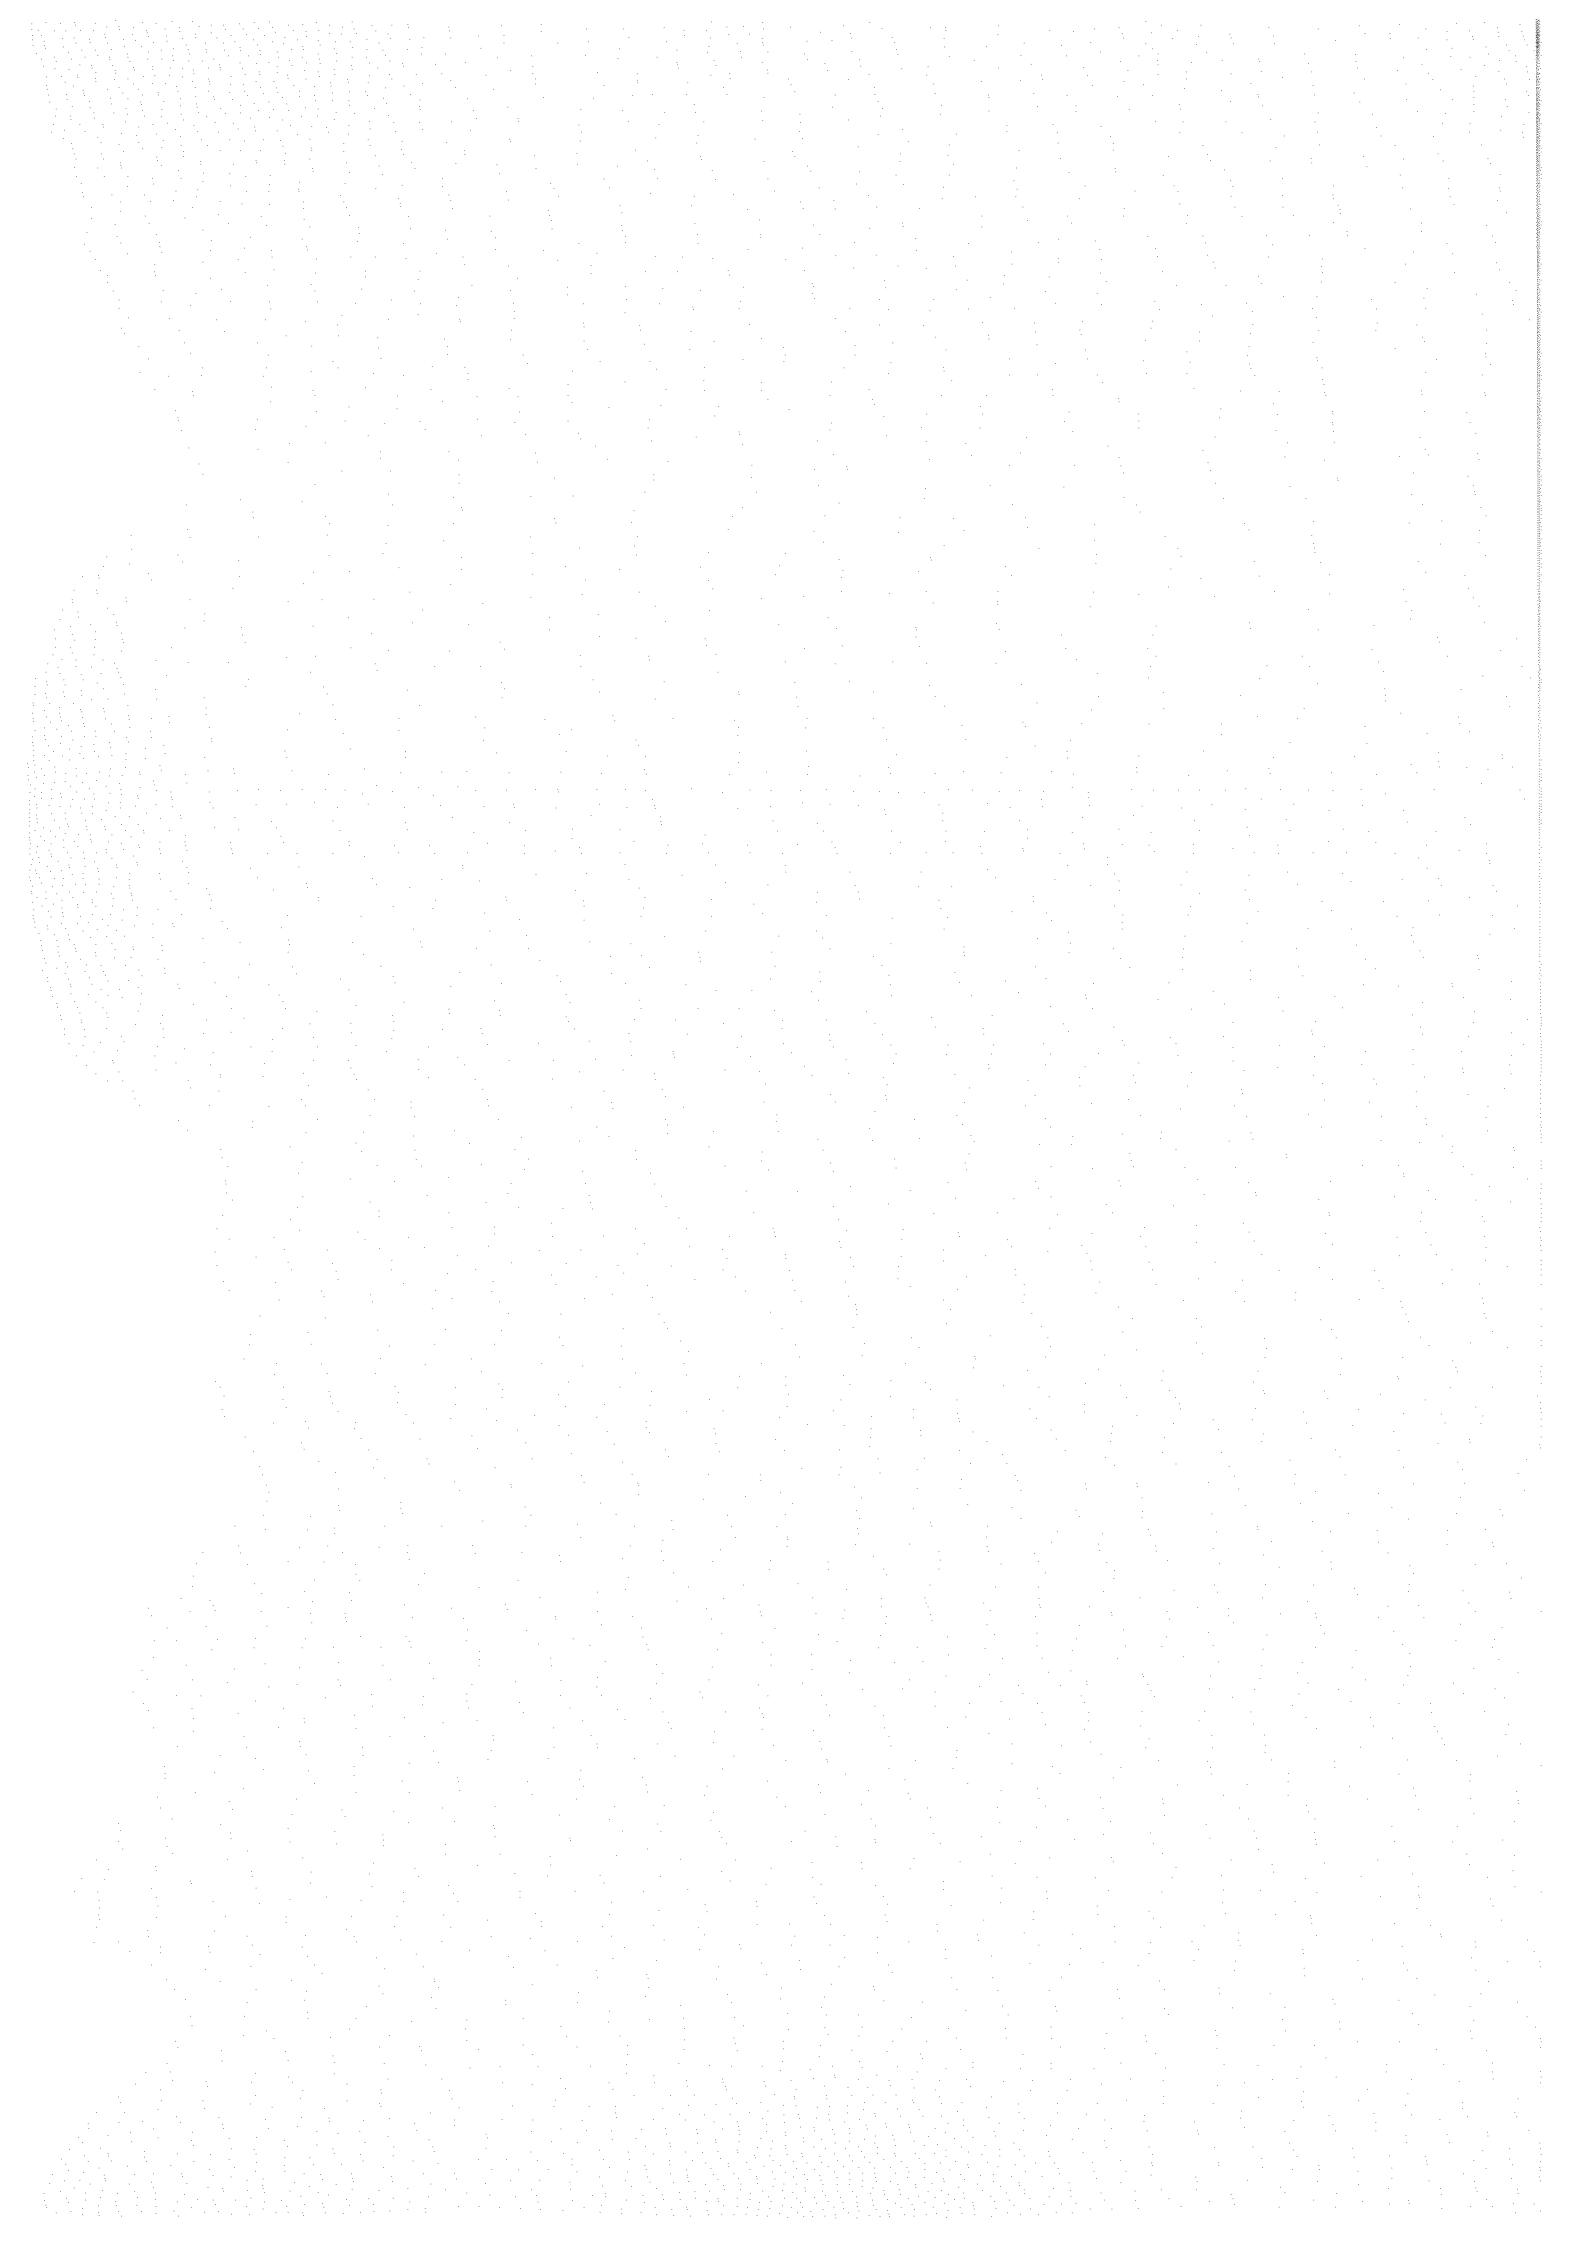

The purpose of this report is to present a description of the FAO's production index and its evolution, published regularly in the FAO Production Yearbook and in the FAO Monthly Bulletin of Statistics, as well as in The State of Food and Agriculture report. The production index is a measure of agricultural output changes, which is calculated at three levels: countries, regions (economic classes, continents), and global. Both the long-term trends and the short-term changes, indicated by the series of production index numbers, are regarded as important information by the data users, since they contribute to the assessment and monitoring of agricultural development. National governments, international organizations, commercial establishments and academic research institutions can be mentioned as the main users of this information.

FAO provides in the Production Yearbook a short methodological note together with the regularly published series. However, in view of the complex character of this statistic, there is a demand for a more detailed explanation and discussion of the methodology of index construction. The present report has been prepared to respond to this general demand, and to describe especially the last revision which was performed in 1986, concurrently with shifting the base period from 1974-76 to 1979-81.

This report is of technical character, addressed mainly to those data users who are interested in methodology. In addition to the technical description it contains results of calculations with different methods, including those, which are not adopted for the standard FAO publications. This information will hopefully assist in the understanding and interpretation of the index numbers.

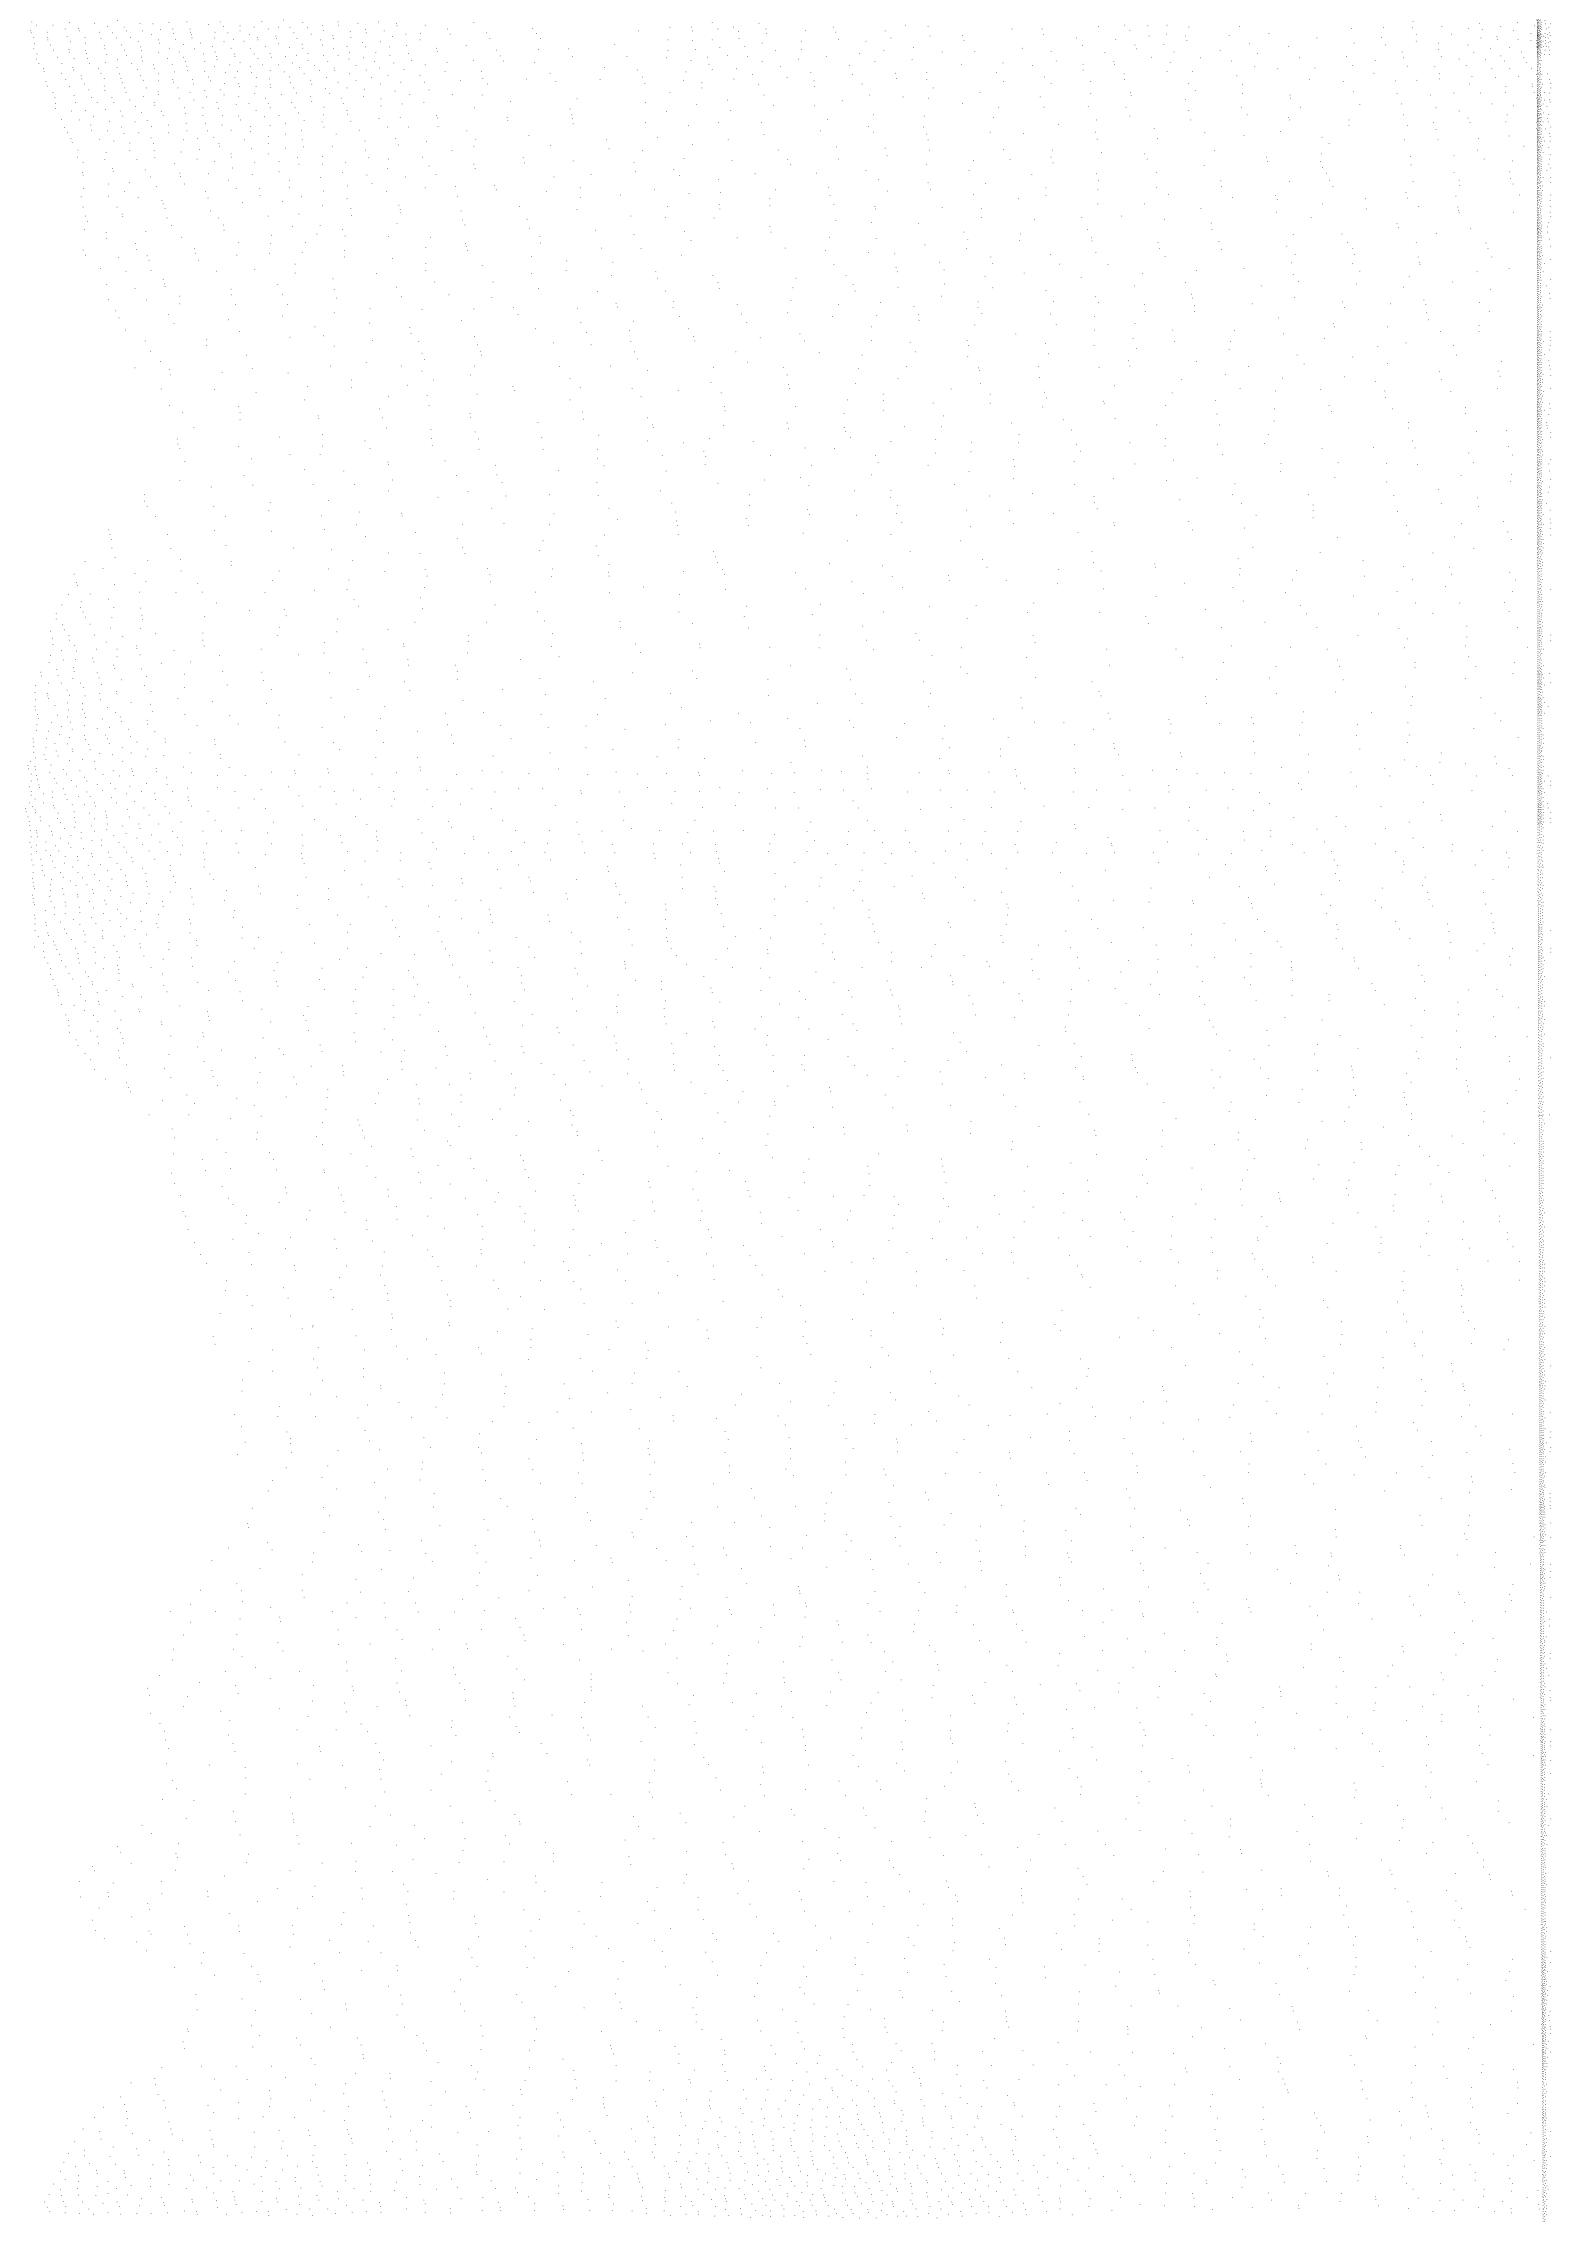

This report was prepared in the Statistical Analysis Service by Dr. G. Parniczky who worked as a consultant. His service is gratefully acknowledged.

## CHAPTER 1

### HISTORY OF THE PRODUCTION INDEX

This chapter provides a brief review of the FAO production index as it evolved from its conception in 1947. The description of the index numbers is supplemented by tables and charts showing the long-term development of world agricultural production, produced by reconstruction and linkage of the historical series.

#### 1.1 Review of the development of the international agricultural production index

FAO's predecessor during the pre-war period, the International Institute of Agriculture compiled aggregate production values by continents, using standard world market prices as weights attached to each commodity. However, no attempt was made to compute indices, based on the aggregate value data, to measure changes of production at constant prices.

After the war FAO itself started to construct volume indices of agricultural production. The first results were published in the 1948 issue of the Yearbook of Food and Agricultural Statistics, Vol. I. Series for "food" and "all commodities" were presented, covering 50 countries and territories separately. No regional or global indices were presented. The formula adopted was Laspeyres, based on the average of 1934-38, or nearest available period, called "pre-war base". According to the short note on methods: "Uniform price-weights based on comparative international prices during the pre-war base period were used for all countries. Adjustments were made to avoid double-counting of feed and other crops used in livestock production". However, seed was not removed from the quantity produced.

Regional and global series of index numbers appeared first time in the 1956 issue of the Yearbook. Using the same base period and methodology as before, FAO published data for seven regions and the world. While China, Eastern Europe and USSR were excluded from the regional coverage because data were not available, the global series included estimates for the missing countries. In the 1956 Yearbook indices were published for the average of the crop-years 1948/49 - 1952/53 and separately for 1953/54, 1954/55 and 1955/56.

Shifting the base period, together with a major revision of the methodology, was performed a few years later and the first results of the new series were published in the July 1959 issue of the Monthly Bulletin of Agricultural Economics and Statistics and in "The State of Food and Agriculture 1959". The principal changes may be summarized as follows:

- i) Refinement of the concept of production: allowances were made for feed and production losses, as well as for seed.
- ii) A new set of regional price weights was adopted representing the averages of (national) wheat price relatives within a given region.
- iii) A new post-war base was set (five year period: 1952/53-1956/57).

Starting with the 1966 issue of the Yearbook calendar-year time reference replaced the crop-years (split-years), and the base period was changed accordingly (1952-56). The Laspeyres formula was retained and the regional wheat-based price relatives were used for weighting.

A shift of the base period took place in 1971 when it was updated to 1961-65, replacing the previous base (1952-56). However, the methodology was not changed. An important revision was performed later, concurrently with the re-basing of the series to 1969-71. The first such results were presented in the 1977 issue (Vol.31) of the Production Yearbook. According to the note on methodology in the Yearbook "the most important change is the use of national average producer prices (1969-71) as weights for computation of aggregate production of each country instead of regional wheat-based price relatives (1961-65 averages) applied to each country of the region".

Indices for continents, regions and the world were computed by summing the country aggregates, which for that purpose were converted into US dollars. The exchange rates of national currencies for US dollars were those published by the International Monetary Fund.

The practice of removing feed and seed from the production data was continued. Removing the intra-agricultural inputs was justified as follows. "The reason for subtracting amounts of seed and feed from the production data is that the FAO index numbers, based on the concept of world agriculture as one farm, measure agricultural production by avoiding double counting of seed and feed (which are already counted in the production data) and the crops and livestock produced from them".

In 1983 the base period of the production index was up-dated to 1974-76, but the methodology was not revised. The revision was performed later, in 1986, together with shifting the base period to 1979-81. This last change involved the introduction of standard international commodity prices for computing the regional and global index numbers, according to the Geary-Khamis formula. A detailed description of this method and the reason for the last revision will be presented in Chapter 3.

During all the stages of development, described above, both commodity and country coverage of the production index has been gradually extended and the general accuracy has improved, as a result of the development of FAO's statistical data base, containing the quantity and price data series. The data base has been expanded as FAO established regular channels of data collection with more and more countries. In addition to the regular channels, FAO estimated the missing data and cross-checked the reported data by using all available information from national and international sources.

The expansion has been especially important concerning the data provided by developing countries. The 1977 issue of the Production Yearbook (Vol.31) e.g. contains index numbers for 145 countries and territories, which already corresponded to an almost complete coverage, together with over 20 international aggregates, such as continents, regions, economic classes. Quality of the basic data, on the other hand, has improved not only because the countries have provided more reliable information, but also as a result of the consistency checking procedures introduced by FAO.

Concurrently with the extension of geographical coverage, new features appeared in the volumes, such as per caput series in addition to the indices of total agricultural and food production, improved format of tabular presentation and more detailed commodity classification. Apart from the yearbooks, the index numbers are also available in various issues of the FAO Monthly Bulletin of Statistics, as special features. The FAO production index is recognized as the best available international measure of agricultural development and tables of the series are regularly reproduced in the United Nations' Statistical Yearbook.

## 1.2 FAO activities on index number methodology

Some of the methodological changes of index number construction, described above, were based on recommendations of expert groups meetings and consultants, commissioned to study the problems involved and to prepare recommendations for future developments. These activities included two meetings of experts on index numbers, the first in 1956 and the second in 1961. In 1967 Mr. E.L. Snowdon was commissioned to prepare a technical paper on this subject.

In 1983 and 1984 the ES Departmental Working Group on Statistics and its subsidiary body, the Sub-group on Statistical methods, were charged to review the methodology of the production index and prepare a report with recommendations for further improvement. After a series of preparatory meetings in the Sub-group, the subject was discussed by the Working Group in March 1984. It was decided to perform a revision of the methodology in 1985, concurrently with shifting the base period from 1974-76 to 1979-81.

While the Working Group recommended to continue the calculation of country indices with national price-weights, it suggested using standard (world) commodity prices for the regional and global series (in conformity with the Snowdon report referred to above) and specified the Geary-Kahmis formula for computing the standard prices. In addition, the Working Group recommended refinements of the definition of production for the purpose of the index number.

The decisions of the Departmental Working Group, summarized above, were submitted to the Statistics Advisory Committee of Experts, which held its 10th Session in September 1984. According to the report on that meeting the Committee endorsed the recommendation of the Working Group on the revision of the index concerning the price-weights. The Committee agreed that the "national farm output" concept, relating to agricultural production was a suitable quantity measure, but it recommended further research in this area.

### 1.3 Historical series of production index numbers

In view of all the changes, revisions and improvements of coverage and quality of basic data, described in Section 1.1, it is not surprising that FAO does not publish long-term series of production index numbers in the regular publications. Indeed, the notes to the tables stress that the series published in previous issues of the yearbook, preceding a shift of the base period, are not comparable with the ones calculated on the new base, especially if re-basing of the series was combined with a revision of the method, which happened several times.

Notwithstanding this warning, it is interesting to link the indices and construct historical series, based on the pre-war period. The result can be regarded as a very crude measure of the volume changes of global agricultural production over almost half a century. A very simple technique was adopted to construct the series: the subsequent base periods of the index, from the start up to 1974-76, were used as bench-mark periods and the usual "splicing" method was adopted to adjust the series between the successive bench-marks, as if it was a chain-index composed of the rather long links.

Results of the calculations are presented in Table 1.1. The list of regions separately presented is incomplete: Near East, Far East, Eastern Europe and USSR are absent, because comparable data were not available in the post-war period to continue the pre-war based series. Nevertheless, the overall series were constructed by estimating the missing data, therefore the "World" represents the global situation, at least in principle. The main finding is that the volume of the global agricultural production around 1983 was 2.6 times higher than that of the pre-war period, i.e. 159 per cent increase was achieved during 47 years, which corresponds to a 2.0 per cent annual average growth rate. To test the plausibility of this result the gross quantity data of the main agricultural products were compiled for the same periods. Unfortunately, only a few global series are available and they do not cover animal products, except for wool. In view of this, livestock numbers were used to indicate the development. Table 1.2 shows the results.

2/ Oil equivalent.

Sources: FAO Production Yearbook 1951, 1984 and supplementary information in the data files of ESS.

The quantity relative of cereals (263 per cent) is very close to the global production index of agriculture (259 per cent), which is not surprising, since this commodity group, composed of wheat, paddy rice, maize, barley, rye, millet, sorghum and mixed grains, has a high weight in the total production index. The variation of the other commodity relatives is high, as expected over a long period; it ranges from 130 per cent to 414 per cent. Potatoes, pulses, wool and sheep are on the low side, whereas tea, sugar and oil crops on the high side of the range. The general pattern of the quantity relatives appears to be consistent with the historical series of production indices.

The historical series of production should be of course studied in relation to population growth. Indices of per caput production are regularly published by FAO. Qualifications must be mentioned with reference to population data, as well as for the agricultural production. Apart from the developed countries, where complete population censuses were regularly organized in both the pre-war and post-war period, pre-war comparisons involve estimates, based on information available to the United Nations. The population data compiled according to the regional breakdown of the historical index series are shown in Annex Table I.

Having in mind the above caveats we may study the production/population relation and draw some conclusions. Chart 1.1 illustrates the long-term trends. The overall growth of the production during the 47 years period was, as we have observed, 159 per cent, corresponding to 2 per cent average annual growth rate. Population, on the other hand, shows a relative increment of 112 per cent and 1.6 per cent average growth. The trend of the production is therefore superior to population, although the difference is not large. The chart shows that this relationship prevails consistently, except for the first sub-period (1934-38 through 1948-52) which includes the years of the 2nd World War.

Table 1.3 shows the total and per caput production indices and average growth rates according to regions. The highest growth rates of the total agricultural production were achieved by the two developing regions (Latin America and Africa), but the highest per caput rate was recorded by Western Europe, whereas both of the two developing regions show zero growth. Even this can be considered as a remarkable performance if we take into account the high population growth rate in these two regions (2.5 and 2.3 per cent respectively, versus 0.7 per cent in Western Europe).

2/ Geometric mean based on terminal averages.

3/ Including regions not specified.

Sources: For production index see Tables 1 and 2.

Population: ESS population data, and United Nations: "World population prospects", Population Studies No. 41, New York 1966.

The global production growth (both total and per caput) is exhibited in Table 1.4. The sub-periods are defined according to the subsequent base periods of the index number, explained in the previous section. As illustrated by the Chart 1.1, the per caput production was below the pre-war level until about 1953. This period was followed by a very high rate of production increase, putting the production level well above the population during the 60's. A stable production-population ratio has been maintained during the past decades, characterized by 0.5 per cent average annual per caput growth rate.

## CHAPTER 2

### DATA ORGANIZATION, BASIC CONCEPTS AND DEFINITIONS

This chapter starts with a review of the data base used for the construction of the production index. The description covers the data sources, storage organization and other relevant features of the basic quantity and price data. The second part of the chapter is devoted to the concepts, definitions, symbols and formulae used throughout this report.

#### 2.1 The data base

The elementary building blocks of production index numbers are the quantity and price data series, i.e. the time series of production quantities and producer prices relating to a given country and commodity. They are stored, together with other basic data, in FAO data base, entitled "Interlinked Computerized Storage and Processing System of Food and Agricultural Commodity Data" (ICS). The ICS contains data series of national aggregates or averages of the production, trade and utilization data of all agricultural, forest and fish products, as well as land use, means of production, population, prices, etc. A comprehensive description of the system is available in the ICS Users' Manual (FAO 1986); the present statement will be confined to the data used for the index numbers.

Data on the quantities produced from each commodity, stored in the ICS, constitute a part of a larger data system, called Supply/Utilization Accounts. The Supply/Utilization Accounts (SUAs) series of agricultural and fish products constitute the core statistics of the System. For each product in a country, in each year, the SUA traces its supplies from production, imports and stocks to its utilization in different forms: addition to stocks, exports, animal feed, seed, manufacture for food and non-food purposes, waste and food. Elements vary according to the commodities. This system helps to check the plausibility of statistical data supplied by the countries and to choose between alternative sources of data and provide a logical framework for estimating missing observations.

#### 2.2 Basic concepts

Production and producers' prices (i.e. prices received by farmers) are defined according to established FAO standards, and data stored in the ICS correspond to these concepts, as far as the data supplied by the countries allows it.

The definition of production in the ICS data system depends on the commodity and can be summarized as follows:

Crop production data recorded in the SUAs refer to the actual harvested production from the field or orchard and gardens, excluding harvesting and threshing losses and that part of crop not harvested for any reason. Production therefore includes the quantities of the commodity sold in the market (marketed production) and the quantities consumed by the producers (autoconsumption).

When the production data available refers to a production period (crop-year) falling into two successive calendar years it is usual to refer production data to that year into which the bulk of the production falls. Crop production data are stored in metric tons (MT).

Definition of production in the livestock sector is more commodity-specific and it is available in the Users' Manual, referred to above, separately for meat, eggs, milk, hides and skins, etc. FAO uses standard weights and performs adjustments by conversion factors to store uniformly defined and comparable data in the ICS. The standard unit is dressed carcass weight for large animals and ready-to-cook (oven ready) weight for small animals. Further details are available in the Users' Manual quoted above.

Information concerning prices refers to the prices received by farmers per unit (usually a metric ton of product at the time the commodity leaves the farm). The producer prices, often termed "farm gate prices", should include all costs incurred by the farmer to produce the commodity and his own profit. These are the prices generally used to calculate the gross value of output for the Statistics of National Accounts. Prices, in general, are the annual average for the calendar year. Producer prices of animals relate to animals for slaughter. They are compiled in units per metric ton of liveweight and thereafter converted into units per metric ton of carcass weight by applying the relationship carcass weight/liveweight. Producer prices are stored in the computer file in the unit of national currency or in sub-multiple of it.

Further details on the price concept are available in the manual on farm and input prices (FAO, 1980), and national practices concerning price data collection and processing are presented in a separate report (FAO, 1986).

### 2.3 Symbols and notation

Notation adopted in this report follows the usual practice (see e.g. Allen 1975, United Nations 1977 and 1979). However, a summary of basic symbols and index formulae is presented below for easy reference:

$q$	=	quantity produced
$p$	=	price per unit
$qp$	=	$v$ = value of production
$o$	=	subscript for the base period
$t$	=	subscript for the current period
$i^q$	=	$q_t/q_o$ = quantity relative (elementary quantity index)
$i_p$	=	$p_t/p_o$ = price relative (elementary price index)

#### Remarks:

- i) The unit of observation is a well specified commodity;
- ii) The unit of measurement is specific to the commodity; standard units are recorded in the ICS (e.g. metric ton).
- iii) Price is recorded in national currency for each country. The construction of regional and global index numbers constitutes a special problem, to be discussed later.
- iv) Summations in the index formulae run through  $i = 1, 2, \dots, n$  commodities, but the subscript  $i$  will be abandoned to simplify notation. E.g.

$$\sum_{i=1}^n q_{oi} p_{oi} = \sum q_o p_o$$

Using the above notation the value index is defined as the ratio of current over base period aggregate values:

$$v = \frac{\sum q_t p_t}{\sum q_o p_o} = \frac{\sum v_t}{\sum v_o}$$

The basic formulae for the quantity (volume) and price indices are presented in Table 2.1. The difference between the aggregative and weighted average forms is only computational, they yield the same result if computed from an identical set of quantity and price data.

If the time span covers more than two periods ( $t = 0, 1, 2, \dots, T$ ) we are dealing with runs or series of index numbers. In this case the formulae become more complex, because, in addition to the types defined for two periods, a combination of the following alternatives can be chosen:

- indices with fixed or moving weights
- indices chained or not chained.

Table 2.1

INDEX FORMULAE FOR TWO PERIODS

Type	Symbol	Formula Aggregated	Formula Weighted mean
QUANTITY INDEX			
Laspeyres	$Q_L$	$\frac{\sum q_t p_o}{\sum q_o p_o}$	$\frac{\sum v_o i_q}{\sum v_o}$
Paasche	$Q_P$	$\frac{\sum q_t p_t}{\sum q_o p_t}$	$\frac{\sum v_t}{\sum v_t / i_p}$
Fisher	$Q_F$		$\sqrt{Q_L Q_P}$
PRICE INDEX			
Laspeyres	$P_L$	$\frac{\sum q_o p_t}{\sum q_o p_o}$	$\frac{\sum v_o i_p}{\sum v_o}$
Paasche	$P_P$	$\frac{\sum q_t p_t}{\sum q_t p_o}$	$\frac{\sum v_t}{\sum v_t / i_p}$
Fisher	$P_F$		$\sqrt{P_L P_P}$

Table 2.2 presents selected runs of volume indices, which represent the types of index series used frequently. For the sake of simplicity only three periods were included and three binary comparisons performed. Note that Laspeyres is usually combined with fixed weights and Paasche with moving weights, with or without chaining. Note further, that the fixed weight index for the comparison "B" in the first line of Table 2.2 is not a proper Laspeyres index, since the weights do not correspond to the actual reference period ( $t = 1$ ). It can be regarded as a ratio of the two quantity indices:  $Q_{2/o}$  over  $Q_{1/o}$ , both of which are true Laspeyres index numbers. The chain indices are constructed from links, representing binary comparisons over adjacent periods.

Laspeyres index with fixed weights is a frequently used formula, but the weights become out of date and product comparability might create a problem after a few years (the index fails to satisfy the "characteristicity" property). Therefore a revision of the weighting system and re-basing of the series to a new reference period takes place at that point of time. There is a consensus that revision should be performed every 5-10 years, and this is indeed the UN recommendation (United Nations, 1979, p.18).

Table 2.2

SERIES OF QUANTITY INDEX NUMBERS

Symbol	Weights	Chained	Comparison: current over reference period		
			$1/_o = A$	$2/_1 = B$	$2/_o = C$
$Q_L$	fixed	not	$\frac{\sum q_1 p_o}{\sum q_o p_o}$	$\frac{\sum q_2 p_o}{\sum q_1 p_o}$	$\frac{\sum q_2 p_o}{\sum q_o p_o}$
$Q_L$	moving	yes	$\frac{\sum q_1 p_o}{\sum q_o p_o}$	$\frac{\sum q_2 p_1}{\sum q_1 p_1}$	AB
$Q_P$	moving	not	$\frac{\sum q_1 p_1}{\sum q_o p_1}$	$\frac{\sum q_2 p_2}{\sum q_1 p_2}$	$\frac{\sum q_2 p_2}{\sum q_o p_2}$
$Q_P$	moving	yes	$\frac{\sum q_1 p_1}{\sum q_o p_1}$	$\frac{\sum q_2 p_2}{\sum q_1 p_2}$	AB

The FAO production index belongs to the category described above, i.e. a Laspeyres quantity index with fixed weights (producers' prices) and revised regularly after a period of 5-10 years. However, the base period is not a single year, as usual in other sectors, but an average of three consecutive years, in view of the year-to-year fluctuations of the agricultural production.

## CHAPTER 3

### THE METHODOLOGICAL ISSUES

The construction of the FAO production index is discussed in this chapter, including the concept of the production, the choice of the formula and other related topics. Alternative procedures are presented, together with numerical examples, illustrating the impact of certain methods on the value of the index number. Particular attention is devoted to explain the reasons of the latest revision of the index, carried out in 1985.

#### 3.1 The concept of production

Various definitions of agricultural production can be considered for the purpose of making index numbers. They represent a range from "gross" to "net", depending on the treatment of double-counting, i.e. the removal of different categories of inputs, used up during the production cycle. Three categories of inputs should be distinguished for the discussion:

- i) Commodities required as inputs for their own production, such as seed, hatching eggs, etc.
- ii) Inputs of other agricultural commodities, e.g. maize for livestock feed.
- iii) Non-agricultural inputs, such as fertilizers, pesticides, fuel oil, etc.

Categories (i) and (ii) are intra-agricultural inputs. The different inputs are shown in Table 3.1. In this table, for the sake of simplicity, agriculture was divided into two sub-sectors; however, more sectors can be created mutatis mutandis, following the same scheme. The category (i) of inputs is located in the main diagonal of the 2x2 section of the table ( $X_{11}$  and  $X_{22}$ ). The off-diagonal elements represent category (ii). Finally, the third line under the 2x2 table represents the category (iii).

Table 3.1

Input-output flows

From \ To	Crops	Livestock production	Total production
Crops	$X_{11}$	$X_{12}$	$G_1$
Livestock prod.	$X_{21}$	$X_{22}$	$G_2$
Non-agriculture	$X_{31}$	$X_{32}$	o

With reference to Table 3.1 the following basic production concepts can be distinguished:

#### 3.1.1. Total production (or "gross-gross" output):

$$G = G_1 + G_2.$$

Commodity-specific definitions of the total production (gross-gross output) are available in the ICS Manual; they have been reviewed in the second chapter (Section 2.2).

According to this concept no deduction is made from the total production value (except for waste, as defined in the ICS). This results in double-counting, e.g. the maize used as livestock feed is reported first as crop production and second as an input contributing to the value of livestock products when the index covers total agriculture. This kind of double-counting does not bias the index as long as the input/output ratios are stable. However, such an assumption can be entertained only in the short-run. Structural changes and technological progress generate significant changes in the long-run, thereby affecting the value of the production index. In view of this, total production is not a preferred concept for index number construction.

### 3.1.2. Final output

Defined for crops:

$$F_1 = G_1 - X_{11}$$

Livestock products:

$$F_2 = G_2 - X_{22}$$

Total agriculture:

$$F = G - (X_{11} + X_{12} + X_{21} + X_{22}).$$

The result of the above deductions is that intra-agricultural inputs (i) and (ii) are removed, whether domestic production or imported, from the total production value. Consequently, double counting is confined to inputs provided by other sectors, outside agriculture. This production measure is in line with the "national farm" concept, adopted in the agricultural accounting system of some countries, whereby the national territory is considered as a single farm, and output is measured by counting only the products which leave that farm.

### 3.1.3. Value added (agricultural GDP)

For crops:

$$A_1 = G_1 - (X_{11} + X_{21} + X_{31})$$

Livestock products:

$$A_2 = G_2 - (X_{12} + X_{22} + X_{32})$$

Total agriculture:

$$A = G - (X_{11} + X_{21} + X_{31} + X_{12} + X_{22} + X_{32}).$$

This is a measure of the "real product" or agricultural GDP, which corresponds to the "gross value added" concept in national accounting.

Value added would be of course a very good concept for the measurement of production changes. However, there are practical difficulties of adopting this production measure by FAO. It was pointed out in Chapter 2 that the SUA data system has a very wide coverage, both geographically and regarding commodities. Concerning non-agricultural inputs, on the other hand, ICS is much less complete, with the single exception of fertilizers (see Fertilizer Yearbook series, published annually by FAO). Consequently, basic data are available for the final sector output, since "utilization" in the SUA data system includes seed, feed, etc. but the data base required for deriving value added aggregates is not available.

In view of the above, it is not surprising, that the final sector output has been FAO's favourite production measure from the beginning of index number construction. It is certainly superior to the index of total agricultural production and it is feasible, but it is not the "ideal" measure of growth for many analytical purposes. Moreover, the final output concept is close to that which serves as a basis for a number of national agricultural production indices, regularly published by countries (country practices are discussed in the next chapter).

Nevertheless, refinements and different interpretations of the final output concept were introduced; the last change took place during the 1986 revision of the production index. Before the revision (up to Vol. 38 of the Production Yearbook) the final agricultural output was interpreted according to the above definitions for the indices of total agricultural production and food production. Indices for sub-sectors (crops, livestock products, cereals), on the other hand, were calculated on a gross output basis, without any deduction of intra-agricultural inputs.

According to the new (revised) method all intermediate inputs of agricultural origin are deducted following the above definition of the final output. Thus, seed is removed from the total production of crops and from all sub-groups, such as cereals, oil crops etc. Feed and seed originating from within the livestock sector (e.g. milk fed, hatching eggs) are removed from the groups "livestock products". For the main two livestock sub-groups, namely meat and milk, only feed originating from the respective sub-group is removed.

The particular change of the production concept, described above, can be considered as a refinement, which has hardly any impact on the index numbers. First, it does not affect the main indices (total agriculture and food) at all. Secondly, the ratio of category (i) inputs to the output (e.g. proportion of seed in the total crop production) is rather stable, even in the long run.

### 3.2 The choice of the formula

Although index number theory offers a large amount of formulae, including "economic" and "statistical" indices, practical applications in general, and officially published series in particular have been confined to the traditional indices.

The apparent contrast between the proliferation of formulae on the one hand, and the absence of applications on the other, can be explained by the pure academic character of the formulae invented recently, especially the "true" index numbers, proposed by the "economic" school. It is on this ground that the International Labour Office rejected the constant-utility approach as a replacement of the traditional consumer price index (ILO 1962). According to a review paper, presented at the 44th Session of the International Statistical Institute, "an economic index number is typically based on an arbitrary preference map, assigned to an imaginary consumer" (Jazairi 1983, p.142). Another author notes that "practice cannot do anything with the infinite number of "true" indices (Koves 1983, p.245). It should be noted that the traditional "statistical" index numbers are quite good approximations of the "economic" indices, under certain assumptions (Allen 1975 p. 69).

As a matter of fact, official statisticians, in charge of producing index numbers, are much more concerned about the practical problems of price and quantity observations than about the formula. Comparability of products over time, sample design, non-response, conceptual problems (e.g. the interpretation of "farm-gate" price) create more problems and generate probably a higher impact on the value of the index than the discrepancy between two formulae, computed from an identical set of price and quantity observations. New techniques have been developed to deal with these practical problems, especially quality changes and sample design (Norwood 1983).

In view of the above it is quite comprehensible that international guidelines consider only the traditional formulae (UN 1977 and 1979). According to the recommendations the choice among them should be governed by the purpose of the index and the actual properties of a given formula, compared to the desirable properties (requirements) associated with a particular purpose. This is a strategy similar to the "test approach" introduced by I. Fisher more than sixty years ago, but of course new requirements are defined, such as additive consistency (aggregation consistency) and "characteristicity" of weights.

There is no single formula satisfying all requirements, since some of the desirable properties are in conflict with others (EUROSTAT 1982, Hill 1985). E.g. "characteristicity" of weights (a property demanded for short-term analysis and forecasting) is perfectly satisfied by a chain index with moving weights, but this formula fails to satisfy other important conditions required by national accounting and other purposes (e.g. proportionality and additive consistency). This is rather unfortunate, because many of the official series, such as FAO's production index, can be considered as "multi-purpose" instrument, associated with a host of requirements, including mutually exclusive pairs. E.g. the FAO index may be used for short-run or medium-run analysis, modelling, forecasting, etc.

Given the limitations of choice imposed by the conflicting requirements of a "multi-purpose" index number, compromise solutions are preferred in practice, and traditional formulae are adopted, which render simple both the construction and interpretation of the index. Laspeyres-formula with fixed weights is one of the most popular choice in national and international practice, especially for the purpose of quantity measurements (UN 1979). In view of this, it is quite comprehensible that FAO chose this formula at the start of the production index and has kept the basic formula ever since, despite certain changes relating to the price-weights, which will be discussed later.

Naturally, the "compromise" dictates that the fixed weights be revised from time-to-time, combined with shifting the base-period. Here again FAO follows general practice by re-basing the production index (regularly) after five years. However, the base period is not a single year, but an average of three successive years; this is a choice justified by the characteristic year-to-year fluctuations of the agricultural production in most countries.

The only issue which needs discussion in this context, is the technique applied for continuing the series over a period prior and after re-basing. There are two methods for solving this problem. The first, applied by FAO among others, is to revalue not only all the years subsequent to the new base at new prices, but also some years preceding the new base period. This technique furnishes unbroken runs on each side of the new base. The second technique, called "splicing", is followed by most countries in national practice (UN 1979 p.18). According to this method the data of all years up to the new base are not revised, but simply switched to the new base. This procedure creates, in effect, a chain index in which the links are composed of comparisons between successive base periods. (The same technique was used in Section 1.3 of this report to create the historical series of production indices).

Both techniques, described above, have advantages and disadvantages. While the first method creates perfectly comparable series on both sides of the new base, covering a certain period, it means a backward revision of already published data (not just adjustments resulting from more accurate data reported since the last publication). In contrast, the second method has the merit of conserving the historical series, because switching to the new base is a simple arithmetic operation, which does not change the proportion between any pair of indices. Moreover, only the second technique is feasible, if the price data of the new base do not match the commodity regime of the pre-revision series, because of new products, disappearing products or other comparability problems. In the particular case of agriculture there is no such restriction, since new products do not appear on the market as frequently as in manufacturing industry. FAO's preference to the first method is therefore explained partly by the relative stable character of agricultural commodities, and partly by the emphasis on comparable (unbroken) series.

### 3.3 The problem of price-weights in national context

While the formula itself has not been the subject of argument during the history of the FAO production index, the choice of the producer prices, used as weights assigned to the individual commodities, was. As Sections 1.1 and 1.2 of this report show, the prices were often debated, and revisions were decided in consequence. The present concept, i.e. national average producer prices, has been used since 1977 (Vol. 31 of the Production Yearbook). The national prices replaced the regional wheat-based price relatives, which had been applied between 1966 and 1976.

This section will be devoted to the discussion of the price-weights used for the construction of national index numbers. The choice of the price-weights used for the regional and other international series will be the subject of the next section.

Using the notation introduced in Section 2.3 the formula of the production index for a given country "j" is

$$Q_j = \frac{\sum_{i=1}^n q_{ijt} p_{ijo}}{\sum_{i=1}^n q_{ijo} p_{ijo}}$$

where the subscript j stands for the country and the other symbols have been defined in Section 2.3.

The quantities produced in each country are weighted by  $p_{ijo}$ , i.e. the national producer price of commodity "i", averaged over the base period (1979-81 for the current series). The consequence of this price definition can be illustrated by a simple hypothetical example, involving two countries and two commodities. Assume that two countries (A and B) produce two identical commodities (X and Y) and both countries have produced the same quantities in the base and in the current period. However, the national price relatives are different in the two countries. Table 3.2 shows this situation with hypothetical data.

Table 3.2

Illustration of the national price effect

Commodity	Country A and B			$p_o$	
	$q_o$	$q_1$	$q_1/q_o$	A	B
X	4	8	2.0	10	3
Y	6	3	0.5	2	5

It is clear that the production index can be anywhere between 50 per cent and 200 per cent (the range between the two quantity relatives), depending on the weights attached to the commodities X and Y. It is also clear, that the production index would indicate the same change for the two countries if uniform prices were used since A and B produced exactly the same quantities. Due to the application of national prices, however, there is a large discrepancy:

$$Q_A = \frac{8 \times 10 + 3 \times 2}{4 \times 10 + 6 \times 2} = 1.65$$

$$Q_B = \frac{8 \times 3 + 3 \times 5}{4 \times 3 + 6 \times 5} = 0.93$$

It appears therefore that country A increased the production level by 65 per cent, while country B decreased it by 7 per cent.

Looking at Table 3.2 we can find the explanation of this apparent inconsistency. The national prices of A attach a relative high weight to commodity X, whose production doubled, and much smaller weight to Y, whose production decreased. The price relationship is opposite in country B. The weighted average form of the Laspeyres index (see Table 2.1), using percentage shares calculated from the base year values, shows more clearly the consequence of the relative prices:

$$Q_A = 0.77 \times 2.0 + 0.23 \times 0.5 = 1.65$$

$$Q_B = 0.29 \times 2.0 + 0.71 \times 0.5 = 0.93$$

It was assumed above that identical commodities X and Y are produced in different countries at different prices. One may argue, however, that there are differences in quality (grade, variety, etc.) between countries producing the same commodity and the prices reflect precisely that difference. If that was the case, the existence of inconsistency could be ruled out, and the application of national prices would be justified.

Although FAO's standard commodity list is fairly detailed, various grades, qualities, or varieties exist almost within every item. However, the question is not the existence of quality differences, but whether or not the national prices are true indicators of these differences.

Evidence compiled from 37 developing countries for the purpose of FAO's price policy study (FAO 1985) does not support the assumption formulated above. The study revealed that deviation between national commodity prices is generated mostly by national agricultural price policy measures, and much less by quality differences. This statement can be proved by the nominal protection coefficient (NPC) which shows the relationship between prices actually received by farmers and those which they would have received in the absence of commodity taxes, subsidies and other forms of government price intervention. The NPCs (corrected for marketing, processing and transport cost) exhibit a variation over a range of 0.35 to 2.38. Protection or implied taxation varies both between commodities and over time within a country, e.g. the NPC level almost doubled in one country between 1981 and 1982. Such abrupt movements cannot be regarded as response to quality changes. (Vide Table B8 p. 100 and Table 2 pp. 113-115 of the FAO report cited above).

Agriculture is, of course, not the only economic sector where national price relatives of comparable products exhibit large deviations, and protection of the domestic producers is not the only reason generating the variance. (For a more general discussion see Clague 1986).

The minor role of quality differences in the variation of price relatives can be shown by reviewing national prices for such commodities which, by specification, can be considered of having the same average quality in all countries. Such commodities and their producer prices in selected countries are given in Table 3.3. The Table also contains price relatives, i.e. the cow milk price equivalent for each commodity. E.g. while in Australia 10.94 tons of milk have to be sold by the farmer for having the same income that a metric ton of hen eggs would give, in the USA it is 3.08 tons, in Canada 2.54 tons. The table also reveals the fact that national price relatives are influenced not only by government policy mentioned before but depend as well on climatic conditions, national resources, farming practices, etc. E.g. while in Canada the price of soybeans is 3.69 times that of sunflower seeds, in the USA the ratio is 6.24.

Table 3.3

Producer prices of selected agricultural commodities in selected countries,

1979

Source: Statistics on Prices Received by Farmers. FAO 1982

\* For the definition of "international dollar" prices see Section 3.4.

Once the assumption of prices proportional to quality is rejected, the use of national prices in the construction of the production index can be legitimately questioned. However, replacing them by uniform (standard) commodity prices, whether global or regional, would be an operation subject to argument as well. There is indeed a conflict between two desirable properties (requirements) of the country indices:

- i) used for the purpose of country specific analysis they should have a "national character";
- ii) used as instruments for comparing the growth performance between countries and territories they should have an "international character" i.e. comparable across countries.

It is clear, that a production index computed with national price-weights satisfies the first requirement, but not the second and vice-versa for the standard prices. Incidentally, the above argument is valid not only for the agricultural production index, but also in a broader context, as the following quotation shows:

"If one considers a national entity in isolation from other countries, the national temporal indices or GDP at constant prices series using only national prices of a base year may be considered better measures of national growth rates than indices or GDP series based on international or regional prices. However, the increasing state of interdependence of the various national economies also renders the use of at least some types of average regional commodity prices, if not world prices, in calculating national quantity indices a useful tool for some analytical economic studies.", (Khamis 1984 p.201).

The impact of different price relatives can be shown by calculating production index numbers for two countries and two commodities selected from among those given in Table 3.3. The two countries are Australia and USA, the two commodities shall be cow milk and hen eggs. The data are given in Table 3.4 below.

Table 3.4

Production and prices of cow milk and hen eggs in Australia and USA

Commodity	Production in '000 MT				Price for metric ton in 1979		
	Australia		USA		Australia	USA	"Internat. dollar"
	1979	1983	1979	1983	..national dollars..		
Cow milk	5 837	5 685	55 978	63 488	119	267	232
Hen eggs	195	214	4 098	4 036	1 305	823	1 146

Source: For quantities: FAO Production yearbook Vol. 37.

For national prices: Statistics on Prices Received by Farmers. FAO 1982.

For international price: ICS data base and see Section 3.4.

The production index numbers for Australia based on Australian prices,  $Q_A^{(A)}$ , on USA prices,  $Q_A^{(USA)}$ , and on standard "international dollar" prices derived by the Geary-Khamis method, thus denoted by  $Q_A^{(G-K)}$ , are given below:

$$\begin{array}{l} Q_A^{(A)} = \frac{5685x119 + 214x1305}{5837x119 + 195x1305} = \frac{676515+279270}{694603+254475} = \frac{955785}{949078} = 1.007 \\ Q_A^{(USA)} = \frac{5685x267 + 214x823}{5837x267 + 195x823} = \frac{1517895+176122}{1558479+160485} = \frac{1694017}{1718964} = 0.985 \\ Q_A^{(G-K)} = \frac{5685x232 + 214x1146}{5837x232 + 195x1146} = \frac{1318920+245244}{1354184+223470} = \frac{1564164}{1577654} = 0.991 \end{array}$$

The respective USA index numbers are as follows:

$$\begin{array}{l} Q_{USA}^{(A)} = \frac{63488x119 + 4036x1305}{55978x119 + 4098x1305} = \frac{7555072+5266980}{6661382+5347890} = \frac{12822052}{12009272} = 1.067 \\ Q_{USA}^{(USA)} = \frac{63488x267 + 4036x823}{55978x267 + 4098x823} = \frac{16951296+3321628}{14946126+3372654} = \frac{20272924}{18318780} = 1.107 \\ Q_{USA}^{(G-K)} = \frac{63488x232 + 4036x1146}{55978x232 + 4098x1146} = \frac{14729216+4625256}{12986896+4696308} = \frac{19354472}{17683204} = 1.094 \end{array}$$

As it can be expected from the theory of index numbers, in both countries the index calculated at "own" prices are higher than those which are based on prices taken from the other country. However, for the sake of international comparability one would be tempted to use the USA dollar prices all over the world. In our case it would show 12.2 percentage points difference between the country's production indices

$$(Q_{USA}^{(USA)} - Q_A^{(USA)}) = 110.7 \text{ p.c.} - 98.5 \text{ p.c.} = 12.2 \text{ p.c.}.$$

If the Australian prices would be taken standard for comparison, the difference between the two countries would be 6 percentage points only

$$(Q_{USA}^{(A)} - Q_A^{(A)}) = 106.7 - 100.7 = 6.0.$$

The standard "international dollar" prices are not giving "preference" to any of the countries involved in the comparison, thus they are to be preferred if international comparison is the main purpose of calculating production index numbers.

Inspite of the demand for different series, FAO publishes only one set of country indices in its regular publications (Production Yearbook and Monthly Bulletin of Statistics). In fact, no national or international statistical organization publishes two sets of data apparently answering the same question (e.g. the change of agricultural production in a given country over a specific period) since this would confuse the general user. In case of the FAO production index preference was given to the national prices, mainly because this measure is not available in national data sources for many countries (see review of national series in the next chapter).

Nevertheless, in order to satisfy all legitimate demand for data, national indices computed with standard price-weights are available on request in FAO's Statistics Division. Moreover, they will be published in special technical reports, such as this one. Annex Table 2 presents both types of index numbers for all countries. Uniform price-weighted series are located in the first line. They are calculated according to the Geary-Khamis formula and will be described in the next section. The second line for each country contains the indices calculated with national prices and it is therefore identical to the series published in the 1985 issue of the Production Yearbook. Minor differences may occur, due to up-dating of the ICS data base between the completion of the Yearbook and this report.

### 3.4 The regional production index

In addition to the country series of production indices, discussed in the previous section, FAO calculates and publishes international indices over continents, various country groups and the world. These will be called henceforth "regional" index numbers.

The method of calculating the regional series before the last revision (1985) was based on the national commodity prices and official exchange rates. The current-year and base-year aggregate values of the individual countries were first converted to US dollars and then summed up over the region. The formula of the regional index, computed over  $m$  countries was

$$Q_g = \frac{\sum_{j=1}^m e_j \sum_{i=1}^n q_{ijt} p_{ijo}}{\sum_{j=1}^m e_j \sum_{i=1}^n q_{ijo} p_{ijo}}$$

where  $e_j$  is the official exchange rate of country "j", indicating the number of US dollars per one unit of the respective national currency, other symbols have been defined already. With some algebraic manipulation this index can be written as the average of country production indices weighted by the corresponding base-year aggregate values:

$$Q_g = \frac{\sum_{j=1}^m v_{jo} Q_j}{\sum_{j=1}^m v_{jo}}$$

where

$$v_{jo} = \sum_{i=1}^n e_j q_{ijo} p_{ijo}$$

and  $Q_j$  is the country index defined in the previous section.

Taking our previous example of two commodities and two countries, i.e. the data of Table 3.4 and the aggregates derived from these data when calculating the country index numbers, the combined index for the two countries would be:

$$Q_g = \frac{1.136 \times 955.785 + 2.0272.924}{1.136 \times 949.078 + 18.318.780} = \frac{1.086.119 + 2.0272.924}{1.078.498 + 18.318.780} = 1.101$$

(where 1.136 is the USA dollar equivalent of the Australian dollar in 1979), or according to the second formula:

$$Q_g = \frac{1\ 078\ 498 \times 1.007 + 18\ 318\ 780 \times 1.107}{1\ 078\ 498 + 18\ 318\ 780} = 1.101$$

The character of the country indices, and their dependence on the national agricultural price policy measures and other national peculiarities have already been demonstrated. Being an average of these country measures,  $Q_g$  shows of course the impact of the individual prices and price relations and fails to satisfy a certain plausible requirement; assuming that the total quantities of all n commodities changed at the same rate, i.e.

$$C = \sum_{j=1}^m q_{ijt} / \sum_{j=1}^m q_{ijo}$$

for all  $i=1, 2, \dots, n$ . One would expect the equality  $Q_g = C$  to be valid, but it is not.

Indeed, disaggregated to the level of individual commodities,  $Q_g$  exhibits a discrepancy from the quantity relatives, aggregated over the region, as demonstrated by Chart 3.1. The chart shows the global quantity changes of maize production, compared to the production index, which exhibits the impact of national maize prices. The deviation between the two lines is not negligible even at this highest level of aggregation. Much larger discrepancies are of course present in the regional series.

Taking our example from Table 3.4 and the values of country index numbers, the discrepancy for both commodities can be shown:

Change of cow milk production :  $(5685+63488) \div (5837+55978) = 1.119$   
hen eggs production :  $(214+4036) \div (195+4098) = 0.990$

Change of production value aggregates in constant 1979 US dollars:

for cow milk:  $(1.136 \times 676515 + 16951296) \div (1.136 \times 694603 + 14946126) = 1.126$   
for hen eggs:  $(1.136 \times 279270 + 3321628) \div (1.136 \times 254475 + 3372654) = 0.994$

The existence of the discrepancy, illustrated above, might be a surprise, because it means that  $Q_g$  fails to pass the proportionality test, whereas the Laspeyres index satisfies this requirement, and  $Q_g$  is supposed to be a Laspeyres quantity index. The reason for this apparent contradiction is that the unit of observation in  $Q_g$  is not the commodity, as defined in the ICS, but a combination of commodity and country, i.e.  $Q_g = C$  if

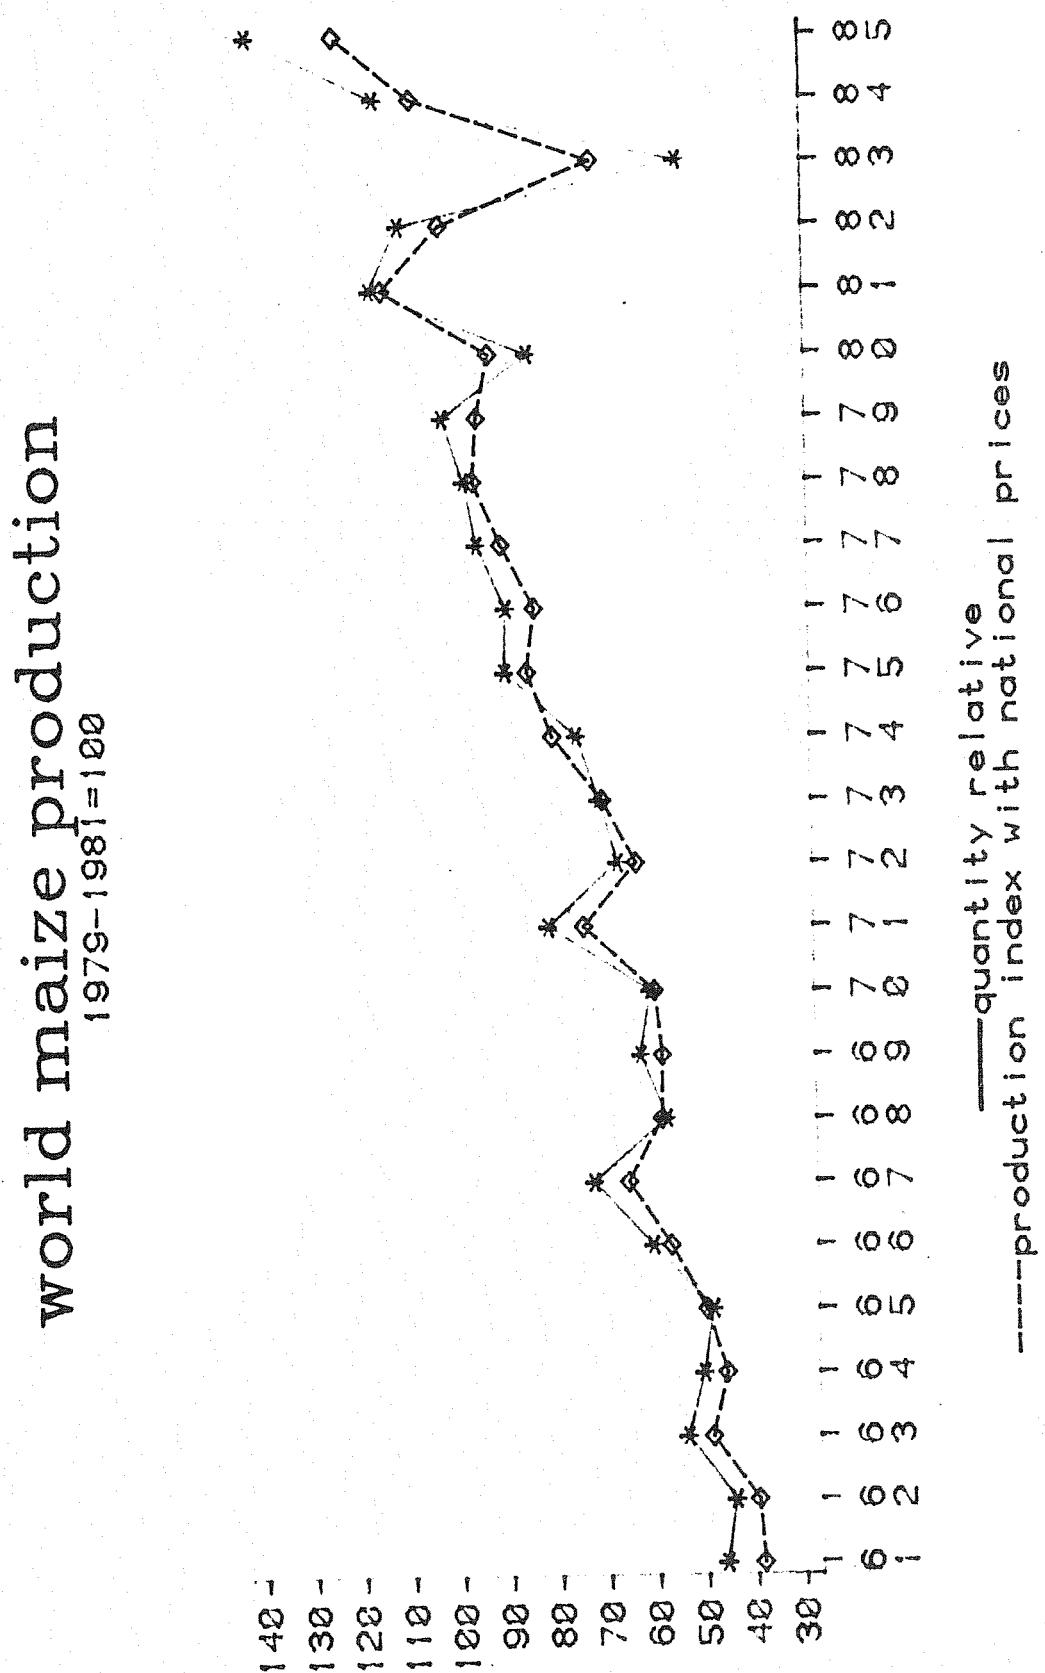

$$C = q_{ijt} / q_{ijo}$$

for all  $i = 1, 2, \dots, n$  and  $j = 1, 2, \dots, m$ .

The dependence of the regional index on national commodity prices and official exchange rates was subject to critiques (vide Khamis 1983 pp.176 - 179). According to this opinion the old methodology of regional and world indices "may result in misleading indicators, seriously affecting assessment of the state of world food and agriculture".

Indeed, comparability is clearly a sine qua non of the regional index numbers. This was acknowledged while FAO designed the last revision, which was implemented in 1986. Since national prices and official exchange rates were identified as the causes of incomparability, it was clear that they should be somehow replaced by new statistics. Substitution of the exchange rates by purchasing power parities, calculated over the field of agricultural commodities, was already proposed by Geary in 1958 (see References). Although this solution would certainly improve the quality of the index, the Geary-formula still fails to pass the "proportionality test" described above.

Chart 3.1

Re-pricing, on the other hand, i.e. replacing the national prices by international standard commodity prices, satisfies the requirements of comparability and proportionality (Khamis 1983). There are many ways to construct such prices and the Geary-Khamis formula was selected for the revision. The same prices are used for the purpose of inter-country comparison of agricultural production level and productivity, and the rationale of this particular formula, versus other possible methods, is provided in the FAO study devoted to international comparison of production aggregates and purchasing power (FAO 1986). The explanation, discussion and references are therefore not repeated here; the rest of this section will be confined to the definition, interpretation and illustration of the standard international commodity prices and the index numbers constructed with them.

For each commodity "i" the standard international price in the base period is defined by

$$p_{io} = \sum_{j=1}^m r_{jo} q_{ij} p_{ijo} / \sum_{j=1}^m q_{ij}$$

i.e. the weighted average of the national prices in the base period, converted to common currency by the factor  $r_{jo}$ , which in turn is defined by

$$r_{jo} = \frac{\sum_{i=1}^n q_{ij} p_{ijo}}{\sum_{i=1}^n q_{ij}}$$

The above formulae of the unknown prices  $p_{io}$  and exchange rates (conversion factors)  $r_{jo}$  constitute a system of  $n+m$  linear equations, which has unique positive solutions, up to a factor of proportionality, under very mild conditions, satisfied by the data. The proportionality factor can be either an exchange rate, identifying one country's currency as the numeraire currency, or any one commodity, as a numeraire commodity (FAO used wheat-based price relatives in earlier years, but they were not calculated by this method, see Sections 1.1 and 1.2). Following the methodology of the International Comparison Project, FAO set the USA currency as numeraire, so that the commodity prices can be regarded as dollar prices. However, they are not US national prices, but international prices, expressed in "dollars" for convenience, to facilitate handling and interpretation.

Using the Geary-Khamis formula international standard prices can be calculated at various levels. The wheat relatives, used by FAO between 1966 and 1977 were regional standards. Regional prices facilitate comparison between the index numbers of countries within a given region, but render inter-regional comparisons more complicated. They are therefore justified only if applied at country level. However, as it was explained earlier, FAO continues calculating the country series with national prices, and international prices are only used at higher level of aggregation, to promote comparisons between regions or between a given region and the world. This objective demands a single set of global commodity prices, and this set was indeed calculated for the revision of the production index, which took place in 1986.

Table 3.5 shows the international dollar prices of the 20 leading commodities, compared with weighted average national prices, converted first to dollars by using official exchange rates. The only difference between the two prices is the exchange rate: the G-K rate, representing the purchasing power parity of the currency over the set of agricultural commodities, versus the official or market rate. As a rule the prices converted by the official rate are higher, but the price ratio shows a high variation, ranging from 101 (soybeans) to 174 (cassava).

Table 3.5

World average producer prices of agricultural commodities  
(1979-81)

Commodity	Dollar/Metric ton		Price ratio B/A (per cent)
	A	B	
Cow milk	226	293	130
Indigenous cattle meat	2033	2563	126
Rice, paddy	205	253	123
Indigenous pigmeat	1364	1763	129
Wheat	148	175	118
Maize	126	136	108
Potatoes	107	140	131

Cotton lint	1331	1487	112
Barley	120	163	136
Grapes	274	387	141
Sugar cane	21	23	110
Indigenous sheep meat	2055	2737	133
Tomatoes	201	272	135
Cassava	77	134	174
Sweet potatoes	81	97	120
Sugar beets	33	46	139

A: Geary-Khamis formula, international dollar price.

B: Weighted average of national prices converted to US Dollars by official exchange rates.

Substituting the standard G-K prices into the formula of the regional production index it becomes

$$Q_s = \frac{\sum_{i=1}^n \sum_{j=1}^m q_{ijt} p_{io}}{\sum_{i=1}^n \sum_{j=1}^m q_{ijo} p_{io}}$$

where  $p_{io}$  is the standard price of commodity "i". In contrast to  $Q_g$  the index can be calculated as a weighted average of the quantity relatives:

$$Q_s = \frac{\sum_{i=1}^n v_{io} Q_i}{\sum_{i=1}^n v_{io}}$$

where

$$v_{io} = \sum_{j=1}^m q_{ij} p_{io}$$

$$Q_i = \frac{\sum_{j=1}^m q_{ijt}}{\sum_{j=1}^m q_{ijo}}$$

Starting with the 1985 issue, the FAO Production Yearbook presents the revised series of the regional production indices, according to the formula  $Q_i$ , replacing  $Q_g$ . Annex Table 2 shows both series for the period 1961-1985. The discrepancy, due to the effect of changing the formula, is very small at global level. Somewhat higher deviations are present at regional level, but the revision does not seem to have affected the general trend. Charts 3.2 and 3.3 illustrate the situation showing the evolution of the production index runs for a developed region (West Europe) and a developing region (Near East).

## CHAPTER 4

### NATIONAL AGRICULTURAL PRODUCTION INDICES

This last chapter presents a review of the national production indices. Unfortunately, not many countries publish such measures, and information on the methodology is incomplete even for those countries which construct production indices.

#### 4.1 Information on national index numbers

National series of agricultural production index numbers have been compiled for 28 countries based on the data sources available in FAO. It appears that the majority of developing countries does not construct production index. Indeed, the FAO country series, described in the last chapter, are recognized by users as the best data source in the absence of original country data. E.g. the German Federal Statistical Office reproduces these series in its regular publication entitled "Statistik des Auslandes".

Comprehensive methodological statements are hardly available for the national indices. As a rule, the tables in the publications have only footnotes and sometimes short technical notes, listing certain features. The remarks which follow are based on this incomplete information. The list of national data sources and other relevant publications is attached to Annex Table 3.

The national production index series show a variety of distinctive features, rendering comparability rather difficult, both across countries, and between a given country and FAO. The main areas of methodological differences can be identified as follows:

##### i) Definition of production.

The EEC countries adopted the final output concept (defined in Section 3.1). However, gross output is used in other countries (e.g. Zimbabwe), and some countries report the volume index of the value added (e.g. Sri Lanka). A precise definition of the agricultural production, used in the index construction, is not revealed in most other publications.

##### ii) Coverage and commodity classification.

The FAO production index covers agriculture, as activities 01 of ISIC, i.e. crop and livestock production excluding forestry and fishery products. Indices with identical coverage are available for the USA, the EEC region and some other countries. In certain cases the broad definition is applied (including forestry and fishery), but an index covering agriculture in the narrower sense can be calculated if the weights are available separately (e.g. Thailand). However, they are not available for a number of countries (e.g. Bangladesh and Algeria). In contrast, Pakistan reports only the index of all crops, but nothing on livestock products. Other coverage restrictions are practiced as well, e.g. Kenya reports only the quantum index of sales to marketing boards. The commodity classification is also different: disaggregated series are published in some countries, (e.g. Thailand), while only the major aggregates are available for others.

##### iii) Time span and base period

Most of the series are calculated for (and based on) calendar years. There are however exceptions, such as India and Swaziland, where crop years constitute the time unit. Base periods are either single years, or averages of two or three years, e.g. Algeria (1967-70), Bangladesh (1972-73), Australia (1979-80). While the developed countries and some developing countries (e.g. Thailand, Sri Lanka) publish up-to-date figures, the indices for most developing countries are available with a time lag of 3-5 years.

iv) Formula and price weights

Laspeyres appears to be the preferred formula for constructing national production indices. This is explicitly indicated in some publications (e.g. Denmark, Fiji, Thailand), or implied in the description "constant prices" (Australia). However, other formulae are used as well, such as the chain index with variable weights (New Zealand). Unfortunately, no information is available on the formula in many of the data sources used for this chapter.

4.2 Comparison of national and FAO series

In view of the comparability problems described in the previous section it is clear that the national agricultural production indices are not comparable across countries. Indeed, they are not designed for international comparison, except of course in certain regions or country groups, such as the EEC. Nevertheless, it is useful to provide a collection of these series, since they are not easily accessible. Annex Table 3 contains a set of the national indices up to the latest figures available in July 1986 in FAO. A list of the national data sources is attached to the table.

Comparability of the national indices with the FAO country series depends on the methods and concepts adopted in the various countries. Since FAO uses the national producer prices as weights, the data should be comparable, at least in theory, provided the production concept, coverage, formula, etc. are also identical. From this point of view the EEC group appears to be closest to the FAO methodology, although the base period is not identical (EEC uses single years), therefore not the same base-year price weights are applied. In other cases, however, there are more differences in concepts and procedures between individual countries and FAO. In order to facilitate comparison two series are presented in Annex Table 3 for each country: the first is compiled from the national data sources and the second from the corresponding FAO series. Both series were re-based to a single year (1980). The incomplete character of the table, in particular the missing data for the last few years, is due to differences in time coverage, explained in the previous section.

Inspite of the different methodology adopted by the national statistical services to construct the production index, some of the national series are very close to the FAO country series, such as the Federal Republic of Germany, as illustrated by Chart 4.1. This was indeed expected for the EEC countries, because they use a common procedure, which is similar to FAO, as far as coverage, production concept and formula are concerned. However, there are some deviations, especially for Sri Lanka. Very close tendency prevails for some other developed countries, e.g. the USA.

With regard to developing countries no uniform conclusions can be drawn from the data. Very close trends are shown for Syria, but rather different for India, and Sri Lanka. Charts 4.2 and 4.3 illustrate this point. In some cases the time coverage is too short to derive conclusions about trends, or tendencies.
