The Agricultural and Food Engineering Working Document disseminates findings of work in progress to encourage the exchange of ideas and experiences related to agricultural and food engineering within agri-food systems. The series aims to bring the findings to the public domain as quickly as possible, even if the presentations are less than fully polished. The papers carry the name of authors and should be used and cited accordingly. The findings, interpretations and conclusions are the author’s own.

The designations employed and the presentation of material in this information product do not imply the expression of any opinion whatsoever on the part of the Food and Agriculture Organization of the United Nations concerning the legal or development status of any country, territory, city or area or of its authorities, or concerning the delimitation of its frontiers or boundaries.

Price risk management is very critical to the success of agriculture, and yet there is a lack of tools used to manage risk as well as a lack of understanding of the tools themselves. Compared to the industrial sector, agriculture is exposed to many more unpredictable risks and uncertainties. Through the supply chain, from the stage of production to marketing, agricultural performance is highly dependent on many exogenous variables. Crop output and productivity are highly susceptible to uncontrollable factors such as climatic disruptions, natural hazards and pest attacks. Physical risks such as pilferage and deterioration can result in a considerable loss of value during storage and transportation. Trading risks of non-delivery and counterparty default also reign high. In many countries, faulty and distortionary government policy incentives have resulted in agriculture planning being highly unresponsive to market demand.

While the undercurrents of the long-term secular decline of commodity prices have impoverished many developing countries, scourges of short-term price volatility manifest themselves in many ways. Revenue uncertainty not only threatens the livelihoods of the agriculturists, but limits farm credit, trapping them in vicious cycles of low investment. The “commodity problem” has been rightly described as a combination of declining terms of trade (i.e. commodity prices rising less rapidly than those of manufactured prices) and price volatility (Page and Hewitt, 2001).

Commodity price risk management is not a new idea. The failure of international efforts such as stabilization funds and international commodity agreements in stemming commodity price fluctuations has been well known. Loss of safety nets due to global free trade and changes in domestic agricultural policy has only added to this vulnerability. This paper focuses on the use of market-based instruments for managing agricultural price risk. Market-based mechanisms essentially entail shifting risks to entities in a better position and more willing to bear them. Being market-based, these could also externalize risks outside the country. Their success does not hinge on government treasuries, and in some cases, could allow governments to disengage from costly and counterproductive policies.

While not the subject of this paper, it must be mentioned that some of these instruments effectively serve as an alternate agri-marketing system, providing a market, price and agri-infrastructure, and can be of relevance in many strategic agri-planning decisions. It should also be mentioned that farmers do not necessarily have to use these instruments to benefit from them. Even basic market reading and access to the disseminated prices can boost their bargaining power towards getting market-linked prices. Most of the instruments introduced here have a long history and are actively traded in many markets. It is unfortunate that lack of awareness and know-how among developing countries has limited their widespread use and has resulted in lagged critical benefits to developing countries.
This paper is designed to acquaint the reader with these market-based instruments. The subject is relevant for any entity associated with or impacted by the integrated areas of agricultural marketing and financing. It is hoped that this paper will help readers better appreciate the advantages of managing risks through markets and give them a clear understanding of the underlying mechanisms as a basis for applying these instruments to better manage their price risk. The potential of applying these price risk management instruments to enhance agriculture marketing and financing is incalculable. While case studies are provided to aid readers’ understanding and appreciation of these instruments, this paper does not deal with the application of these instruments.
An introduction to market-based instruments for agricultural price risk management is based on Innovations of agricultural commodity price risk management: an approach to market-based instruments (2005) by Myong Goo Kang, former Rural Finance Expert of FAO and now with the Korean Ministry of Agriculture. The paper was then revised and elaborated on by Nayana Mahajan, former research consultant, UN Conference on Trade and Development (UNCTAD), and currently Assistant Manager with the Multi Commodity Exchange (MCX) India. The authors sought to diligently describe and exemplify concepts and tools in a comprehensible and easy-to-understand manner for all users.

The authors and FAO would also like to thank Barbara Hall, who has extensively edited the document. Special acknowledgement is given for the incisive guidance of Lamon Rutten, former Chief, Commodity Finance and Risk Management, (UNCTAD) and currently head of MCX India, the encouragement of Shivaji Pandey, former Director, Agricultural Support Systems Division, and Doyle Baker, Chief of the Agricultural Management, Marketing and Finance Service (AGSF), who fully recognized the importance of agricultural risk management. Many thanks go to Calvin Miller, Senior Officer of the Rural Finance Group (RFG), AGSF, who was a permanent adviser and mentor in the research and writing of the paper. Finally, special thanks go to Trish Foshée, Director, Sales and Marketing, Institute for Financial Markets, Washington DC, U.S.A., who helped clarify concepts and present them intelligibly.
Market-based instruments for managing agricultural price risk are a practical and non-intervening alternative for managing commodity price volatility. This market-based approach differs significantly from the often failed national and international regimes of price controls. Unfortunately, they have been less embraced in developing countries where institutional strength and a mere lack of awareness of the use of the instruments have deprived these countries of their benefits.

This paper focuses on five of the most important instruments of price risk management. Section I covers an introduction and discusses commodity price risks and the change from a stabilization approach to a market-based one. Section II provides a comprehensive understanding of the concepts and mechanisms and examples of these instruments: forward contracts, which are bilateral contracts, provide a customized solution in locking in (although not perfectly) the future price of the agri-produce; futures and options contracts, which are traded on an exchange (like a stock), similarly help in locking in the future price, but with a varying flexibility structure as against a forward contract; swaps, which like forward contracts are bilateral agreements for managing price risk, change an undesired type of cash flow to the desired one; and agricultural insurance, most commonly available through comprehensive products of revenue management, provides a safeguard against both price and yield risk. Section III provides a summary of market-based price risk management instruments and recommendations for encouraging their use.

Some policy measures are touched on in the paper, such as the encouragement of the use of options, and application of these instruments in government price risk mitigation and in price support programmes. It also provides measures towards awareness-building, which would provide a thrust in both developing markets and in providing direct dividends to all stakeholders.
I. Introduction

1. Commodity price risks

Over the last two decades, commodity prices have been more volatile than those of manufactured goods. Commodity price uncertainty, whether caused by government policy, foreign exchange rates, climatic disasters, or political/civil instability, is inherent in commodity markets.

Price volatility leaves a farmer uncertain whether he will receive a high price or a low price at the time of sale. The problem is, however, not limited to how much cash a farmer receives for his harvest. Every investment decision a farmer makes during the crop cycle is a difficult one because he does not know whether he will be able to pay back the loan for the investment (i.e. labour, fertilizer, equipment and repairs). The expected commodity price, prices of competing crops and government programmes play important roles in determining the area to be planted. Uncertain prices pressure a borrower’s ability to repay and thus make agriculture financing a risky proposition for lenders. In the absence of appropriate risk management instruments, financiers are reluctant to finance traders given the cash-flow uncertainty. Often, they will raise interest rates to cover uncertain risks, or simply refuse to provide credit. As a result, it is not surprising that a lack of price risk management is one of the major reasons that poor farmers stay poor (World Business Council for Sustainable Development, 2004). Farmers’ associations may also run similar risks: if they advance their members’ credits to be reimbursed through future deliveries of crops, they run the risk that at the moment that the crop is sold, prices may have fallen to levels too low to enable loan reimbursement (UNCTAD, 2002).

From a macro-perspective, price volatility can be devastating: more than 50 developing countries depend on three or fewer leading commodities, such as coffee, sugar cane, cotton, wheat and maize, for at least half their export earnings. The prices earned on international commodity markets impact the government’s fiscal revenue, public expenditure, foreign reserves and its creditworthiness, and are thus of prime importance to the domestic economy (World Business Council for Sustainable Development, 2004).

IMF Research (Cashin, 2003) emphasizes fluctuations in world commodity prices and terms of trade as being the most important external shocks that would affect macroeconomic performance and external balances of developing countries. For commodity-dependent countries, debt servicing is also closely linked to commodity prices. Commodity risk management has the potential of simplifying governments’ budgetary planning, improving budgetary control, and avoiding the need for crisis management due to unforeseen revenue shortfalls.
In several African countries, price liberalization and marketing reforms brought about a collapse of the marketing boards, which resulted in the fall of forward markets supported by them. Forward transactions are important to producers as they secure a price in advance of harvest, reducing their exposure to market price fluctuations and enabling producers to adjust their use of inputs (UNCTAD, 1999). Although it is impossible to completely eliminate the impact of these structural factors, the instruments of risk management introduced in this paper allow participants in the physical commodity markets to transfer some of the price risk to others – for instance, other physical market participants or possibly investors/speculators – who may have an opposing view on the future direction of the market.

Chapter I highlights the failure of historical efforts at stabilizing prices and introduces the market-based approach, which poses unchallengeable alternatives. Chapter II examines four important instruments of commodity price risk management: forwards, futures, options and swaps. A systematic description is provided for the essential concepts and the risk management mechanisms that underlie these instruments. The paper also briefly looks at some insurance-based products that can be used to manage price risk. A previous paper by the co-author (Kang, 2005) covered innovative agricultural insurance products and their alternatives as financial tools for yield risk management. The concluding Chapter III summarizes the instruments, provides some recommendations of caution to their users and offers some suggestions to policy-makers on encouraging their use.

2. FROM A STABILIZATION APPROACH TO A MARKET-BASED APPROACH

A. Stabilization approach

Over the past half-century, the international community and governments have attempted to manage commodity price risks by stabilizing price volatility or making the price distribution less variable through market interventions. Key among these mechanisms were compensatory mechanisms, stabilization mechanisms and international commodity agreements, which are briefly reviewed below.1

The International Monetary Fund (IMF) established the Compensatory Financing Facility in 1963 to help member countries cope with temporary export shortfalls caused by exogenous shocks by making available non-concessional credit. The European Community offered its own compensatory financing scheme, STABEX (Stabilisation des recettes d’exportation), for the purpose of stabilizing export earnings of the agricultural sector in the African, Caribbean and Pacific (ACP) states. By their very nature these schemes were designed to provide financial assistance to adjust to external commodity price or volume shocks, rather than provide a tool for ex ante price risk management (Varangis and Larson, 1996). Many of the schemes failed because they were based on administratively set benchmarks that required large resource transfers in years of low prices. These administrative prices were often the outcome of political bargains and failed to reflect market fundamentals. With limited borrowing capacity and generally unhedged exposures to price risk, the stabilization programmes were difficult to

1 For the history and functions of these international financial mechanisms, see the International Task Force on Commodity Risk Management (1999).
maintain when payments were required over consecutive years (the International Task Force on Commodity Risk Management, 1999).

In developing countries, domestic price stabilization was targeted through marketing boards that tried to regulate and manage supply through national stockpiles and buffer stock schemes. But even if they were to be used for their stated objectives, commodity stabilization schemes would still not have been effective because of the way commodity prices typically behave. Most commodity prices revert eventually to their mean – a requirement for a stabilization fund (or a buffer stock scheme) to be viable – but only very slowly, with an average reversal time measured in years, not months. As such, a commodity stabilization fund has to be very large to be effective or the country needs to have ample access to foreign borrowing. But a large fund is not feasible for domestic political reasons, and sovereign risk generally prohibits the necessary access to foreign borrowing. Because a small fund is not effective, there is little scope for countries to stabilize domestic commodity prices through foreign borrowing when the fund’s resources run out. An additional problem with domestic price stabilization schemes is that they redistribute the risks within the country (usually from producers to the government), rather than diversify them outside the country to entities better able to bear such risks (Varangis and Larson, 1996).

Major International Commodity Agreements – sugar (1954), coffee (1962), cocoa (1972), natural rubber (1980) – were initiated under the auspices of the UN Conference on Trade and Development (UNCTAD), aiming to influence world prices by employing instruments of buffer stocks and export quota. The unsatisfactory performance of the commodity agreements concerned: conflicting interests between producing and consuming members; inadequate financial resources; failure to account for changes in production and consumption patterns; and failure to adjust unrealistic price goals in the face of persistent price declines during the 1980s and into the 1990s. By 1996 no agreements remained with price stabilization components. These agreements ran into difficulties because they tried to maintain not only stable but also high prices, and because of disagreements and lack of discipline among members (Varangis and Larson, 1996).

**B. Market-based approach**

As the poor performance of stabilization schemes became more evident, academics and policy-makers began to distinguish between policies that try to change price distribution either domestically or internationally, and policies that used market-based solutions for dealing with market uncertainty. They turned to policies that emphasized risk management instead of efforts to manage agricultural markets.

As an example, in 1994 the internal and external marketing of cotton was liberalized in Uganda. The cooperative unions, burdened by large debts, were forced to sell most of their ginneries to the private sector. At least two of the cooperative cotton unions, the North Bukedi

---

3 Concerning the theoretical and empirical studies that contributed to a change in thinking from price stabilization to risk management, see Larson, Varangis and Yabuki (1998) and Varangis, Larson and Anderson (2002).
Cotton Company and the Lango Cooperative Union, overcame their problems by taking a more proactive role in marketing. They started using these instruments and had brokers and commission agents communicating vital information on a daily basis. They first used their access to risk management markets in order to be able to guarantee minimum prices to their farmers (Ngategize, 1997).

The key advantages of market-based instruments over price stabilization schemes are elucidated below (adapted from Varangis and Larson, 1996):

- Unlike facilities such as the international commodity agreements and government buffer stock schemes, which tried to manage price volatility by influencing the price, market-based instruments provide certainty of future revenues (or expenditures), and thus ensure the user of concrete cash flows.

- Market-based instruments rely on market prices rather than administrative prices, thus shifting risks to viable financial markets that are better able and willing to assume risks. For developing countries with no such market, commodity-derivative instruments shift the risk to traders or speculators in industrialized countries who are willing to take the price risk. In most cases, they cost less than government price intervention programmes.

- Commodity-derivative instruments can improve the terms of commodity financing. They can be used to lock in future revenues and ensure the lender that these revenues will cover repayment of the loan. They can therefore increase the creditworthiness of the borrower. This is especially important for the recently liberalized commodity subsectors, where the quick establishment of credit flows is crucial to the success of reform.

- Commodity futures markets remain the most efficient price formation mechanisms, providing reliable benchmarks for physical trade. Because a wide group of participants can use the market, each participant brings into the price formation process the information possessed on future demand and supply conditions. In contrast to cash markets, futures markets are highly transparent yet anonymous, making price manipulation more difficult.

- Another important benefit of exchange-traded instruments is the low cost of executing transactions, liquidity and also standardized requirements regarding quality, quantity and delivery dates, etc.

It should be mentioned that these markets are not a panacea for farmers’ problems – such markets do not exist and are never likely to exist for all commodities – and can give only temporary reprieve from a secular fall of prices. They can also be very complex and difficult for small-scale farmers unless they are well organized and trained. Nevertheless, enabling access to these markets could greatly help farmers in developing country improve their lives, particularly as the vast majority of them can now cope with these price risks only by avoiding “risky” investment decisions, relying on their meager savings and adjusting their consumption – at best, inefficient solutions that often lock them in a vicious cycle of poverty (UNCTAD, 2002).
II. Instruments for commodity price risk management

Price risk hedging instruments introduced in this paper can be categorized under the umbrella of *derivatives*. A derivative is defined as an instrument whose value depends on the value of an underlying variable. While this definition may not be fully comprehensive at this stage, derivatives can perhaps be better understood as financial instruments based upon a common *forward pricing* strategy, which involves setting the price, or a limit on price, for a product to be delivered in the future. As a basic example, a commodity derivative is an instrument that permits one to buy or sell the commodity (the *underlying*) at a future time, at a price tentatively fixed today. Common underlying products in derivatives are stocks, currency, bonds, and commodities. Further, derivatives could also be classified on the basis of the markets where they are available. There are two broad categories here: (i) the standardized instruments that are traded on commodity exchanges (here the key derivative instruments are *futures* and *options*); and (ii) over-the-counter (OTC)* instruments which are privately negotiated (here the key derivative instruments are *forward contracts* and *swaps*).

Commodity exchange (see Annex 1 for a list of key commodity exchanges)* is a financial market where different groups of participants trade commodity-linked contracts, with the underlying objective of either trading the commodity or transferring exposure of commodity price risks. Organized commodity futures exchanges have existed for more than a century. Exchanges have traditionally been defined by “pit” trading through an open outcry environment where traders and brokers shout bids and offers in a trading pit or ring. More recently, most exchanges have adopted electronic trading platforms where market participants post their bids and offers on a computerized trading system. In its original and simplest form, the OTC market resembles the traditional forward trade in commodities – a direct interaction between two companies, in this case, client and «intermediary» (with the intermediary being a bank, a trading house or a brokerage firm) (UNCTAD, 1998).

---

* OTC is the market or transaction arranged bilaterally between two parties without the participation of an exchange. Prices in OTC markets are set by dealer trading rather than the auction system of most organized exchanges (Moles and Terry, 1997).
* Also see Santana-Boado and Gross (2006) for a very comprehensive overview of the status of commodity exchanges.
1. FORWARD CONTRACTS

A. Forwards

A forward contract is an agreement between the seller and buyer to deliver a specified quantity of a commodity to the buyer at some time in the future for a specified price or in accordance with a specified pricing formula. The terms and conditions of the forward contract are therefore usually specific to each transaction.

There are three essential concepts in using forwards. First, given that no cash transfer occurs when the contract is signed, the seller of the commodity is obliged to deliver the commodity at maturity; however the buyer does not have to pay money up front (except for transaction fees). Second, since the sole guarantee that a forward contract will be honoured is the reputation of the two parties entering the agreement, there is an inherent credit or default risk: the counterpart of the forward transaction may fail either to deliver the commodity or to pay the agreed price at maturity (UNCTAD, 1998). Third, forward contracts are primarily merchandising vehicles, whereby both parties expect to make or take delivery of the commodity on the agreed upon date. It is difficult to get out of a forward contract unless one gets the counterparty to rescind the contract (CFTC, 2005).

B. Price risk management using forwards

The general mechanism is as follows: a producer or trader holds (or purchases in the spot market) a certain commodity to insure against adverse price movements by selling the same amount of that commodity in the forward market at the negotiated price. There may be many modalities in working out this forward price and other terms of the contract. In this case, he would take a short position in the forward market. (When a person buys forward or futures contracts, he is said to have gone long or to be holding a long position.) When the forward contract matures, the trader sells the commodity at the specified price, thereby avoiding the risk of a price decline in the intervening period (UNCTAD, 1998). One disadvantage of the forward contract for a producer is that the seller is legally bound to deliver a given quantity of a commodity on or before a specified date. If production falls short of the contracted quantity, the seller is required to purchase a sufficient amount of the commodity from another source in order to satisfy the contractual obligation.

Types of forward contracts:

As forwards are negotiated contracts, various possibilities arise in structuring them. Some of the broad guiding elements in structuring a contract are: the basis for pricing; flexibility in timing the pricing; flexibility over timing the receivables; and the ability to participate in favourable price movements. The key forward contracts are mentioned below; in addition some international trading houses such as Cargill provide proprietary contracts for their customers (see box 1).

---

6 This section was largely drawn from the website of the Risk Management Agency (RMA), the US Department of Agriculture (USDA) (www.rma.usda.gov/pubs/rme/fctsht.html), Harwood et al. (1999), Stasko (1997); an authoritative paper by UNCTAD, Farmers and farmers’ associations in developing countries and their use of modern financial instruments (UNCTAD, 2002); and the risk management resources available at Cargill Aghorizons.

7 For detailed notes on the merits, demerits and mechanism of each of these forward contracts, see www.cargillaghorizons.com/eah/eahpublic.nsf/pages/basis?OpenDocument.
**Fixed price contract:** A fixed price (or flat price) contract is one of the most common types of forward contracts. In a fixed-price forward contract, the farmer commits himself to delivering at an agreed time a certain quantity of commodities of a specified quality. Normally, the farmer is only paid on delivery, although this type of contract can also be used to obtain pre-harvest financing. Premiums and discounts may be established for the produce that does not meet specified quality standards. The farmer carries the opportunity risk of losing potential gains when market prices rise.\(^8\)

**Price-to-be-fixed contract:** Price-to-be-fixed (PTBF) contracts, also called executable orders (in sugar trade) or on call contracts (in cotton trade), are the most common form of export contracts for commodities from Latin America. They are also very common in Asia, and although still common in Africa, are relatively less used. Unlike other forward contracts where the used reference prices are commonly futures market prices, in this case the seller (or the buyer, in case of processors, importers or end-users) has the active ability to fix the prices at the moment deemed most opportune.

**Deferred pricing contract:** A deferred pricing (or delayed pricing, price later, no price established) contract provides that the farmer delivers the commodity and transfers ownership on the contract date but maintains control over when it is priced. This contract allows the seller to separate the pricing decision from the delivery decision. The risks of storage are passed to the buyer at the time of delivery and the contract may also be used as a substitute for storage when unavailable. The price may equal the elevator’s bid price or an adjusted futures price at a time selected by the farmer. While this gives the farmer the opportunity to benefit from price rises, he also retains the risk that prices will fall between the time the contract is entered and the date on which the sales price is determined. This is one of the most widely used instruments for small-scale farmers, especially where there is an established level of confidence in the buyer.

---

\(^8\) If the producer locks in a price with a fixed price contract, the buyer usually protects himself by using the futures market. If a grain merchant enters into a number of fixed price contracts with soybean producers, he will sell an approximately equal amount of futures. If he does not do so, he would be left open to the possibility of heavy losses in the event that the commodity’s prices fall. Such hedging mechanics in the futures market will be elaborated in the next section.
Deferred payment contract: A deferred (or delayed) payment contract specifies the price to be paid and transfers ownership upon delivery while postponing payment. This contract may also offer farmers tax advantages by deferring income from the sale of a commodity to the next tax year as a tax-saving strategy for the current year.

Minimum price contract: This forward contract is similar to a fixed-price forward contract, except that it guarantees a minimum price with an opportunity to participate in future price gains. From the farmer’s side, this eliminates an important risk factor, and the incentive to default on the contract is less than that with fixed-price contracts. On the other hand, the buyer (elevator or packer) can also hedge the assumed risks by taking opposite positions. The farmer can be required to pay a certain price to take advantage of this benefit. In practice, the vast majority of farmers in developing countries have no access to forward contracts that contain this kind of price risk management component. For example, a recent study of coffee marketing in several coffee-producing countries (Varangis and Simmons, 2000) found that, except in Guatemala, very few growers were able to sell coffee forward, and if they could, it was often at very high implied rates of interest (because buyers discount the price they offer to take into account performance risk).

Reference price forward contract: This form of forward contract uses reference prices, at times futures prices, but more often average export prices of a country, to price forward contracts. On delivery, farmers are automatically paid the price of the day or period when they make their delivery. This type of arrangement is quite common in contract farming and outgrower/nucleus estate systems. It is also the basis for the standard pricing formula for most developing country sugar producers, who receive a fixed percentage of the sales prices of their sugar.

Two other important forward contracts: the basis contract and the hedge-to-arrive contract are explained in the following section.

2. Futures

A. Futures

Futures contracts were invented as a way to standardize forwards. In its simplest sense, a futures contract is a standardized forward contract that is exchange traded. It should therefore be emphasized from the start that a future is not a stock or a commodity, but can be thought to trade like a stock. The buyer (seller)\(^{10}\) of a futures contract agrees, as in a forward contract, to purchase or sell a specific amount of a commodity, security, currency, index or other specified item on a stipulated future date. However, there need not be an actual sale or purchase of goods at the stipulated time. Futures contracts are usually closed by making an

\(^{9}\) For this and the next section on "options", refer to Kleinman (2004).

\(^{10}\) The buyer of a contract who agrees to receive the item is said to be in a long position, and the seller who agrees to deliver the item is said to be in a short position. The origin of “long” and “short” comes from the buyer’s situation in which he is buying more than he is selling so that his working stock of the item increases (i.e. becomes “long”), and the seller’s situation in which he is selling more than he is buying so that his working stock of the item becomes depleted (i.e. runs “short”) (Pass et al., 2005).
opposite transaction (offset), i.e. the buyer of a future sells the future some time before the expiration of the contract. It should be noted that futures pre-determine an approximate price, but the effective cost of purchase or sale may vary according to market conditions.

Futures, unlike forwards, are standardized and traded on exchanges. For example, every soybean contract traded on the Chicago Board of Trade (CBOT) is for 5,000 bushels, every gold contract traded on the New York Mercantile is for 100 troy ounces and for a specific grade. While both forwards and futures perform the same economic function of ascertaining cash flows, futures are a significant improvement because they provide liquidity and a performance guarantee due to being exchange traded. The standardization enhances liquidity by making it possible for large numbers of market participants to trade the same instrument. Trades among the members are settled through the exchange’s clearinghouse that guarantees the credit risk, i.e. in the eventuality of either the buyer or seller defaulting in their obligations, the commodity exchange would make good.11

B. Essential concepts

Margins: The striking and almost sole difference between futures and forwards is that futures are traded through organized exchanges, while forwards are traded privately. However, both buyers and sellers are required to make a good faith deposit (margin) with their brokerage firm to ensure their respective commitments. The margin is typically a small percentage of the value of the trade. Therefore, in trading futures the entire sum of the trade does not have to be paid while entering the transaction. There are various kinds of margins. It should be noted that while margin payments are not a true cost (one gets back the margin deposit at the end of the trade plus any profits or minus any losses), commissions or brokerage charges comprise transaction costs. Here another integral concept is marking to market: at the end of each day, a trader’s margin account is adjusted in line with the closing price of the futures contract. Gains and losses on futures contracts are credited and deducted on a daily basis. For example, an increase in wheat prices would be credited to the margin account of the futures buyer and deducted from the margin account of the futures seller.

Selling short: Selling short refers to selling a futures contract. For those new to derivatives, this concept may appear a bit strange. Can one sell futures without owning the commodity today? The beauty of these instruments is that as trading entails buying and selling a commodity in the future, it is equally easy to either buy or sell in the futures market. In fact, one need not own the commodity at all as positions can be closed by the trading mechanism, i.e. by taking an opposite trade.

Settlement of futures: Settlement of a trade refers to the various mechanisms by which an existing or open position can be closed. This can be done in three ways: by reversing the open position (offset), by taking physical delivery of the asset, or by cash settlement.

11 It should be noted that sophisticated instruments, such as Exchange for Risk (EFR) transactions provided by an exchange, permit the holder of a forward (or another OTC product) to unwind his/her position on the exchange, effectively converting the forward into a future. Parties to an EFR transaction must be the same as those participating in the OTC transaction. See the CBOT for a primer on EFR transactions.
Futures are most commonly settled by closing out the open position, i.e. without making or taking delivery of the underlying commodity. In general, futures markets are used to manage or hedge price risk (the mechanism is explained later) and not as a means for acquiring or disposing of the underlying commodity. Participants who trade (any instrument) with the objective of managing price risk and not of speculation are called hedgers. There are also several

Trading information of two corn futures contracts traded on the former day on the CBOT is shown above. The contract size is 5 000 bushels of corn, i.e. upon buying one futures contract of corn, one buys 5 000 bushels of corn.

Month reflects the months in which the contract expires.

The first three numbers in each row show the opening price, highest price and the lowest price achieved in trading during the day. The opening price represents the prices at which contracts were trading immediately after the markets opened. High and low refer to the maximum and minimum prices attained in course of the day's trading.

Settlement refers to the average of the prices at which the contract traded immediately before the end of the trading session. This price is important as it is normally used for marking to market the trade. Change reflects the change in settlement from the previous day.

Lifetime low and lifetime high refers to the highest and lowest prices achieved in the trading of this particular contract in its lifetime.

Open Interest (OI) is an important indicator. It refers to the total number of contracts that are outstanding. Hence, it is the sum of all the long positions or of all the short positions. A seller and a buyer combine to create only one contract. Therefore, to determine the total open interest for any given market, we need to know the totals from either of the sides. OI measures the flow of money into the futures market. Together with price data, OI can be used to confirm price trends of the markets. For example, an increase in open interest along with an increase in price is said to confirm an upward trend. Similarly, an increase in open interest together with a decrease in price confirms a downward trend.

The last line shows the estimated volumes of trading in contracts of all maturities for the day and the volumes of the previous day. Volume represents the total number of shares or contracts that have changed hands in a day. It also shows the open interest of all maturities in the previous day (Monday).

Source: Options, Futures & Other Derivatives (Hull, 2006).
other reasons for which hedgers rarely take or make physical delivery against futures: the futures’ delivery grade may not be the same as that which the hedger needs or produces; the futures delivery location may be inconvenient or unsuitable for the hedger; or the futures delivery date may not match the hedger’s timing for delivery or receipt of the commodity.

In case the position is not closed out before the expiry date, positions could either be physically delivered or cash settled – this may also depend on the exchange’s policy and could vary across commodities. Delivery refers to taking physical possession (for a future’s buyer) or making delivery (for a future’s seller) of the underlying commodity. Typically less than two percent of the total volumes in traded futures markets result in delivery. In comparison, cash settlement does not entail any physical transfer of the commodity; the futures holder either receives or pays the difference in futures prices. For example, if a corn buyer purchases a two-month corn futures at US$3/bushel, and in two months at the time of delivery the price of the contract rises to US$3.4/bushel, under cash settlement the futures buyer receives the difference of US$0.4 per/bushel.

Reading futures markets: An ability to read futures markets would surely help crystallize the concept of futures. An extract of a commodity futures quote is given in box 2. Additionally, it is recommended that the reader browse some key commodity websites such as www.cbot.com etc to further enhance his understanding. The standardized elements (see box 2) of a futures contract are: quantity of the underlying commodity; quality of the underlying commodity; settlement date for the trade; units of price quotation; and minimum price change. Some familiarization with newspaper quotes should help understand futures better.

C. Price risk management using futures

Futures are an important tool for price risk management. It is important to recognize that hedging through futures does not necessarily improve financial outcome; it reduces risk by making the outcome more certain. The underlying principle is that given that cash and futures prices generally move in the same direction, by taking an opposite position in the futures market (i.e. a farmer hoping to sell three months later, sells futures today and buys back the futures three months later), the profits (losses) of one market can offset the losses (gains) of the other market. It should be noted that in such a case the futures markets are not being used to buy or sell the commodity but to hedge price risk.

Price risk management for the commodity seller: Farmers or merchants who own a commodity can protect themselves from a decline in commodity prices by selling a future or taking a short futures position. (In lay terminology, the logic of the mechanism can also be understood as taking today a position in the futures market that would be taken after a few months in the physical market). When the commodity is actually sold in the market, the short position that was taken in the futures markets is closed out by buying it on the exchange. As futures and spot prices generally move together, losses (gains) in the physical market will be partially offset by gains (losses) in the futures market.

Example: At the planting time in April, a corn producer hopes to secure the selling price of the expected yield of 15 000 bushels in the harvest period. At that time the six-month corn futures contract (October contract) is trading at US$2.50 per bushel. He decides to hedge the entire expected yield by selling three April corn futures contracts on CBOT at a price of
US$2.50 per bushel (the standard contract size of a CBOT corn futures contract is 5,000 bushel).

At harvest time, the October futures falls to US$2.00/bushel and local cash prices fall to US$1.88/bushel. The producer offsets his futures position by purchasing back three April corn futures contracts, making a profit of US$0.50 per bushel. He sells the corn in the physical market to the local elevator at the cash price. The corn producer’s effective selling price, ignoring transaction costs, works out to US$2.38 per bushel (US$1.88 plus US$0.50).

In case futures prices rise to US$3.50 and local cash prices to US$3.38, the producer makes a loss of US$1 (US$2.50 less US$3.50) in the futures market. He sells the commodity for US$3.38 in the cash market, again ignoring transaction costs, his net sales price works out to US$2.38 (US$3.38 less US$1). In either of the conditions his revenue does not change and is constant at US$35,700 (see below). Thus, by hedging with futures, the producer could avoid revenue fluctuation resulting from adverse price movements. The producer’s hedging outcomes are summarized in Table 1.

*Price risk management for the buyer:* Commodity buyers can protect themselves from a potential rise in input costs by buying futures or taking a long futures position. When the commodity is actually purchased in the market, the long futures position is closed by selling it on the exchange. As futures and spot prices generally move together, losses (gains) in the physical market would be partially offset by gains (losses) in the futures market.

Example: In May, a wheat-importing government wishes to lock in its future cost of wheat to be purchased in August. To protect itself against prices being higher than the existing futures price of US$140 per tonne, it buys August futures at US$140 per tonne. In the case that August wheat futures rise to US$155 per tonne in August, the government would gain US$15 per tonne (US$155 less US$140 per tonne) on closing out the futures position. Given that futures and cash prices move in the same direction, let us assume that cash prices also rise to US$155. The government purchases wheat at US$155 per tonne in the spot market. The cash price of US$155 per tonne and the profit of US$15 on the futures position result in a net purchase price of US$140 per tonne. It should be pointed out that this results in the effective futures price that was trading in May.
Now consider the case where August wheat futures fall to US$130 per tonne in August. The government loses US$10 per tonne on the closing out of the futures position. Let us assume that the cash price of wheat falls to US$128 per tonne. The government purchases wheat at US$128 per tonne in the spot market. The cash price of US$128 per tonne plus the US$10 per tonne gain in futures results in a net purchase price of US$138 per tonne. This effectively results in a cost price that is less than that of May futures.

**Basis risk:** As seen in the above example, hedging does not guarantee that the profit or loss in the futures market will fully offset the loss or profit in the physical market. This is the so-called **basis risk.** Basis is defined as the difference between spot and futures prices. The expected purchase or sales price in hedging with futures can therefore be said to be the sum of the futures (when the futures contract is purchased) price plus the basis at the time of closing out. Basis may arise for numerous factors: the specific physical commodity to be hedged may not have the same price development as that of the standardized futures contract; the markets to which a company exports are not necessarily the same as those where futures markets are located; price developments on the customer market can be different from those on the futures exchange; the quantity to be hedged may not equal the underlying contract; and the relation between futures prices and spot market prices can be temporarily disturbed, for example, by attempts to manipulate the market or by technical squeezes caused by a shortage of supply (UNCTAD, 1998).

The basis is important because it is the single major factor that will affect the outcome of a hedge. In essence, the hedger is speculating on a basis change rather than a price change. However, even though prices vary greatly from year to year, the basis typically does not change dramatically and generally can be predicted based on historical patterns. Basis risk can improve or worsen the hedger's position. In case of a short hedge strengthening of the basis, i.e. where spot prices are greater than futures prices, the hedger would improve his position while weakening of the basis would worsen his position. In case of a long hedge, strengthening of the basis would worsen the hedger's position, while weakening of the basis would strengthen his position.

**Forward contracts based on futures** (After being familiarized with futures, it might be easier to understand these forward contracts that are based on futures.)

**Basis contract (also known as fix price later, unpriced or basis fix contract):** A basis contract is another type of a deferred pricing contract. There are two elements to this contract: futures value of the commodity and a pre-determined **basis.** The price of this contract is determined by applying a specified **fixed** basis to a particular futures price, usually when desired by the farmer. For example, a contract may state on 1 July that a farmer sells a specified quantity for November delivery at US$0.20. (The 1 November cash price minus a set basis of 20 cents, or the 1 November futures price plus a set basis of 20 cents.) Thus, the farmer has eliminated the **basis** part of price risk, but has retained the risk of futures prices. Sellers generally use the basis contract when the basis level is attractive but overall prices are unattractive due to low futures prices. Since the basis tends to be most narrow when futures levels are low, most sellers use the basis contract when they are confident that the futures price will go up.

**Hedge-to-arrive contract (no basis established contract):** A hedge-to-arrive (HTA) contract is opposite to the basis contract. It fixes the futures price but leaves the basis level to be determined at a later date (usually no later than the date of delivery). When a HTA contract is agreed, the buyer
of the commodity immediately sells futures consistent with the time that the seller agrees to make delivery of the physical commodity; in this way, the futures price is locked in. No matter whether prices subsequently rise or fall, the seller’s cash price will be based upon the price of the futures position initiated by the buyer. When the seller delivers the physical, the buyer will determine the cash price by adjusting the locked-in futures price by the basis that prevails at that particular time. In other words, the basis is variable throughout the life of the contract. The seller eliminates futures price risk with a HTA contract but assumes basis risk. When a producer believes that the basis will narrow, he might use this type of contract. Since the futures price is established in the contract, any gain or loss to the producer will be on the basis. This contract enables farmers to lock in a favourable futures price when the basis is unfavourable. However, the risks for the provider of these instruments can be very difficult to manage; many US cooperatives lost major sums of money in the late 1990s when they were unable to maintain the margin requirements of the exchanges necessary to continue covering these contractual arrangements with producers.

**Long-term hedges (issues of rollover) and futures markets**

Consider the way longer-term hedging operates. A sugar mill seeking a two-year hedge on sugar prices would ideally wish to buy a two-year futures contract. However, in practice the contract could be traded only for a period of one year on the exchange or could be illiquid in the far-end contracts. In such a situation the sugar mill could buy the one-year contract, which is liquid, close (offset) this contract when it nears maturity, and buy another longer-term contract. This is called a **rollover**, which effectively helps him buy a two-year contract. However, in undertaking any rollover operations, attention should be paid to the relation between futures prices in the various expiry months. This relation can have major implications for those wishing to use futures to hedge long-term positions.

When prices of **further-out** (further expiry month) futures contracts are trading higher than the futures contracts maturing earlier, markets are said to be normal, in **contango**, or carrying a charge. For instance, when March cotton futures trade at 53 hundredweight/lb, (ct/lb) April cotton futures at 59ct/lb, May cotton futures at 66 ct/lb etc. markets are said to be in contango. This is easy to understand as futures prices are to reflect the cost of carry, i.e. costs of storage, interest rate on investment, and loss due to loss of weight or deterioration in quantity. However, commodity markets also display the reverse pattern, where **near month** contracts trade higher than distant month contracts. Such commodity markets are said to be inverted or in **backwardation**. For instance, in a backwardation market, March cotton futures would trade at 65 ct/lb, April cotton futures at 62 ct/lb and May cotton futures at 58 ct/lb. Backwardation can be attributed to the convenience yield, i.e. the value of having a commodity at one’s disposal, as there may be benefits of holding the commodity physically that are not obtained by holding a futures contract. Backwardation could also be due to perceived or real near-term shortages, or due to a contract maturing in the peak season.

**D. Indirect benefits of commodity futures**

**Price discovery:** An important function of futures markets is to reveal price information about expected cash markets. Because futures are an anonymous exchange, prices quoted on

---

12 This section was largely drawn from Apostolou and Apostolou (2000) and Alizadeh and Nomikos (2005).
futures exchanges are widely accepted and used as references prices for the underlying commodity. This is known as price discovery. Two significant applications of price discovery are explained below.

Price discovery in production planning: Futures prices represent the best estimates of well-informed traders at a given point of time, reflecting the current expectations of the market regarding the spot prices that will prevail in the future. Therefore, futures provide strategic information that helps in estimating the profitability of different commodities. Essentially, when futures price levels cover both fixed and variable\(^\text{13}\) costs of a commodity, production is likely to be profitable. If it covers variable costs but not fixed costs, loss is minimized by producing the commodity. If it does not cover variable costs, producing the commodity is likely to be a loss-making proposition. (Harwood et al., 1999).

Price discovery in storage planning: The price of storage offered by the market is indicated in the carrying charge. Carrying charges can be understood as the cost to hold a commodity, and are reflected in the storage and interest costs. Carrying charges can exist in the futures (spreads) and in the basis. Farmers can profitably store crops after harvest if their own storage costs are lower than the market price of storage, which is indicated in the spread or basis. By selling a future they could then receive the higher market prices and pay their lower storage costs. Futures also help in making spaced out purchases avoiding storage hassles of large cash purchases.

Reference prices: Futures prices reflect the current expectations of the market regarding the level of spot price that will prevail in the future. Futures prices that are “discovered” in the competitive, open auction market of a futures exchange provide cash market participants a reliable measure to price spot and forward contracts. A survey conducted in the mid-1990s among Nebraska producers revealed that of those using basis contracts, 49 percent indicated the use of this tool to price 75-100 percent of their crop. In another survey in four states (covering producers of cotton, maize, soybeans and wheat), it was found that with the exception of cotton, 79-87 percent made indirect use of futures and options markets (through the pricing clauses in their sales contracts). In the case of cotton, the figure was 38 percent (see Harwood et al., 1999).

Agriculture infrastructure: The infrastructure of commodity exchanges can play an important role in enhancing the competitiveness of agriculture markets. Requirements for reputed warehouses, scientific storage systems, stringent delivery standards, quality monitoring systems and robust telecommunications, \textit{inter alia}, can play an integral role in modernizing agriculture.

E. Participants in commodity futures
Based on the motive of participation, those engaged in commodity futures can be grouped into three key categories: (i) hedgers who actually face price risk and hope to limit this by participating in the futures markets; (ii) fund managers who seek to diversify the risks of their portfolios by investing partially in a weakly correlated asset class such as commodities; and (iii) speculators who hope to profit from the fluctuations in commodity prices.

\(^{13}\) Variable production costs are costs – such as for seed, fertilizers, custom work, and rent for land or storage space – that vary with the level of output. This contrasts with fixed costs, such as interest and depreciation on buildings and equipment, which must be met regardless of the level of output (Harwood et al., 1999).
Hedgers can further be categorized into three user classes: producers, consumers and processors, and traders.

Farmers/producers associations: By including futures trading in a marketing plan, a producer can ascertain cash flows and offset potential losses from falling commodity prices. To illustrate, a farmer who thinks the price of corn may decline by harvest time can sell corn futures early in the season. If prices decline, a profit in the futures contract will compensate for the lower price received for the harvest.

Consumers and processors: Many bulk purchasers of agricultural commodities require price risk management tools to help stabilize input prices. For example, a popcorn manufacturer who thinks that the price of corn is going to rise, or a biscuit manufacturer looking to buy wheat a year later, could benefit from input price management strategies. Consumers concerned with price fluctuations for agricultural inputs commonly use a buying hedge (buy futures) to manage this price risk.

Traders: Traders are important participants in the futures markets. Like exporters, they often buy goods from producers before they sell them, or they may sell the goods before buying them (i.e. essentially fixing the price at end and being open to market vagaries in the other end). As commodity production is seasonal, restricted to a few months and consumption spread over the year, this creates price uncertainty for traders. The existence of a futures market stems this uncertainty and thus encourages the trader to buy commodities in the surplus or marketing period, i.e. when goods arrive in the market. As they rush to buy stock when it arrives in the market, they support the price, potentially boosting producer returns. Another important role is that of market making: as traders use futures markets for hedging risks of purchases and sales, they enhance the liquidity of the market.

Portfolio managers: Passive asset managers such as pension funds, mutual funds, insurance and investment companies tend to allocate at least 5 percent of their portfolios to commodities. Allocating part of their portfolio to commodities makes their overall portfolio returns less volatile. Commodity portfolios exhibit negative correlation to bonds and stocks. A study (Ithurbide and Vincent Chaigneau, 2005) of the seven stock market crashes since 1970 reveals that commodities have yielded positive returns in most of those periods. The diversification benefit tends to increase when the returns of the commodities have a high average standard deviation and exhibit low inter-correlation. In recent years, bond portfolio managers have increasingly used commodity instruments as a hedge against inflation.

Speculator: A speculator is one who does not produce or use a commodity but risks his own capital trading futures in the hope of making a profit on price changes. While speculation is not considered one of the economic purposes of a futures market, speculators improve the functioning of markets by providing liquidity.14

---

14 Liquidity refers to the ability to buy or sell an asset quickly and in large volume without substantially affecting the asset’s price. A high level of liquidity is a key characteristic of a good market for a security or a commodity (Downes and Goodman, 2003).
3. OPTIONS

A. Options
Options can provide the seller of a commodity with the assurance of receiving a minimum selling price and the buyer of paying a maximum purchase price – they are therefore like insurance. In addition to the above “insurance”, options are attractive since they may permit the buyer of an option to participate in favourable price movements. Options can be therefore used to provide downside protection while retaining some degree of upside potential.

What, then, is an option? Buying an option contract gives the holder or buyer of the option the right (note: there is no obligation) to buy or sell a specified quantity of a commodity (also called the underlying) for a specified price on or before a specified date in the future. It is common practice in grain trade calls and puts to refer to options on futures (i.e. the futures contracts are the underlying; this product is detailed later in the section).

Options can be both exchange traded and privately negotiated or OTC (like forwards). OTC options (more common in currency markets) have the obvious flexibility in providing a customized contract, but have the inherent disadvantages of illiquidity, counterparty risk and higher costs. While the core risk management principles are common for the two, this section elucidates mechanisms of exchange-traded options (i.e. standardized options), which are more commonly used in commodity markets.

Compared to futures and forwards, using options is a different proposition. There are two basic types of options: call options and put options.

Call options give the buyer of the call option (long call) the right to buy the underlying commodity at a specific price (exercise price). The seller of the call (short call) has an obligation to deliver the commodity on the exercise of the option.

Put options give the buyer of the put option (long put) the right to sell the underlying commodity at a specified price (exercise price). The seller of the put (short put) has an obligation to buy the commodity on the exercise of the option.

B. Essential concepts
Option premium: Option premium represents the cost of buying an option; it is a non-refundable payment that the buyer of an option pays to the seller at the time of buying the option (note: futures contracts require margin payments). An important difference between trading futures and options is that in futures markets, the futures price is traded (like cash markets), while in trading options, it is the option premium that is traded (see box 3).

Strike price/exercise price: This refers to the specified price for which the underlying commodity may be purchased (in the case of a call) or sold (in the case of a put). The premium could depend on a wide range of variables such as the price of the underlying commodity, volatility of the underlying, strike price, time until expiration and risk-free interest rate.

Settlement of options: Options can be exited in three ways. The first way is to offset the trade by taking an opposite position. In doing so, the option buyer sells the option. This can be done
by the buyer or seller of the option. The second way is to exercise the option. Here the commodity is physically bought or sold through the exchange. Only the option buyer (call or put) has a right to do so. Based on the rules of exercise, there are two styles of options: American options and European options. An American-style option may be exercised at any time prior to its expiration. A European-styled option may be exercised only on the expiry date. The third way to exit is to do nothing, allowing the option to expire.

Reading options: Understanding the following trading data of an option on a May corn futures as traded on the CBOT should enhance the reading of option markets.

### C. Price risk management using options

It is commonly explained that a seller of a commodity would hedge risks of falling prices by buying a put option. This guarantees him a minimum selling price. However, the seller’s contractual status, i.e. whether he has an existing contract (for example, a contract farming arrangement) in the spot market that assures a minimum price, could also influence his strategy. When a seller or buyer has a contract farming type arrangement that guarantees a fixed price, options would not be used to get a minimum price assurance because this is already assured in

**Underlying contract price: 238'6 (06 May future)**

One CBOT Corn futures contract is for 5,000 bushels

**Strike** in the second column represents the strike price for which the Call or Put option can be bought. 260'0, or 260 cents, is read as US$2.6. (The fourth digit is to be read as 1/8 cent/bushel, thus 170'4 would be read as US$1.7 1/8 [US$1.7+4/8 cent]).

**Last** refers to the last traded price and change captures the price movements. Note that except for the strike price, all other prices are that of the option premium.

The next three columns show the **opening option price**, the **highest option price**, the **lowest option price** and the closing option price achieved in trading during the day.

**Settlement** refers to the average of the prices at which the contract traded immediately before the end of the trading session. Settlement price is important because the **marked to market price** is based on this. Change reflects the change in settlement price from the preceding day.

**Hi and Lo limits** refer to the range in which options can trade in a day. It indicates the highest and lowest price that options can take in a given day.
the physical contract. In this case, options would then be used to allow flexibility to profit from favourable price movements. In such a case, therefore, the seller of a commodity would buy a call option that would yield profits in the eventuality that prices rise. Options have also been used by governments (see box 5) and supply chain partners (see Box 6) to help farmers reduce price risk. The following examples, illustrate the use of options from both the buyer’s and seller’s perspective, under two circumstances, one when there is a fixed contract and two when there is no fixed contract.

**Seller risk management when there is no existing physical contract guaranteeing a minimum price**

A cocoa farmer is concerned about falling market prices and chooses to protect himself by buying a put option. He buys a put option expiring in three months, having a strike price of US$800 at a premium of US$10. This gives him the right to sell a standard batch of cocoa at an agreed price of US$800. Three months later at harvest time, cocoa prices fall to US$770 per tonne and the put option is trading at US$25. The farmer has two alternatives. He could exercise the option, delivering cocoa at US$800 per tonne at the stipulated warehouse and realize a net price (less premium costs) of US$790 per tonne. Alternatively, if he does not wish to deliver the cocoa, he could sell the put option (close/offset his position) at a profit of US$15 (US$25-US$10), effectively getting a selling price of US$785 (US$770+US$15) per tonne. If cocoa prices rise to US$825 per tonne, he will let his option lapse and sell the cocoa at the higher market price.

**Seller risk management when there is an existing physical contract assuring a minimum price**

In the above example, consider a case where the cocoa grower has a contract farming agreement with the chocolate manufacturer whereby he has agreed to sell the standard batch of cocoa at a fixed price of US$800 per tonne. Three months later, cocoa prices in the market increase to US$840, which results in an opportunity loss of US$40 per tonne for the grower. If the farmer had bought a call option, it could have helped the farmer participate in the

---

15 This example was taken from Pass *et al.* (2005).

---

**Box 4**

**Put options enhance terms of credit**

Rabobank with the International Task Force (ITF) have conducted pilots for coffee in Nicaragua, Uganda and Tanzania. The period of coverage ranged from one to six months consistent with physical transactions. 250 in Nicaragua, 450 in Uganda and a few thousand in Tanzania have benefited from the scheme. All initial transactions were put options and premiums ranged from 2-9 percent of the strike price. Rabobank executed most of these ITF transactions. Many thousands of African farmers, making up the membership of one specific large cooperative, saved half of their traditionally paid lending fee of 18 percent. Another major result of hedging was that local banks extended credit to counterparts whom they had refused before.

World Business Council for Sustainable Development, 2004
upward price movement. He could yield some gains by simply closing out his call option, which would have gained value on account of rising cocoa prices. (The price of the underlying is the key determinant that guides the price of an option. When market prices rise, call options gain value, i.e. the price of the option premium increases, and when market prices fall, put options gain value.)

**Buyer risk management when there is no existing physical contract assuring a maximum cost of purchase**

A chocolate manufacturer concerned about rising cocoa prices seeks protection by buying a call option, which gives him the right to buy a standard batch of cocoa at an agreed price of US$800 per tonne after three months. This option costs US$10 per tonne. Three months later, cocoa prices in the market rise to US$820 per tonne and the call option is trading at a price of US$17. Like the cocoa farmer, he has two alternatives before him. He could exercise the

---

16 This example was taken from Pass *et al.* (2005).
option, buying wheat at US$800 per tonne at the stipulated warehouse and pay a net cost (plus premium costs) of US$810 per tonne. Alternatively, if he does not wish to take delivery, he could sell the call option (close/ offset his position) at a profit of US$7 (US$17-US$10), giving him an effective cost of US$813 (US$820-US$7) per tonne. If market prices fall to US$780, the chocolate producer does not exercise the option and is free to buy cocoa at the favourable market price.

**Buyer risk management when there is an existing physical contract assuring a minimum price**

In the above example, consider a case where the chocolate manufacturer has a contract farming agreement with the cocoa grower whereby he buys the standard patch of cocoa at a fixed price.
of US$800 per tonne. Three months later cocoa prices fall to US$780 and the manufacturer faces an opportunity loss of US$20 per tonne of cocoa to be purchased. If the manufacturer had bought a put option, it could have helped him participate in the downward price movements. The manufacturer could yield some gains by simply closing out his put option, which would have gained value on account of falling market prices.

Using put options as minimum support prices: The use of put options can provide an alternate procurement mechanism for the government. Put options can provide farmers not only with a minimum selling price, but with a much better market-determined MSP. The use of market-based mechanisms does not distort market prices. An evident hitch in any such programme would be the resistance of the farmers to bear the costs. As an intermediary step, the government could consider paying or sharing the cost of the premium.

Hedging strategies with options: Innumerable trading strategies can be created with options and futures. Strategies that are speculative should be distinguished from those useful for hedging. One key hedging strategy is the fence strategy, which reduces the cost of the options and also range bounds the returns, i.e. the option buyer no longer has the potential to earn unlimited profits.

Fence strategies with options: A hedging strategy arrived at by buying a put and selling a call or buying a call and selling a put results in a fence. The fence combines two of the simple (outright) trades to constrain the price effects at extremes – limiting the costs associated with price movements in one direction while at the same time giving up some of the benefits of price movements (The Institute for Financial Markets, 2003). In this trade, the premium received for selling an option offsets the premium paid for buying an option. Two fence strategies for sellers and buyers of a commodity are illustrated below:

**Example:** Fence strategy for the commodity seller - buying a put option and selling a call option.

This spread trade of buying a put option and selling a call option can be used by the producer/farmer who wishes to hedge the risk of falling commodity prices. Suppose a cocoa growing farmer buys a December Cocoa 750 put at US$21 and, at the same time, sells December Cocoa 850 calls at US$21 (i.e. he receives US$21). Thus, at any given point the farmer has the right to sell his cocoa futures at US$750. If the buyer of the call exercises the call, the cocoa farmer has the obligation of selling the cocoa futures at US$850. Therefore, this trade ensures that the farmer is protected between the two limit prices of US$750 and US$850, as shown in Figure 1. As a result of the offsetting of the two premiums, the trade cost is zero. While writing options can lead to unlimited loses, in this case it is important to recognize that the seller of the call (the farmer) owns the commodity i.e. he writes a covered call. He does not therefore face the eventuality of being forced to buy at a higher price in the market to fulfill the delivery obligations.

**Example:** Fence strategy for the commodity buyer – buying a call option and selling a put option.
A coffee processor is concerned over rising prices of coffee. He caps his costs by undertaking a fence strategy. He buys a November 925 call at US$13 (premium paid) and at the same time, sells a November 800 put at US$12 (premium earned). Thus, at all times the processor has the right to buy the coffee at US$925. If the buyer of the put exercises his put, the processor has the obligation of buying the coffee at US$800. Thus with the help of the two trades, the processor is protected between the two limit prices of US$925 and US$800. The cost of entering this trade is US$1 (the difference between the premiums paid and earned) to the processor.

**Hedging with options vs. futures:** An interesting question arises – of the two popularly exchange traded instruments, options and futures, which would be more suitable for developing countries? While entering a futures contract only requires payment of an initial margin (no explicit cost), futures can potentially generate large and uncertain losses on the settlement or closing of the futures position. In the case of options there is a permanent entry cost, but after paying the one-time premium, there are less cash-flow problems because there is no risk of unexpected margin calls. Further, the cost of purchasing options can be minimized by adopting suitable trading strategies. Thus, given the cost and cash flow certainty in using options, they may be more suitable tools for developing countries.

**D. Other option properties**

If a hedger decides to minimize price risk by hedging with options, the first question arises is, at what strike price? Options are termed _in-the-money, at-the-money, or out-of-the-money_ depending on the relationship between the strike price and the price level of the underlying contract.

- An _at-the-money_ option is one that would lead to a zero cash flow to the holder if exercised immediately, i.e. the price of the underlying commodity equals the option’s strike price.

- An _in-the-money_ option is one that would lead to a positive cash flow to the holder if exercised immediately, i.e. the price of the underlying commodity is more than a call option’s strike price and less than a put option’s strike price.
• An out-of-the-money option is one that would lead to a negative cash flow to the holder if exercised immediately, i.e. the price of the underlying commodity is less than the call option's strike price and more than the put option's strike price.

The purchase of an in-the-money, at-the-money, or out-of-the-money option depends on the level of price insurance desired. While an in-the-money option offers more price insurance (a lower price ceiling for a processor), the premium paid is higher.

Another related concept is the intrinsic and time value of an option. Intrinsic value reflects the amount by which an option is in-the-money; it is therefore the difference between the exercise price of the option and the underlying commodity. Anything paid for an option in addition to its intrinsic value is time value. Time value refers to the money that buyers are willing to pay for the possibility that the intrinsic value of an option will increase over time. Time value of an options contract shrinks as the expiration date approaches; with less and less time for a major change in market opinion, there is a decreasing likelihood that the options contract will increase in value.

E. Options on commodity futures
Options on futures require delivery of the underlying futures contract (and not commodity) on the exercise of the option. In agriculture markets, options often refer to options on futures. For example, the underlying for the wheat option traded on the CBOT is the wheat futures contract.

On exercising a call option on futures, the buyer of the option acquires a long position in the futures contract and a cash amount equal to the difference between the most recent futures settlement price and the strike price of the option. If a put option on futures is exercised, the option holder acquires a short position in the underlying futures contract and the difference between the strike price and the most recent futures settlement price. Options on futures are more attractive than options when it is cheaper or more convenient to deliver the futures contract than the commodity. They assume more importance in fragmented spot markets (Hull, 2006).

4. Swaps

A. Swaps
Swaps were developed in the OTC market as long-term price risk management instruments. A commodity swap contract (or simply swap) obligates two parties to exchange a floating price for a fixed price (or vice versa) for a given amount of a commodity at specified time intervals. In other words, a swap is an agreement between two parties – the hedger and the hedge provider – in which the hedger (a commodity user or producer) agrees to pay a fixed price and receive a floating price for a specified volume of a commodity over a specified period. In a swap with two parties, there is typically a consumer and a producer of the commodity, and a bank or any other financial institution that acts as an intermediary. A swap agreed directly between a consumer and producer and not through an intermediary has the advantage that the intermediary carries risks associated with the performance of the swap. Commodity swaps have been more used in the oil industry.
B. Essential concepts

Settlement
Swaps are settled periodically on a net basis. Swap transactions do not entail physical delivery of commodities. Depending on whether the prevailing market price is above or below the predetermined price, one party would make a payment.

Costs of a swap
Entering a swap typically does not require the payment of a fee. There are no periodic margin calls as in futures or any initial cost outlay as in the case of options. However, because of the high counterparty risk in the swap transactions, banks may require upfront cash collateral to cover a predetermined level of risk exposure.

Key advantages of swaps
Operational benefits of swaps: As a commodity swap is a pure financial transaction, it has the advantage of allowing the producer and consumer to hedge their price exposure without directly affecting their commodity production, distribution or procurement activities. The hedge seeker has no obligations to deliver the commodity to the bank. The price risk is therefore separated from the physical risk.

As instruments of risk management, swaps offer a simple method of managing price risk that does not involve detailed understanding and access to the currency and futures markets. Swaps can also provide protection against exchange rate movements by allowing the transaction in the currency of one’s choice. Since a swap is a one-time negotiation, no major periodic decisions have to be made and they do not require constant monitoring. Swaps do not involve hassles of exchange-traded brokerage and margin calls; this makes them more convenient tools of price risk management. These are some key factors that make swaps easier tools of risk management for developing countries.

Long-term risk management: Unlike futures and options, swaps were developed to meet the relatively long-term price risk management needs and are generally available in the over-the-counter market (i.e. they are negotiated and not exchange traded). A key advantage of swaps is that they allow market participants to improve their cash flow predictability beyond one to two years; futures for agricultural commodities by contrast are traded only for 12 to 18 months (Faruqee and Coleman, 1996).

C. Using swaps for price risk management
Fixed-floating swaps are the most basic swaps available in any commodity or financial market. This swap obligates two parties to exchange a floating price for a fixed price (or vice versa) for a given amount of a commodity at specified time intervals. The fixed price is determined by the bank and the reference price could be based on an agreed futures contract, an index or a reference price quoted in a price guide.  

Example of a consumer swap: The agency of a wheat-importing government enters into a long-term contract in which the exporter agrees to sell 250,000 tonnes of wheat every six months over the next five years. The agency wishes to lock in the dollar costs at the time the contract is signed. The agency enters into a commodity swap contract with a bank. The fixed term for the swap is US$130 per tonne and the floating rate is to be based on the spot rates that would prevail at the time cash flows are exchanged. Thus, the importer agrees to pay the bank a notional (because the above sums are not really exchanged) sum of US$32.5 million (250,000 tonnes x US$130 per tonne) every six months for the next five years. The bank in return agrees to pay the exporter a notional value based on the spot price of wheat that would prevail on the day that the bank receives its payment from the importer. The difference between the above two notional cash flows is settled every six months between the two parties of the swap contract. Note: in exchanging these cash flows, the importing agency is transacting with the bank and not the exporter. If the spot prices of wheat rise to US$132 in the spot market, the importer receives 500,000 (2 x 250,000) from the bank. This compensates the importer for the increased cost of US$2 (US$132 minus US$130) that he incurs in the spot market. In this way a commodity swap locks in a price of US$130 per tonne for the importing agency.

Example of a producer swap: A wheat farmer would like to receive a fixed price for 300 tonnes of wheat over the next two years. The variable leg of the swap is based on the closing price of the USD wheat futures contract on the CBOT on the pricing date, converted to Australia dollars based on the USD/AUD exchange rate. The bank calculates the fixed price to be paid to the farmer as US$200. If the reference price falls to US$190, then on the payment day the bank pays the farmer the difference between the fixed and reference price, i.e. US$1,000 (US$10 x 300). This payment compensates the loss in selling wheat at the reduced market price. If the reference price rises to US$220, the farmer would have to pay the difference, i.e. US$6,000 (US$20 x 300), effectively netting US$200 under both conditions.

It is possible to integrate an option clause in the contract to permit the producer to profit from price rises, but in the case of commodities this is often prohibitively expensive due to the premium costs of longer-term options. These costs can be partly mitigated by selling options to the bank or by other clauses that give up part of the benefits on prices increasing beyond a certain level.

Swap markets: For some agricultural goods, the existence of liquid and well-established futures markets limits the need for swaps (as positions on the futures market can be rolled over to create a synthetic swap). However, there is a major technical barrier to the rapid development of swaps for producers. This barrier lies in the fact that the prices to be used in swaps are difficult to determine when they are based on the prices of futures contracts that are in backwardation most of the time and where the level of backwardation is highly volatile. When one covers a swap with a consumer by rolling over futures, backwardations provide profits (as a counterparty, the intermediary would be notionally selling the commodity to the consumer. The intermediary would in turn cover this position by taking an inverse position, i.e. buying a future. Rolling over such a position would entail selling the near month and buying the further-out month, which is trading at a lower price, while contangos result in losses; in the case of a swap with a producer, the opposite is the case.18 Thus, under conditions of backwardation,
swaps with consumers are much easier to offset by futures transactions than are swaps with producers.

5. **Insurance**

As seen in other instruments, the essence of the risk management instruments is risk-sharing, as it is in insurance. However, agriculture insurance is more commonly used for non-market related perils such as crop losses from climatic disasters and pest attacks. Application of insurance in managing price risks is seen more often in revenue management and under contract farming arrangements. Price insurance is more effective for those products for which objective price data is available. To avoid moral hazard and adverse selection problems, loss assessment should be based on a reference price (futures price, spot market price), which cannot be influenced by the farmer.

Revenue insurance: Revenue insurance was designed to provide comprehensive protection — not just yield or price protection. It covers sharp drops in expected revenue, possibly resulting either from a decline in yields or prices, or a combination of the two. Farmers are compensated when any combination of harvested yield times the harvest price results in insurance revenue that is less than the revenue guaranteed. The origins of revenue insurance are found in the need for the private sector to fill the gap left by a reduction in the government financial safety net. The following revenue insurance plans provided by the Risk Management Agency of the USDA are illustrative of the potential ways in which revenue insurance can be provided.

*Group Risk Income Protection (GRIP)* makes indemnity payments only when the average county revenue for the insured crop falls below the revenue chosen by the farmer, i.e. the insured is paid in the event that the county average per-acre revenue falls below the insured’s county trigger revenue. The trigger revenue is calculated by multiplying the GRIP price by the expected county yield and then multiplying this by 90, 85, 80, 75, or 70 percent (based on the chosen protection). The GRIP price is the average CBOT futures price for the five business days prior to March 1.

*Adjusted Gross Revenue (AGR)* insures the revenue of the entire farm rather than an individual crop by guaranteeing a percentage of average gross farm revenue, including a small amount of livestock revenue. The plan uses information from a producer’s Schedule F tax forms and the current year’s expected farm revenue to calculate the policy revenue guarantee.

*Crop Revenue Coverage (CRC)* provides revenue protection based on price and yield expectations by paying for losses below the guarantee at the higher of an early-season price or the harvest price.

---

19 For more about insurance, refer to Kang (2005). The paper also explains two products for managing livestock price risk: Livestock Risk Protection (LRP) and Livestock Gross Margin (LGM).
20 See www.rma.usda.gov for details on the policies.
Income Protection (IP) protects producers against reductions in gross income when either a crop’s price or yield declines from early-season expectations.

Revenue Assurance (RA) provides dollar-denominated coverage by the producer selecting a dollar amount of target revenue from a range defined by 65-75 percent of expected revenue.

While the state provides subsidy in the above-mentioned schemes, another model in managing costs could involve payment of part premium by the input vendors who could in turn be reimbursed from the sales revenue.

Price insurance through contract farming: Contract farming arrangements, where farmers are contracted to produce as per the procurer’s requirements, can have in-built price insurance through the pricing clauses of the contract. For example, in the cotton sector in India (Chennai), procuring mills are purchasing cotton at the higher of the fixed or market price. If the mill fails to procure the quantity agreed, the federal procurement agency purchases the rest at the market price subject to the minimum declared price of the government. The above contracting model effectively provides price insurance as given by an option. (Note: an option also assures a minimum price, even under any favourable price movement.) In yet another model, the company may enter into a contractual arrangement with the producer and guarantee a price for the purchase of the product under agreed conditions or even guarantee a minimum level of revenue on a per-acre basis.

The major drawback of price insurance is a high correlation of prices, which is associated with a high degree of systemic (i.e. non-diversifiable) risk. Generally, systemic risk can be dealt with more effectively using derivatives products such as options, futures and swaps. (Essentially, any price insurance policy can be replicated with a long put option strategy, the strike price of the option being a trigger level of insurance and the option price, i.e. premium being a premium of insurance.) Thus, the availability of price insurance may also depend on the availability of derivatives markets where the insurers can dispose of the excess risk due to high correlation of price risk or on the availability of sufficient reinsurance capacity (Alizadeh and Nomikos, 2005).
III. Summary and recommendations

Forward pricing instruments such as futures, options, or forward contracts do not prevent or reverse a persistent deterioration in commodity prices, or sudden spikes in prices, but if used correctly they can effectively serve farmers and agro-businesses as a tool for smoothing out short-term (within the year) price fluctuations. This chapter summarizes the market-based price risk management instruments and offers some recommendations for the users and policy-makers.

1. SUMMARY OF THE MARKET-BASED PRICE RISK MANAGEMENT INSTRUMENTS

Forward contracts allow the seller or buyer of a commodity to set the price of a given quantity in advance through privately negotiated mechanisms. Forward contracts are customized, giving the negotiator flexibility over the quality, quantity and time of the transaction. Various types of forward contracts are discussed. Key among these is the price-to-be-fixed (PTBF) contract, where the seller has the ability to fix the prices at the moment deemed most opportune. Deferred pricing contracts allow the seller to deliver a commodity at one period of time but permit the price to be fixed at a later date. One type of deferred pricing contract is the basis contract, which fixes the basis at the time of delivery, but leaves the futures price open. The hedge-to-arrive contract works in the opposite manner; it fixes the futures price leaving the basis open. Deferred payment contracts allow delivery and pricing to occur at one period of time, but actual payment to take place at a later date. This is especially advantageous for tax purposes. The minimum price contract guarantees a minimum price with an opportunity to participate in future price gains.

Futures contracts are similar to forward contracts but standardized and exchange traded. There are two ways in which they could be used for risk management. In the first mechanism, firms planning to buy or sell in the physical market can instead trade on the commodity exchange. Upon expiration of the contract they would have to either give or take delivery, thus locking in a tentative price. (They are subject to the risk of price movements between the period when the contract is entered and closed.) In the second, more commonly used mechanism, the buyer or seller in the physical market takes an opposite position in the futures market. As cash and futures prices move in the same direction, the losses/gains in the physical market get compensated by the gains/losses in the futures position.

Options are a useful price risk management tool for agricultural producers. Their function is similar to insurance. They can limit the option buyer’s downside while assuring gains from any favourable price movements. There are two basic types of options: puts and calls. A put option provides a commodity seller protection from falling prices. In the eventuality of falling prices, the option buyer has the right to sell the commodity at the higher-than-market price. Similarly, a call option provides a commodity buyer with protection from increasing prices. In the
eventuality of increasing prices, the option buyer has the right to buy the commodity at the lower-than-market price.

Swaps are multi-period, price-fixing contracts. A commodity swap is an agreement whereby a floating price for a commodity is exchanged for a fixed price for the same commodity over a specified period for a defined volume. The floating price is normally the prevailing market (spot) price for the asset and the fixed price is the price, which is negotiated and agreed before the initiation of the swap contract. Swaps are pure financial instruments where no exchange of physical goods takes place. This feature distinguishes swaps from futures and options contracts, where making or taking delivery of the physical commodity is always an option before the agriculturalist.

Insurance in agriculture has essentially been concerned with providing protection from perils of crop failures. Revenue insurance, which provides protection against both falling prices and crop yields, offers farmers a comprehensive solution. Price insurance is also being applied under contract farming arrangements.

2. RECOMMENDATIONS FOR ENCOURAGING THE USE OF MARKET-BASED PRICE MANAGEMENT INSTRUMENTS

A. Recommendations for users

Prior to trading price risk management instruments, especially futures and options, the user must consider all possible means in which they could be used to manage price risk. Three possibilities arise:

- Futures and options can be traded directly to either hedge risk or trade the commodity on the exchange.

- The price information can be used for pricing physical contracts.

- Access to the price dissemination systems can be used as a reference for negotiating fair prices. The implicit benefits of market intelligence, especially to enhance the bargaining power of small-scale farmers, should be well recognized.

In making any such decision, the user must critically examine existing technical capabilities and availability of resources for sustained access to these markets. The current commodity derivative markets are based on large volumes, and to access them, sizable infrastructure (hardware, know-how, capital, market information, etc.) is necessary. In some cases, the costs of accessing these instruments (margin calls in futures and premiums in options) and the minimum trading units may prove to be prohibitive for small-scale farmers.

Farmers can benefit from all of these to a much larger extent if their farmer organizations and their agro-businesses effectively use them, i.e. if some form of intermediation is available. Governments could also intermediate for small-scale farmers, as was exemplified in Mexico.
An UNCTAD paper extensively discusses models and case studies in which risk managements were arranged or intermediated by farmers’ associations. Intermediaries such as farmers’ associations are in a formidable position to reach out to their members. They can provide risk management functions and also facilitate access to risk management markets.

Farmers’ associations can play a key role in the area of risk management education towards facilitating risk management. At the very least they can make farmers understand the advantages of managing price risks through market-based instruments. Further, they could increase awareness of integral issues in participating on exchanges. The quality requirements of the exchanges, the consequences of defaulting on contractual obligations and available means to redress grievances are a few examples. They could also partner with other expert organizations to conduct comprehensive training and simulated workshops towards enhancing know-how on the subject. As a second step, they could build strategic partnerships that could potentially reduce the cost of using these instruments and open avenues for obtaining easier financing, among other things.

With the aim of providing risk management functions, they can provide small-scale farmers with the benefits of an assured price and hedge this risk by selling a future or buying a put on their own account. Alternatively, they can play the role of a broker, aggregating the requirements of small-scale farmers and transacting on their behalf. They could also intermediate by arranging forward contracts for the farmers.

Choosing a brokerage firm and broker: Since futures and options are traded only through registered brokerage firms, as a first step a brokerage firm would need to be selected. Although brokerage firms are closely regulated by the financial supervisory authorities, it is important to be careful in choosing a brokerage firm and an individual broker (Barrie, 2002). The following criteria serve as a mini-check list in choosing an appropriate broker.

Disciplinary record: The brokerage firm should be of the highest moral integrity. “Moral integrity” means that they should have a track record of transacting with their customers in a fair and equitable way. One can check this with a regulatory association that keeps records on the registered brokers and brokerage firms.

Length of time in business: Many brokerages go out of business in the first five years of operation. Attention should therefore be paid to their period of existence – five years is a comfortable benchmark. It should also be verified that the same firm has not been doing business in another name.

Services: The most important service to the customers is quality research and information. The research department should produce nightly reports, recapitulating the trading day’s events and news. There should be in-house expertise in fundamental research as well as technical analysis.

---

21 Farmers and farmers’ associations in developing countries and their use of modern financial instruments, (UNCTAD, 2002). This paper, with its many case studies, is dedicated to the issue of how farmers’ associations can facilitate price risk management in developing countries.
Broker: Having decided on a firm, a trader should then decide on an individual broker in the firm. The broker's job is to handle and execute his orders, keep him informed of potential news, and advise him on risk management. The trader should make sure that the broker has a thorough understanding of all commodities – or at least the ones he is specifically interested in.

B. Policy recommendations
Notwithstanding the effectiveness and advantages of derivatives for price risk management, farmers’ use of market-based instruments for hedging is limited in developing countries. It is estimated that less than two percent of the volume of futures and options instruments is attributed to developing countries. There are a number of reasons given to the low participation of agricultural producers:

- Domestic security nets through policies of price support and direct subsidy may provide insulate agricultural producers from market vagaries
- There is a lack of awareness and know-how of these instruments; further there may be barriers of technology or telecommunications that hinder further access.
- Costs of trading (margin deposits and option premium) may restrain access to small-scale producers.
- The minimum size of contracts traded on organized exchanges often far exceeds small- and medium-sized producers’ annual quantity of production.
- Regulatory policies may pose restrictions on the trading of such products.
- Sellers of such instruments, generally international banks and brokerage houses, are often unwilling to engage with a new and unfamiliar customer base of small-scale producers.

Governments can play a significant role in providing a conducive environment for the instrument providers and their customers (farmers, traders). Here are some specific policy recommendations to governments for encouraging the widespread use of price risk managements.

Training and capacity building
An important barrier to using these market instruments is a general lack of familiarity with their strategic uses. Further, there are misconceptions about hedging being the same as speculation, and policy-makers are often unaware of the costs of risk management in terms of foregone higher revenues. Therefore, stakeholders (including producers, traders and government agencies) must undertake sufficient training and capacity building to gain very thorough understanding of risk management procedures, including the operation of derivative markets and their use for hedging, before they become clients. Capacity-building initiatives

must not neglect the intermediary institutions – especially, cooperatives, banks and other financial institutions, and local traders – that are in a position to aggregate demand of individual farmers to enable risk management instruments of a minimum size to be traded on international markets (World Bank, 2004a).

**More flexibility in the provision of put options**

An objection expressed by farmers to forward pricing instruments is that while they are concerned about extremely low prices, they do not want to foreclose the prospect of above-average prices. This makes farmers a natural candidate for using put options where they have the flexibility of gaining from favourable price movements. However, farmers face many obstacles in using them:

- Grade specifications and quality parameters applicable in delivering contracts might not match that of the produce.
- At the very least there may be regulatory barriers that prevent the use of these instruments.
- Expiration dates and specifications tied to the contracts may not match their cropping cycles.
- Accessibility is a critical issue. Small-scale farmers might not have the scale to trade the minimum contractual lots of the exchange.
- Limited capital may pose a problem in paying premium costs.
- Technical issues such as pricing options and trading strategies involved in trading options are complex and may discourage many users.

To deal with these obstacles, some special considerations can be given by the instrument providers (financial supervisory authorities and exchanges). For example, the Commodity Futures Trading Commission (CFTC), assuming federal regulatory authority over all commodity futures markets in the United States, introduced a pilot programme in agricultural trade options, which permits any registered merchant to offer option contracts to farmers for delivery to that merchant, with any strike price, expiration date, delivery conditions, and up-front premium that the merchant and farmer find mutually acceptable.

For mitigating the farmer’s burden of premium, the largest US grain merchant, Cargill, Inc., demanded that the rules for trade options permit producers to write covered calls. An example is a min-max contract that guarantees producers that they will receive no less than a pre-negotiated floor price in exchange for agreeing to receive no more than an offsetting ceiling price. The min-max contract has the essential characteristics of a fence, consisting of a simultaneous purchase of a put and writing of a call.

---

23 These examples were cited from Gardner (2000).
24 See Fence strategies with options (p. 22).
Use of derivative markets for price or income support programmes

In addition to risk mitigation for farmers and agribusinesses, derivatives can be used by governments for addressing macro level price instability. Compared to government price stabilization programmes, the use of commodity derivative instruments by the government has the following advantages (Varangis and Larson, 1996):

- less expensive to manage and operate;
- consistent with the international trade agreements (the World Trade Organization, etc.);
- provides producers with benefits comparable to traditional programmes;
- market-neutral as premiums are established in open markets.

The US and Canadian Governments have implemented pilot projects that use commodity-derivative-based instruments to provide participating producers with an alternative to traditional farm income support programmes25 (for details, refer to Varangis and Larson, 1996).

The use of market-based risk management alternatives by governments should be a transitory step from which the private sector develops price hedging instruments with the government remaining involved only until such private sector alternatives develop. Thus, the sequence is from traditional government farm price support programmes to ones where the government uses market-based hedging tools, to the evolution of the private sector in directly hedging price risks (for details, refer to: Varangis and Larson, 1996).

Use of derivative markets for stable revenues

At the government level, revenues and/or expenses (through export taxation, or income and expenditure taxes) that are dependent on commodities (oil, metal or agricultural) can be better secured from using commodity derivative markets. If revenues unexpectedly decline due to a fall in commodity prices, the government needs to either cut expenditure or run a deficit and borrow in the international markets. Commodity price hedging in the derivative markets can minimize the unpredictability of their foreign exchange revenues.

25 Also see Santana-Boado and Gross (2006) for a very comprehensive overview of the status of commodity exchanges.

*The New York Cotton Exchange (NYCE), the oldest commodity exchange in New York, was founded in 1870 by a group of cotton brokers and merchants, and merged with the Coffee, Sugar, and Cocoa Exchange in 1998 to create the New York Board of Trade (NYBOT).

**Europe’s first cross-border grouping of stock exchanges and derivatives markets was formed in 2000 by the merger of the stock exchanges of Amsterdam, Brussels and Paris. In December 2001, Euronext acquired the shares of the London International Financial Futures and Options Exchange (LIFFE) and was renamed Euronext.liffe. In 2002, it merged with the Lisbon Stock Exchange.
The origin of modern exchanges (where futures and options are traded today) goes back to the 19th century in the United States when businessmen started to organize market forums to make the buying and selling of agricultural commodities easier. In 1849-1850, the CBOT started offering a *to arrive* forward contract, which permitted farmers to lock in the price and deliver the grain later for the future delivery (on arrival of the ship).

As trading of forward contracts increased, the Board decided that standardizing those contracts would streamline the trading and delivery processes. In the mid-19th century, futures markets developed as an effective means of managing price risk and overcoming counterparty risks. Trade in these “tradable” forward contracts became centralized in organized commodity futures exchanges, where contract performance was guaranteed by a clearinghouse collecting margins, rather than by individual traders or a trading house’s “good name”. Everyone could henceforth secure future prices without any real risk of counterparty default. Agricultural commodities (grains) futures started trading at the CBOT in 1865. Meat and livestock futures contracts were introduced at the Chicago Mercantile Exchange in 1957. Some developing countries have also a long history in commodities futures trading. During the late 1800s the Buenos Aires Grain Exchange traded futures in grains. In India, futures trading was first introduced on the Bombay Cotton Exchange and the Bombay Oilseeds & Oils Exchange as early as 1921 and 1926, respectively.

With increased government intervention and more interventionist policies in commodities markets, which had prevailed since the 1940s, a decline came in the use of commodity risk management instruments, especially in developing countries. It is ironic that the development of markets for price risk has often been hampered by policies designed to address shortcomings of markets for price risk or other development strategies. For example, buffer stock schemes designed to provide multi-period price smoothing sometimes led to larger-than-expected inventories and ultimately became unsustainable, although in some cases they were successful in reducing volatility – at least temporarily. In addition, domestic stabilization programmes decoupled domestic prices from international markets. Futures and other risk management markets shrank or sometimes disappeared as a result. In a similar way, brokerage houses and associated regulatory laws and institutions were not needed in countries where marketing boards mandated farm-gate prices country-wide.
Trading ceased on the once-thriving exchanges such as the grain exchange in Argentina, the cotton/oilseeds exchanges in India and the cotton exchange in Egypt. The disappearance of the Liverpool Cotton Exchange in the 1960s can be attributed to the commitment of the US Government to purchase cotton at a fixed price. It was not until the 1980s that the failure of price stabilization schemes and the adoption of market liberalization policies improved opportunities for the development of markets for commodity risk management products. Indeed, most of the current futures exchanges in developing countries started after 1980. Consequently, the rise in global markets for risk management instruments is in part due to a changing approach to commodity problems by developed and developing countries.

The origins of the principles of options can be traced to pre-biblical times. However, formal trading of commodity options on exchanges has been confined to the last 30 years, when the standardized, exchange-listed, and government-regulated options were introduced first on the CBOT in 1973.
