Of the pooled egg yolks TRR (0.078 mg/kg), 46.9% (0.037 mg/kg) were extracted and 53.5% (0.042 mg/kg) were un-extracted. The aqueous:methanol-soluble extract accounted for 34.5% (0.127 mg/kg) of the egg yolk residue. Component C-14 (10.5%, 0.008 mg/kg) was the most abundant metabolite in the egg yolk. Other metabolites found in this fraction were component C-10 (5.72%, 0.004 mg/kg) and C-11 (2.16%, 0.002 mg/kg). Following solvent partitioning of the chloroform-soluble residue (12.4%, 0.010 mg/kg), the hexane-soluble fraction accounted for 9.9% of the TRR (0.008 mg/kg) and the acetonitrile fraction accounted for 2.5% (0.002 mg/kg).

Of the TRR in skin with adhering fat (0.041 mg/kg), 75.6% (0.031 mg/kg) were extracted and 27.7% (0.011 mg/kg) were not extracted. The aqueous:methanol-soluble fraction accounted for 65.8% (0.027 mg/kg) and contained the highest percentage of component C-10 (36%, 0.015 mg/kg). Also detected was C-14 (3.51%, 0.001 mg/kg). Solvent partitioning of the chloroform-soluble fraction (9.8%, 0.004 mg/kg) resulted in hexane- and acetonitrile-soluble fractions, each containing 4.9% TRR (0.002 mg/kg).

Of the TRR in liver (0.186 mg/kg), 72.1% (0.134 mg/kg) were extracted and 24.7% (0.046 mg/kg) were un-extracted. The chloroform-soluble fraction accounted for 15.6% (0.029 mg/kg) and the aqueous:methanol-soluble fraction accounted for 56.5% (0.105 mg/kg). Following the acetonitrile/hexane partitioning of the initial chloroform-soluble residue, six components were detected in the acetonitrile fraction (8.6%, 0.016 mg/kg). C-5 amounted to 1.32% (0.002 mg/kg), C-3 accounted for 1.42% (0.003 mg/kg) and C-4 accounted for 0.62% (0.001 mg/kg). The concentrations of components C-1, C-6 and C-7 were < 0.5% (< 0.001 mg/kg). Three components were found in the liver aqueous:methanol fractions, C-10 (18.9%, 0.035 mg/kg), C-11 (1.13%, 0.002 mg/kg) and C-13 (1.59%, 0.003 mg/kg).

Of the TRR in kidney (0.378 mg/kg), 73.7% (0.279 mg/kg) were extracted and 33.3% (0.126 mg/kg) were un-extracted. The chloroform-soluble fraction accounted for 6.6% (0.025 mg/kg), and the aqueous:methanol fraction accounted for 67.1% (0.254 mg/kg). Following the acetonitrile/hexane partitioning of the initial chloroform-soluble residue, five minor components were detected in the acetonitrile fraction (3.3%, 0.012 mg/kg). Component C-4 accounted for 0.72% (0.003 mg/kg), C-3 for 0.52% (0.002 mg/kg), and C-5 for 0.66% (0.002 mg/kg). The concentrations of components C-1 and C-2 were less than 0.2%. Four components were found in the aqueous:methanol fraction: C-10 accounted for 11.1% (0.042 mg/kg), C-14 (7.26%, 0.027 mg/kg), C-12 (5.14%, 0.019 mg/kg) and C-11 (0.71%, 0.03 mg/kg).

Low levels of radioactive residues were found in muscle (0.022 mg/kg). Of the TRR, 68.3% (0.015 mg/kg) was extracted and 35% (0.008 mg/kg) was un-extracted. The nature of the extracted residue was not characterized.

Of the excreta TRR, 77.0% of the TRR were extracted of which 9% was recovered as chloroform-soluble and 68% were recovered as aqueous:methanol-soluble. Six compounds were found in the chloroform extract. One was identified as dithianon and accounted for 0.44% (0.087 mg/kg). The other components found in the chloroform-soluble fraction were: C-4 (1.65%, 0.332 mg/kg), C-3 (1.90%, 0.382 mg/kg), C-5 (0.641%, 0.129 mg/kg), and C-1 (0.183%, 0.037 mg/kg). Five components were found in the aqueous:methanol-soluble fraction. These were C-14 (8.52%, 1.71 mg/kg), C-10 (6.39%, 1.28 mg/kg), C-12 (5.64%, 1.13 mg/kg), C-13 (4.3%, 0.864 mg/kg), and C-11 (3.16%, 0.635 mg/kg).

Of the TRR in blood (0.275 mg/kg), 42.3% (0.116 mg/kg) were extracted and 58.8% (0.162 mg/kg) were not extracted. Two components were found in the chloroform extract (4.73%, 0.013 mg/kg), corresponding to C-4 (3.1%, 0.008 mg/mg), and C-5 (0.41%, 0.001 mg/kg). One component was found in the aqueous-methanol extract (37.6%, 0.103 mg/kg), corresponding to C-10 (28.2%, 0.002 mg/kg).

The metabolites were not identified.

Plant metabolism

The metabolism of dithianon has been studied in citrus, apples, spinach and wheat.

Oranges

The metabolism of dithianon in citrus was investigated by Hubert (1991, 1992), Mayo (1994), Schlueter and Memmesheimer (1994, including an amendment by Schlueter, 1996) and finally by Schlueter (1998).

Hubert, 1991, DT-640-015; Hubert, 1992, DT-640-016 (amendment to DT-640-015)

A single orange tree was treated with ¹⁴C-dithianon at a specific activity of 49.4 μ Ci/mg. The test plot consisted of an area of the test tree (ca. 1.2 m $\times$ 1.2 m) containing 50 fruits and the surrounding foliage. The test solution was applied three times as a foliar spray at the rate of 1.87 kg ai/ha. Applications were made when the oranges were approximately 2.5 cm in diameter and at

approximately 30-day intervals after that. Fruit and foliage were sampled at each spray application (pre- and post-application sampling) and at full commercial maturity.

The oranges sampled at full commercial maturity were rinsed with dichloromethane and the rinse was analysed. Orange (whole fruit, peel, pulp) and leave samples were homogenized frozen (liquid nitrogen) and analysed by means of oxidative combustion followed by a measurement using liquid scintillation counting. Extensive extraction and fractionation procedures (using chloroform, acidic acetone, dichloromethane and methanol as solvents) were applied in conjunction with two-dimensional thin-layer chromatography for characterization of ^{14}C -residues in peel, pulp and final harvest fruit rinse. The TRR in fruits and foliage are presented in Table 16. The reported LOD by LSC was 0.022 mg/kg (based on a calculation using 0.2 g as a representative sample weight and a specific activity of 7820). The highest concentration of radioactivity (3280 mg/kg) was found in foliage samples taken from the treated plants at the 31-day post application sampling point. The highest concentration in the whole oranges from treated plants was 92.8 mg/kg found in oranges harvested at day 60. The TRR in peel, pulp and rinse at final harvest was 17.6, 0.85 and 109 mg/kg, respectively, based on the individual matrix masses. The concentrations are 5.9, 0.92 and 64.4 mg/kg, respectively, when based on the mass of whole oranges. The results of the distribution of TRR of the acidic acetone fraction are provided in Table 17.

Table 16 TRR in fruit and foliage of oranges after application of ^{14}C -dithianon (DT-640-015)

Sample	Sampling point	Day	TRR (mg equivalents/kg)
Foliage	Pre application	0	< 0.022
	Post application		954
	Pre application	31	1010
	Post application		3280
	Pre application	60	2800
	Post application		782
	Final harvest	121	1430
Whole fruit	Pre application	0	< 0.022
	Post application		19.1
	Pre application	31	10.5
	Post application		68.8
	Pre application	60	35.6
	Post application		92.8
Peel	Final harvest	121	17.6
Pulp	Final harvest	121	0.85
Rinse	Final harvest	121	109

Mayo, 1994, DT-640-018; Schlueter and Memmesheimer, 1994, DT-640-020; Schlueter, 1996, DT-123-045 (amendment to DT-640-020), Schlueter, 1998, DT-123-066

Mature oranges were treated two times with $^{13}\text{C}/^{14}\text{C}$ -dithianon (treatment interval: 4 weeks) at a specific activity of 27.8 $\mu\text{Ci}/\text{mg}$. ^{13}C -labelling was used in order to facilitate mass-spectroscopic identification of unknown metabolites and fragments by their characteristic $^{12}\text{C}/^{13}\text{C}$ -mass doublets. An air brush sprayer was used to apply test material to the 30 fruit on the tree. Each fruit was sprayed to

almost run-off. During the application, the leaves adjacent to the fruit were also sprayed. The nominal application rate was 0.44 kg ai/ha (actual 0.39 kg ai/ha). Samples were taken 2 weeks and 4 weeks after the last application. Upon arrival in the lab, oranges were stored frozen until analysis. In the 1994 studies (DT-640-018, DT-640-020), two oranges from the first and five oranges from the second sampling occasion were randomly selected and analytically processed as follows:

The weight of the oranges was determined and residues were washed from the surface by submerging the samples two times in dichloromethane/acetic acid (1000:1) and one time in acetone/acetic acid (1000:1) at solvent temperatures of -20 °C.

Following surface extraction and after peeling the oranges, the peel and pulp samples were separately homogenized. The peel was extracted two times with dichloromethane/acetic acid (1000:1) followed by one extraction step using acetone/acetic acid (1000:1). The radioactivity in the extracts was determined by LSC, all peel extracts were combined according to sampling date and solvent and investigated further by TLC.

Equal amounts of the peel extracts and the third surface rinse (acetone/0.1% acetic acid) were combined, concentrated and diluted with acidified deionized water and the aqueous solution extracted 3 × with dichloromethane. The radioactivity in the organo-soluble (dichloromethane) and water-soluble fraction was determined by LSC.

Different metabolite fractions from the organo-soluble radioactivity were purified by TLC and HPLC and partly further investigated by TLC. The polar components of the water-soluble radioactivity were further subjected to a derivatization with pentafluorobenzyl bromide. An aliquot of the aqueous layer was evaporated nearly to dryness using a rotary evaporator. After the addition of tetrabutylammonium-fluoride in a Na₂HPO₄/KH₂PO₄-buffer (pH 8) and a mixture of pentafluorobenzyl bromide in dichloromethane solution, the reaction mixture was sonicated for 1 hour. Thereafter, the solution was subjected to partitioning with dichloromethane and analysed by TLC.

Following determination of the radioactivity by combustion analysis and liquid scintillation counting, aliquots of the non-extractable peel residues were subjected to enzyme cleavage using protease. The reaction mixtures were filtered, the undigested residue was washed with buffer solution and freeze dried. After the determination of radioactivity the buffer solution was subjected to a further partitioning with dichloromethane. Finally, the organic layer was investigated by TLC.

The pulp was analysed in the same way as described for the peel. For thin-layer chromatographic (TLC) purposes of metabolite identification, reference compounds were co-chromatographed with the surface rinse and extractable residues from peel and pulp.

In the 1998 study (DT-123-066), the samples out of the 1994 study (DT-640-020) were re-analysed to characterize and to identify metabolites occurring in and on the peel of mature oranges. After initial storage stability investigations using the same extraction procedures, the remaining oranges (28 DAT) were further investigated using the following techniques:

Thin layer chromatography using normal phase and reversed phase (RP-18) plates

Liquid/liquid partition experiments

Reversed phase HPLC of the organo soluble peel extracts

Purification of fractions, components by solid phase extraction (SPE, C 18), HPLC semi-and preparative TLC fractionation, gel chromatography (2 different gel systems)

HPLC-MS investigations

Hydrolytic cleavage reactions using hydrochloric acid.

The TRR in the surface, peel and pulp of oranges treated with ¹³C/¹⁴C-dithianon are shown in Table 18. After two applications of radio-labelled dithianon on mature oranges, most of the radioactivity was found in the surface wash. On oranges sampled 2 weeks after application the TRR accounted 94.2% and after 4 weeks 87.25% of the TRR. After peeling, the radioactivity accounted

between 5.44% (2 weeks after application) and 12% (4 weeks after application) in the peel as well as between 0.36% (2 weeks after application) and 0.75% (4 weeks after application) in the pulp. Generally, half of the radioactivity was detected in the extractable portion and the remaining radioactive material was bound to the PES fractions.

^a 1st and 2nd surface rinse

^b 3rd surface rinse, 1st and 2nd peel extraction

In 1998, the residues of ^{14}C -dithianon were re-analysed (oranges from 4 weeks post applications only). No significant differences between the first and the second determination of radioactive residues were found. The measured data sets of the second analysis in comparison to the previous results are summarized in Table 19. The results of distribution and characterization of radioactive residues compartments as surface wash, peel and pulp are summarized in Table 20.

Table 19 TRR, comparison of the results reported in 1994 (DT-640-020) and in 1998 (DT-123-066)

Matrix	TRR, % (analysed 1994)	TRR, % (re-analysed 1998)
1 st surface rinse	85.6	82.2

^{e)} Water-soluble fraction from solvent partitioning

^{f)} The fraction was derivatized with pentafluorobenzyl bromide, then solvent partitioned

Thin-layer chromatography of surface washes showed that the major radioactive component (approximately 92%) was the parent dithianon. This corresponds to approximately 80% of the TRR. The surface washes of the radioactive residues obtained from the five treated oranges collected 28 days after treatment contained 87% of the total terminal residue. TLC and HPLC analysis showed that 92% of the radioactivity recovered in the dichloromethane/0.1% acetic acid rinses (or 80% TRR, 4.22 mg/kg) was unchanged dithianon. The identification was confirmed by mass spectrometry.

Initial TLC investigations of the peel extracts showed the presence of mainly polar compounds and a proportion of radioactivity migrating with reference compound dithianon. In order to separate the polar and the less polar fractions, equal amounts of the peel extracts and the third surface acetone/acetic acid extract were combined and subjected to a partitioning with dichloromethane and water. Approximately 60% of the radioactivity contained in the combined peel extracts proved to be organosoluble. The TLC of the organic layer revealed three prominent metabolite fractions (Pe01, Pe03 and Pe05, corresponding to 0.055 mg/kg, 0.051 mg/kg and 0.034 mg/kg, respectively), which were isolated from the TLC-plates and further investigated. One- and two-dimensional thin-layer chromatography revealed that the radioactivity contained in fractions Pe01 and Pe03 did not represent single metabolites but a number of more or less polar degradation products: TLC investigations of fraction Pe01 indicated the presence of at least 4 different compound fractions none of which exceeded 0.018 mg/kg (0.34% TRR). Furthermore, the TLC-chromatogram of fraction Pe03 showed at least two metabolite fractions representing only 0.17% and 0.75% of the TRR (0.009 mg/kg and 0.040 mg/kg). In the case of Pe05 a small amount of unchanged dithianon was identified (0.014 mg/kg) by LC/MS investigations following purification by HPLC.

The radioactive residues remaining in the aqueous solution after the above mentioned partitioning were further subjected to derivatization with pentafluorobenzyl bromide. As a result, approximately 56% of the originally water-soluble residue could additionally partitioned into dichloromethane. TLC investigations of the organic layer revealed the presence of several product fractions, which did not exceeded 0.045 mg/kg or 0.86% of the TRR.

The non-extracted peel residues, which amounted approximately 5.12% of the TRR (0.27 mg/kg) were subjected to enzyme cleavage reaction. After incubating aliquots of the non-

extracted peel residues with pronase E, about 62% of the original non-extracted radioactivity was found in the buffer solution. Further partitioning of the aqueous solution with dichloromethane proved 0.01 mg/kg of the radioactivity to be organosoluble whereas 0.157 mg/kg remained in the aqueous solution. TLC investigations of the organosoluble compounds again revealed the presence of several products. Also in this case, all metabolite fractions represented only traces of the radioactivity found on or in whole oranges (0.001–0.005 mg/kg).

Radioactive residues found in pulp at 28 days after application accounted for 0.75% of the TRR (0.039 mg/kg). After homogenization and extraction of the pulp samples, only 0.30% of the TRR (0.015 mg/kg) proved to be extracted and 0.45% (0.024 mg/kg) as non-extracted. Also in this case, the combined pulp extracts were subjected to a partitioning with dichloromethane and water in order to separate the polar and the less polar metabolite fractions. A portion of 34% of the radioactivity, originally in the pulp extracts, was transferred into the organic layer, whereas 66% remained in the aqueous solution. The TLC investigations of the organosoluble compounds revealed the presence of different metabolite fractions, each representing only traces of the terminal radioactive residue (< 0.002 mg/kg).

From all results obtained in the course of the DT-123-066 (1998) and the previous study DT-640-020 (1994), it can be stated that the main portion of the TRR found on or in whole oranges treated with $^{13,14}\text{C}$ -dithianon, remained on the surface of the fruits (87%). Furthermore, the majority of this surface residue (approximately 80% of the TRR) was still the unchanged parent compound. The remaining radioactive residues, ca. 12% (6.9 ERR + 5.12 PES) of TRR in the peel and ca. 0.8% (0.3% ERR + 0.45% PES) of TRR in the pulp, was composed of a large number of mostly polar compounds none of which can be considered major.

Apple

The fate of dithianon was characterized in apples by Hawkins (*et al.* 1991) and Mayo (1993). Apple trees grown outdoor were treated with 100 μL droplets of a formulation that contained ^{14}C -labelled dithianon at a concentration between 0.07% and 0.1%. The number of applications ranged from 1 to 4 and 5 treatments. Apples and leaves were harvested directly after the application as well as 21 days after successive 2-weekly ^{14}C -dithianon applications or 15 days after 5 successive 2-weekly ^{14}C -dithianon applications.

The samples (apples and leaves) were surface washed (within 1 hour after harvesting) by soaking in dichloromethane with 0.1% acetic acid. Surface wash was repeated three times and combined for measurement of radioactivity. A fourth surface wash was carried out with acetone with 0.1% acetic acid. Apples were subsequently peeled and the peel and flesh extracted separately by homogenizing with acetone, centrifugation, and separation of the extract from the residue. Washes, extracts and post-extracted residues were analysed for total radioactive residues (TRR) by liquid scintillation counting (LSC) and combustion. The TRR was determined as the sum of the total radioactivity in the surface rinse, the extracts and the post-extracted residues of the remaining plant parts after combustion. Thin layer chromatography (TLC) on normal phase and reverse phase TLC plates was used for the characterization and identification of the ^{14}C -dithianon-derived residues in the washes and extracts the apples and leaves. For measurement of proportions of radioactive components, radio-chromatograms of TLC plates were obtained. To aid in the identification, the radioactive samples were co-chromatographed with appropriate reference compounds and these were located by quenching of a fluorescent indicator under UV light at 254 nm.

The radioactive residues in treated apples and leaves, expressed in mg/kg dithianon equivalents and as portion of the applied dose of ^{14}C -dithianon are summarized in Table 21. TRR after 4 to 5 application of dithianon onto apple fruits and leaves were determined to be between 2.6 and 5.4 mg/kg in apple fruits and in leaves between 217 to 485 mg/kg.

Table 21. Radioactive residues in apples and leaves after treatment with ^{14}C -dithianon, mean values $\pm$ SD (DT-640-013).

Sampling interval	Fruits		Leaves	
	TRR, mg/kg	TAR, %	TRR, mg/kg	TAR, %

1 hour after 1 st application	Not reported	91.9	Not reported	92.7
21 days after 4 th application	5.4 ± 2.5	69.6 ± 8.4	217 ± 72	49.3 ± 9.6
15 days after 5 th application	2.6 ± 0.7	61.3 ± 1.6	485 ± 118	41.2 ± 6.6

Most of the recovered radioactivity was found in washed surface fraction of both apple fruit (81.4% to 89.7% of TRR) and leaves (90.3% to 94.0% of TRR) (see Table 22).

Table 22 Distribution of radioactivity in apple matrices after application of ¹⁴C-dithianon (DT-640-013)

Sample	TRR, %

PES	5.1	0.6

The nature of ¹⁴C-dithianon residues in various apple matrices was characterized by TLC. TLC of surface washes showed that the major radioactive component was co-chromatographed with the parent dithianon. The parent accounted for means of 72.7% to 82.0% (apples) and 69.7% to 85.7% (leaves) of the TRR corresponding to 2 to 4 mg/kg (apples) and 151 to 415 mg/kg (leaves), respectively (see Table 23). Only dithianon could be identified in the extracted residues.

Spinach

A greenhouse study was conducted in 1999 by van Dijk (2000, DT-640-023) to elucidate the metabolic fate of dithianon in spinach.

For the study, three plastic containers (70 cm $\times$ 50 cm; soil depth: 40 cm), each providing an application area of 0.35 m², were filled with silt loam soil and were sown within a depth of 2-3 cm with 43 g of spinach seeds per m² or 15 g/container. Two containers were established for treatment with a WP formulation of ¹⁴C-dithianon (plot A) and one container (plot B) for treatment with the blank formulation to provide control samples.

¹⁴C-labelled dithianon at the 5, 6, 9 and 10 positions of the naphthoquinone ring (specific activity 1.569 MBq/mg, radiochemical purity 98.1%) was mixed with ¹³C-labelled dithianon (purity 98.1%), also labelled at the 5, 6, 9 and 10 positions, and non-labelled ¹²C-dithianon (purity 99.9%) to yield material with a specific activity of 0.092 MBq/mg (5526 dpm/ μ g; or 2.49 μ Ci/mg).

The ¹³C-dithianon was added as a mass marker to aid in mass spectrometric analysis and identification of the radioactive residues derived from dithianon in the spinach samples. The labelled material, hereafter is referred to as ¹⁴C-dithianon.

Three applications of test substance, formulated as a WP with blank formulation were made over plot A at 38 days (early 6-leaf stage), 51 days (6–8-leaf stage) and 61 days (8-leaf stage) after sowing at nominal dose rates of 1 kg ai/ha/application. Spinach samples (above-ground parts) were collected on the day of the first, second, and third application, and 20 days after the third application. The spinach plants in Plot B (control) were treated with the blank formulation.

All plant samples were analysed for TRR by combustion and LSC. The TRR values for the whole plant samples were determined by summing the radioactive residue in the surface rinses with the radioactive residue in the rinsed plant samples. The radioactive residue in the rinsed plant is referred to as the post rinse residue (PRR). ¹⁴C-dithianon-derived residues in the spinach samples in the surface rinse and extracts of the PRR were taken for characterization and identification by TLC (normal and reversed phase) and reversed phase HPLC by co-chromatography with reference compounds and, where possible, by mass spectrometry. The limit of quantitation of the radioassay for the determination of the TRR was validated at 0.01 mg/kg by combustion of control spinach (0.5 g) fortified with 25 dpm of ¹⁴C-dithianon. The TRR in spinach leaf, expressed as mg/kg equivalents of ¹⁴C-dithianon, are summarized in Table 24.

Table 24 TRR in spinach samples following three applications of ¹⁴C-dithianon (DT-640-023).

Sampling Interval		TRR in mg/kg and (%)		
Days After Sowing (Growth Stage)	DAT ^a	Total (unwashed spinach)	Rinse	Rinsed Spinach (PRR) ^b
38 (early 6-leaf stage)	0DAT1	91.4 (100)	86.4 (94.6)	4.93 (5.4)
51 (6-8 leaf stage)	0DAT2	112.7 (100)	103.1 (91.5)	9.58 (8.5)
61 (8 leaf stage)	0DAT3	305.8 (100)	292.9 (95.8)	12.9 (4.2)
81 (final harvest)	20DAT3	149.5 (100)	143.9 (96.2)	5.67 (3.8)

^a DAT denotes days after treatment; for example, 20DAT3 denotes 20 days after treatment three

^b PRR: post rinse residues (TRR in the rinsed spinach)

The results showed that the surface rinse accounted for $> 90\%$ of the TRR and the post rinse residue (PRR) accounted for $< 9\%$ TRR at each sampling interval. During the three treatments, the PRR concentrations increased from 4.93 mg/kg after the first treatment to 12.89 mg/kg after the third

treatment. Because of the growth that increased plant mass, the PRR decreased from 12.89 mg/kg on the day of third treatment to 5.67 mg/kg 20 days later.

The post rinse residues (PRR) in spinach from all sampling intervals accounted for 3.8–8.5% of the TRR, with the majority of the radioactivity released by exhaustive extractions (3.4–7.5% TRR released by extractions). The extraction steps included aqueous acetonitrile, enzymatic treatment (pronase and cellulase), and reflux with methanol/ammonia (8 : 2) all in the presence of 0.1% acetic acid. The non-extracted PRR residue was very low, accounting for $\leq 1\%$ TRR at all sampling intervals. Extraction results of the incurred radioactivity in the spinach forage derived from ^{14}C -dithianon are summarized in Table 25. At harvest, 20 days after the third application, radioactivity in the three extracts ranged from 0.9–1.5% TRR (1.36–2.18 mg/kg).

^c Sequential extraction and washes of post-rinse residue (PRR) followed by enzyme treatment and base/acid hydrolysis.

NP: Not performed

The surface rinses and selected extracts were analysed by TLC, reversed phase HPLC, and mass spectrometry, where appropriate. The radioactivity recovered in the surface rinse was due exclusively to parent compound for all sampling intervals. The identification of parent was confirmed by HPLC, TLC, GC-MS and EI-MS (electron impact/mass spectrometry). The radioactivity profiles of the residues extracted from the surface rinsed spinach at the different growth stages and treatment timings were qualitatively similar.

For all sampling intervals, dithianon accounted for 92–96% of the TRR and was identified in the surface rinse. The extractable residues contained at least 14 ‘Regions Of Interest’ (ROIs), five of them being very polar, occurring in amounts of 0.1–0.5% of TRR at harvest. No dithianon was detected in the extracted residues at any of the growth stages and treatment timings. By HPLC and TLC analysis of the spinach extracts with the reference compounds, ROI 6 was identical to reference compound 2-hydroxy-naphthoquinone (R1, CL 231509). ROI 7 was identical to reference compound 5,10-dioxo-5,10-dihydro-naphtho[2,3-b]-1,4-dithiin-2,3-dicarboxylic acid diamide (D15, CL 902200). ROI 14 was contained a minor sub-fraction identical to reference compound phthalic acid (R2). A summary of the quantified and identified radioactive residues in spinach samples collected at harvest (20 days after the third application, 20DAT3) is provided in Table 26.

^a Residue from rinse

^b Residue from extracts/washes, enzyme and base treatment

The main residue component in spinach, accounting for more than 90% of the TRR, was unchanged parent compound. In the post rinse spinach residues, no parent was detected. Besides multiple polar minor unknown components, metabolites identified by co-chromatography with the authentic reference compounds were 2,3-dicarboxylic acid diamide derivative (D15; CL 902200), 2-hydroxy-naphthoquinone (R1; CL 231509) and phthalic acid [benzyl 1, 2-dicarboxylic acid, (R2)]. This indicated that absorbed dithianon, which accounted for 3.8–8.5% of the TRR, was completely metabolized by the spinach plants.

In summary, besides the multiple unidentified polar minor components, based on the metabolites that were identified and characterized in spinach plants, the metabolism of dithianon in spinach first undergoes hydrolysis of the cyano groups to yield the diacid diamide (CL 902200). Further aromatic oxidation of the sulfur atoms and cleavage of the dithiine ring followed by hydroxylation of the naphthoquinone ring to yield metabolite CL 231509. The naphthoquinone undergoes further aromatic oxidation and cleavage to yield phthalic acid. The proposed metabolic pathway in spinach is shown in Figure 1.

Figure 1 Proposed metabolic pathway of ¹⁴C-dithianon (BAS 216 F) in spinach (DT-640-023).

Wheat

The metabolism of dithianon in wheat was investigated by Mayo (1994, DT-640-019), Schlueter and Grahl, 1994 (1994/7001689), Schlueter, 1996 (DT-640-021, amendment to report 1994/7001689), Schlueter, 1998 (DT-640-017) and Hawkins, 1991 (DT-640-014).

Mayo, 1994, DT-640-019

A field study was conducted in 1992 to characterize the nature of dithianon and its metabolites in spring wheat. For the preparation of the test substance, the materials were mixed to provide ¹²C- and ¹³C-dithianon in a 1:1 ratio and ¹⁴C-dithianon at a nominal specific activity of 30 μ Ci/mg. The plants had been treated at two growth stages, "Zadoks 59" and "Zadoks 61" (equivalent to BBCH 59 and 61). The application rate was at both sprayings equivalent to 1.5 kg ai/ha. Samples of wheat were taken at 2 hours after the second application (0 days), at 20 days after and finally at 35 days after the second application. At 0 and 21 days, the plants were separated into stems and ears and at 35 days into grain, husk and straw.

Schlueter and Grahl, 1994, 1994/7001689; Schlüter, 1996, DT-640-021 (amendment to 1994/7001689)

The wheat samples generated in report DT-640-019 were further investigated. The samples were washed with acetonitrile/hydrochloric acid and the washings were removed by centrifugation. The plant material was homogenized and extracted with acetonitrile/hydrochloric acid and the extracts were removed. The surface rinse and extracts were analysed for TRR by LSC, the non-extracted residues were analysed by combustion followed by LSC. The surface rinse and extracts were partitioned with hexane/ethyl acetate, dichloromethane and dichloromethane/diethyl ether. The radioactive dithianon-derived residues in the wheat extracts were analysed by TLC and reversed phase HPLC. The TRR in all plant parts were determined as the sum of the TRR of the extracts and the non-extracted residues. The non-extracted residues were subjected to a variety of hydrolysis and extraction procedures to release additional radioactivity. The extracted plant material was further treated with acidic, basic and enzymatic cleavage and with selective extraction of main wheat cell wall components. The TRR in wheat samples, expressed as mg/kg equivalents of ^{14}C -dithianon, are summarized in Table 27.

Table 27 TRR in wheat samples following 2 applications of ^{14}C -dithianon at 1.5 kg ai/ha per application (1994/7001689; DT-640-021)

Sampling time (DAT) ^a	Sample type	TRR in mg/kg
0DAT2	Immature stems	61.0
	Immature ears	51.9
20DAT2	Immature stems	74.9
	Immature ears	67.6
35DAT2	Mature straw	68.1
	Mature grain	1.9
	Husks	60.6

^a DAT: days after treatment; for example, 20DAT2 denotes twenty days after treatment two.

The distribution of radioactivity in the extracts of immature and mature wheat commodities is provided in Table 28. For all samples, the surface rinsed residues were partitioned using hexane followed by dichloromethane/ethyl acetate, resulting in 21–48% TRR recovered in the hexane fraction, 27–44% TRR recovered in the dichloromethane/ethyl acetate fraction, and 0.2–2% TRR remaining in the water-soluble fraction. The extracted residues of all samples were also sequentially partitioned using hexane followed by dichloromethane/ethyl acetate. Following partitioning of the surface rinse and the extracts of the wheat samples, the major portion of the extractable residues was partitioned into organic layers.

^a DAT: Days After Treatment; for example, 20DAT2 denotes twenty days after second treatment

^b Surface rinse with acetonitrile/concentrated hydrochloric acid (99:1, v/v) at -20 °C; residues in surface rinse were

solvent partitioned as indicated

^c Extract 2 × with acetonitrile/concentrated hydrochloric acid (99:1, v/v); residues in extract were solvent partitioned as indicated

^d ERR: Extracted Radioactive Residue (sum of surface rinse and fractions)

^e PES: Post Extraction Solids

^f For 0DAT2 wheat, 18% of RRR in stems and 21% of RRR in ear was released by acid hydrolysis

^g For 20DAT2 wheat, 41% of RRR in stems and 27% of RRR in ears was released by acid hydrolysis

^h For 35DAT2 wheat, 17% of the RRR in straw, 24% of the RRR in husk and 57% of the RRR in grain was released by acid hydrolysis

ⁱ For 35DAT2 straw, 32-39% of the RRR was released by base hydrolysis, versus 20% RRR released by pronase E, 13% RRR released by cellulase, and 10% RRR released by pectinase

The non-extracted residues amounted to 30, 33, and 36% of the TRR in the straw, husk and grain, respectively. Radioactivity remaining in the non-extracted plant material of all samples was subjected to acid hydrolysis, which released approximately 20–60% of the radioactivity.

The PES-fractions of samples taken 35 days after the second application (35 DAT2) were further analysed. Non-extracted residues in wheat straw were subjected to alkaline hydrolysis, which released approximately 30–40% of the radioactivity. Furthermore, the PES-fractions of straw and grain were additionally subjected to sequential enzymatic treatments (pronase E, cellulase and pectinase). For the PES of wheat straw, 3% of the TRR was associated with the pectin, 11% TRR was associated with the lignin, 5% TRR was associated with the non-cellulosic polysaccharides, and 3% TRR was associated with cellulose. The corresponding results for the PES of wheat grain were 15, 16, 2, and 3% TRR, respectively. Results from the further treatments of the non-extracted residues in wheat straw and grain are presented in Table 29.

Schlueter and Varga, 1998, DT-640-017

The wheat samples generated in 1992 by Mayo (1994, DT-640-019) were further investigated in order to quantify, characterize and identify metabolites occurring in and on wheat. Focus of the additional study was on further investigations of the extractable radioactivity.

In order to prove the storage stability, the TRR, the extraction behaviour and the distribution of the radioactivity in the extracts were investigated and compared with the previous study. When the additional investigations started, the samples had been stored for a period of 32 months. Samples of plant material were washed with acetonitrile/hydrochloric acid and the washings were removed by centrifugation. The plant material was homogenized and extracted with acetonitrile/hydrochloric and

the extracts were removed. The surface rinse and extracts were analysed for TRR by LSC, the non-extracted residues were analysed by combustion followed by LSC. The surface rinse and extracts were sequentially partitioned with hexane, dichloromethane/ethyl acetate and ethyl acetate. The extracts have been further and extensively characterized using as techniques:

TLC using normal phase and reversed phase (RP-18) plates

Reversed phase HPLC

Liquid/liquid partition experiments

Purification of fractions by HPLC fractionation

Derivatization with pentafluorobenzyl bromide

HPLC-MS

In order to prove the storage stability of the samples under investigation, the samples were first subjected to the same work-up procedures. The results of the investigations are summarized in Table 30. The data indicate that the samples had been stable over the period of storage. In deviation to the study of 1994 (1994/7001689; DT-640-021), no further characterization work of the non-extracted radioactivity has been carried out.

During the conduct of the plant metabolism studies, more experience was gained with regard to the instability of dithianon in plant extracts (especially under alkaline conditions). Dithianon was found to be unstable during concentration using a rotary evaporator, but also during TLC analyses under normal phase conditions. In deviation to the studies performed before specific consideration was given to the sensitive and careful work-up of the sample material. Reducing purification and concentration procedures to the minimum extent minimized any artificial degradation of dithianon. Due to this fact, higher amounts of the parent were found in the 1998 study. The TRR partitioned into the organic layers were further subjected to TLC and HPLC investigations. The results of these investigations are shown in Table 31.

Table 31 Quantification of dithianon and unknown extracted residues recovered in wheat matrices (DT-640-017)

Sample		Dithianon		Remaining radioactivity	
DAT ^{a)}	Matrix	mg/kg	% of TRR	mg/kg	% TRR
0	stem	40.46	79.8	5.74	11.2
	ears	48.21	83.5	5.06	8.7
20	stem	52.46	65.7	5.11	6.5
	ears	60.75	76.5	7.52	9.4
35	straw	29.67	61.6	3.05	6.3
	grain	1.13	50.9	0.46	21.2
	husk	61.12	66.1	10.59	11.4

^{a)} DAT: Days After last Treatment

Besides the parent compound fraction, considerable amounts of radioactivity (up to approximately 10% TRR) proved to be spread over the total length of run (in the case of TLC analysis) or elute constantly from the column (in the case of HPLC) without any single major substance peak. Due to this fact, the extracts obtained after sample homogenization were chosen for further characterization or identification of the fractions (metabolites) M1 to M4. The quantitation of the metabolites M1 to M4 in the extracts is shown in Table 32.

Table 32 Quantification of fractions M1 - M4 contained in the 2nd extracts of wheat commodities (DT-640-017)

Days		Residues mg/kg (% TRR)						
		0		20		35		
Matrix		Stems	Ears	Stems	Ears	Straw	Grain	Husk
Fraction M1		NQ	0.2 (0.4)	0.38 (0.5)	0.66 (0.8)	0.21 (0.4)	0.02 (0.8)	0.61 (0.7)
Fraction M2		NQ	NQ	NQ	NQ	NQ	0.01 (0.6)	NQ
Fraction M3		0.5 (1.0)	0.79 (1.4)	0.42 (0.5)	1.08 (1.4)	0.27 (0.6)	0.07 (3.3)	1.02 (1.1)
Fraction M4		NQ	NQ	NQ	0.38 (0.5)	NQ	0.01 (0.6)	NQ

NQ: not quantified

In the extracts obtained after sample homogenization, four fractions (M1 - M4) were found which amounted to $\geq 3.3\%$ TRR. HPLC isolation and purification of these metabolites was attempted. In the course of these attempts, the main fractions (M1 and M3) proved to be of considerable instability again. Therefore, the four fractions were directly subjected to HPLC/MS without any further purification but no interpretable results were obtained. Since M3 is the most abundant peak, it was additionally subjected to derivatization with pentafluorobenzyl bromide. Following this procedure, about 92% of the residue could be partitioned into dichloromethane. HPLC investigations of the organic layer revealed the presence of at least four product fractions which either indicates artificial degradation of the metabolite occurring during the isolation and/or the derivatization procedure itself. The occurrence of more than one derivative could also result that peak M3 consists of more than one component. No further investigation of the products formed was carried out.

Hawkins et al., 1991, DT-640-014

Winter wheat has grown in an outdoor environment. A plot of 1 m² was sprayed with ¹⁴C-diathinon formulated as SC when the wheat was at approximately growth stage Zadoks 39. The second treatment was carried out 19 days after the first spray (Zadoks 59). The application rate at both sprayings was 150 mg/m², equivalent to 1.5 kg ai/ha. Samples were taken 2 hours after the second spray (0 days) and then at 14 and 39 days post treatment and finally the whole crop at 31 days after the second spray. At 0 and 14 days, the wheat was separated into stems and ears and at 39 and 51 days into grain, husk and straw.

At 0 days, TRR in ears and stems were 29.76 mg/kg and 18.46 mg/kg respectively and at 14 days 12.27 mg/kg and 7.92 mg/kg respectively. TRR in grain, husk and straw were 0.303 mg/kg,

21.72 mg/kg and 16.2 mg/kg respectively at harvest (51 days). The TRR in grain analysed after 2 months storage at -15 °C was 0.431 mg/kg. The samples were washed with acetonitrile/hydrochloric acid cooled to -20 °C to remove surface residues. After the washes, the samples were macerated with acetonitrile/hydrochloric acid at -20 °C. The results are summarized in Table 33.

Table 33 TRR in washes and extracts of wheat matrices after the last 2 applications of ¹⁴C-dithianon (DT-640-014)

Sample		Wash		Extract		Residues remaining	
Day	Type	mg/kg	%	mg/kg	%	mg/kg	%
0	Ears	24.98	83.9	3.79	12.7	0.99	3.3
	Stems	15.54	84.2	1.77	9.6	1.14	6.2
14	Ears	9.41	76.7	2.10	17.1	0.76	6.2
	Stems	6.10	77.0	1.06	13.4	0.76	9.6
39	Grain	0.146	48.2	0.066	21.8	0.091	30.0
	Straw	10.36	64.0	3.04	18.8	2.81	17.3
	Husk	14.20	65.4	4.91	22.6	2.61	12.0
51	Grain (A)	0.248	49.8	0.069	13.9	0.181	36.3
	Straw	19.44	34.5	14.91	26.5	22.0	39.0
	Husk	18.25	46.2	9.66	24.4	11.63	29.4
51	Grain (B)	0.211	49.0	0.058	13.5	0.162	37.6

Grain (A): sample A was analysed at harvest time

Grain (B): sample B was analysed 2 months after harvest

Residues remaining (PES): TRR in the wheat matrices remaining after washing and extracting with acetonitrile/hydrochloric acid at -20 °C.

The harvest samples of grain, straw and husk were extracted further with acetonitrile/hydrochloric acid, 2 × methanol and methanol/hydrochloric acid at room temperature. These further extracts accounted for 18.4%, 17.8% and 18.0% of TRR in grain, straw and husk, respectively. The residues remaining in the samples after these further extractions accounted for 16.5% (0.083 mg/kg), 16.7% (9.42 mg/kg) and 13.7% (5.42 mg/kg) of the TRR for grain, straw and husk respectively.

The characterization of the radioactivity in the washes and extracts of wheat matrices have been examined by TLC. At all times the major component was unchanged dithianon. At harvest dithianon represented 53.5% of TRR in grain after extraction and ca. 65% of the TRR in the extract. For husk and straw, dithianon represented 55.6% and 45.9% of the TRR in the sample after extraction and 63% each of TRR in the extract.

Environmental fate in soil and water-sediment systems

The FAO Manual (FAO, 2009) explained the data requirements for studies of environmental fate. The focus should be on those aspects that are most relevant to MRL setting. For dithianon, supervised residue trials data were received for foliar spray on permanent crops such as citrus fruits, tree nuts, pome fruits, stone fruits, grapes and hops. Therefore, according to the FAO manual, neither environmental fate nor rotational crops studies are required. For information on hydrolysis and photolysis see chapter “Physical and chemical properties”, Table 1.

RESIDUE ANALYSIS

Analytical methods

The Meeting received descriptions and validation data for analytical methods for residues of dithianon in plant and animal commodities. Residue analytical methods for dithianon rely on HPLC with UV-detection or LC/MS-MS for plants and HPLC with electrochemical detection or LC-MS/MS for animal matrices. Typical LOQs achieved for plant and animal commodities fall in the range of 0.01–0.05 mg/kg. Methods have been subjected to independent laboratory validation.

Plant commodities

Dithianon is used since more than 30 years as fungicide in fruit, vegetables and cereals crops. In this time period, many residue analytical methods have been developed. The HPLC methods described in this section were performed over the past 20 years; they have been used for the analysis of the samples generated during the supervised field trials, processing fraction studies and storage stability tests (see Table 34). New methods have been developed from 2006 to 2011 and are based on LC-MS/MS and also include a second transition as confirmatory technique (see Tables 35 – 37). The analysis of the most recent supervised field trials and studies on residues in processed commodities occurred with method No. L0152/01, which is, with the exception of minor modifications, identical to method SOP-PA.0281. The further developments of SOP-PA.0281 have been performed to include the degradation product CL 1017911, known from the hydrolysis study at exaggerated temperatures in buffer solutions, in the analytical method. With this elaborated method further information can be obtained on the presence/absence of CL 1017911 on RAC and processed products (see Table 38).

The analytical methods are described briefly as follows:

Grapes, juice, wine, beer, method no. RLA 12616V (Smalley 2001, DT-244-065 including amendments 1 and 2)

Analyte: Dithianon Method: HPLC-UV D LOQ: 0.01 mg/kg
 Description: Dithianon is extracted from the grape and processed commodities with concentrated hydrochloric acid/acetonitrile 1:2 (v/v). After further washing with acetonitrile, the extract is subjected to liquid-liquid partitioning with dichloromethane. The dried residue is reconstituted in acidic methanol (1% acetic acid) and a portion cleaned up using gel permeation chromatography (GPC) with acidic methanol (0.06% acetic acid) as the eluant. The collected solution is evaporated to approximately 0.5 ml and re-dissolved in acetonitrile/water/acetic acid (60:38:2). Quantitative determination is carried out by HPLC (column: Luna Phenyl Hexyl) with UV detection, using acetonitrile/water/acetic acid (60:38:2) as mobile phase. Specificity of the method may be confirmed using a diode array detector.

Apples and processed commodities, method no. RLA 12616.03V (Smalley 2001, DT-244-068 including amendments 1 and 2)

Analyte: Dithianon Method: HPLC-UV D LOQ: 0.01 mg/kg
 Description: Dithianon is extracted from the apple with concentrated hydrochloric acid/acetonitrile 1:2 (v/v) as described above for grapes (DT-244-065)

Grapes, must, wine, method no. FAMS 028-02 (Weitzel, 1996, DT-244-054)

Analyte: Dithianon Method: HPLC-UV D LOQ: 0.01 mg/kg must, wine; 0.02 mg/kg grapes
 Description: Dithianon is extracted from the grapes, must and wine with concentrated hydrochloric acid/acetonitrile 1:2 (v/v). After further washing with acetonitrile the extract is subjected to liquid-liquid partitioning with dichloromethane. After evaporation of the organic phase, the residue is reconstituted in acidic methanol (1% acetic acid) and a portion cleaned up using gel permeation chromatography (GPC) with acidic methanol (0.01 M of acetic acid in methanol) as the eluant. The collected solution is evaporated to 0.5 ml and redissolved in methanol/acetic acid (99:1, v/v). Quantitative determination is carried out by HPLC (column: Nucleosil100-phenyl) with UV detection, using acetonitrile/ water/acetic acid (575:423:2, v/v) as mobile phase.

Apple, method number FAMS 028-02 (Weitzel, 1996, DT-244-055)

Analyte: Dithianon Method: HPLC-UV D LOQ: 0.02 mg/kg
 Description: Dithianon is extracted from the apple with concentrated hydrochloric acid/acetonitrile 1:2 (v/v) as described above for grapes (DT-244-054).

Grapes, method number HUK 460/38 (Todd, 1992, DT-244-045)

Analyte: Dithianon Method: HPLC-UV D LOQ: 0.05 mg/kg grapes
 Description: Dithianon is extracted from grapes with concentrated acetic acid/acetonitrile 1:15 (v/v). After further washing with acetonitrile, a second extraction was conducted with concentrated acetic acid/acetonitrile

1:15 (v/v). Aliquot of the extract is subjected to two times liquid-liquid partitioning using n-hexane, hydrochloric acid, water and sodium chloride. The n-hexane solution is concentrated to approximately 0.5 mL on a rotary evaporator and the residue is reconstituted in acidic dichloromethane (1%) and subjected to column chromatography using activated silica gel and acidic dichloromethane as the eluant. The collected solution is evaporated to 0.5 mL and re-dissolved in methanol/acetic acid (99:1, v/v). Quantitative determination is carried out by high pressure liquid chromatography (HPLC) with UV detection, using acetonitrile/methanol/water/acetic acid (55:10:35:1, v/v) as mobile phase.

Apple and pear, method number HUK 460/38 (Jones, 1989, DT-244-037)

Analyte: Dithianon Method: HPLC-UV D LOQ: 0.05 mg/kg
 Description: Dithianon is extracted from the apple with concentrated hydrochloric acid/acetonitrile 1:2 (v/v) as described above for grapes (DT-244-045).

Must, red and white wine, method number FAMS 009-01, HUK 460/55-01R (Curl, 1992, DT-244-048)

Analyte: Dithianon Method: HPLC-UV D LOQ: 0.05 mg/kg
 Description: Dithianon is extracted from must and wine, acidified with concentrated hydrochloric acid and extracted 4 times with n-hexane. The organic fraction is reduced in volume to near dryness and re-dissolved in 0.1% acetic acid in dichloromethane and subjected to column chromatography using activated silica gel and acidic dichloromethane as the eluant (0.1%). The collected organic solution is evaporated to 0.5 ml and re-dissolved in methanol/acetic acid (99:1, v/v).

Apples, grapes, lettuce, whole oranges, wheat grain, rape seed, hops, method number SOP-PA.0281 (Class and Richter, 2006, 2006/1032406;

Analyte: Dithianon Method: LC-MS/MS LOQ: 0.01 mg/kg, except hops LOQ: 1 mg/kg
 Description: The analyte is extracted from the plant materials with acetonitrile/water/2 N HCl (70/25/5, v/v/v). A portion of the extract is centrifuged and an aliquot of the supernatant is diluted for determination by LC/MS-MS, monitoring for each analyte two parent-daughter ion transitions (MRMs). The first transition is used for quantitation whereas the second can be used for confirmatory purposes.

Wheat, sunflower, lettuce, green-apple, hops, ILV of SOP-PA.0281 (Jones, 2007, 2007/1017102; Bross, 2010, 2010/1062111)

Analyte: Dithianon Method: LC-MS/MS LOQ: 0.01 mg/kg, except hops LOQ: 1 mg/kg
 Description: The analyte was extracted from the homogenized plant materials with acetonitrile/water/HCl. A portion of the extract was centrifuged and an aliquot of the supernatant was diluted for determination by LC-MS/MS, monitoring each analyte with at least two parent-daughter ion transitions (MRMs).

Citrus, apple, grape, wine, plum, method number L0152/01 (Lehmann, 2011, 2010/1021354)

Analytes: Dithianon, CL 1017911 Method: LC-MS/MS LOQ: 0.01 mg/kg
 Description: The analytes were extracted from the homogenized plant materials with acetonitrile/water/2N HCl. A portion of the extract was centrifuged and an aliquot of the supernatant was diluted for determination by LC-MS/MS, monitoring for each analyte at least two parent-daughter ion transitions (MRMs).

Animal commodities

Bovine muscle, fat, whole milk, chicken eggs, method number M 3435 (Nejad and Connolly, 2001, DT-245-007; Nejad and Connolly, 2001, DT-245-008 amendment to DT-245-007)

Analyte: dithianon Method: HPLC-ECD LOQ: 0.01 mg/kg

Description: Residues of dithianon are extracted from chicken egg, bovine whole milk, bovine muscle and fat with acidic acetonitrile. Acid organic extracts are cleaned up by liquid-liquid partitioning followed by GPC. Residues of dithianon are determined by HPLC with an electrochemical detector operating in the reductive mode. Confirmation of dithianon residues > 0.01 mg/kg is provided by HPLC/Negative Ion Electrospray Ionization Tandem MS.

Bovine muscle, fat, whole milk, chicken eggs, method number M 3435 (Bross, 2006, 2006/1034178)

Analyte: dithianon Method: HPLC-ECD LOQ: 0.01 mg/kg

Description: Samples were extracted and cleaned up as described above (DT-245-007). Residues of dithianon are determined by HPLC with an electrochemical detector (see above) operating in the reductive mode. Confirmation of dithianon residues > 0.01 mg/kg is provided by HPLC/Negative Ion Electrospray Ionization Tandem MS.

Cow liver, kidney, fat, milk, method number L0135/01 (Schweda, 2009, 2009/1045474; 2009/1045475)

Analyte: dithianon Method: LC-MS/MS LOQ: 0.01 mg/kg
 Description: Dithianon residues are extracted with a mixture of acetonitrile/water/2 N hydrochloric acid (70:25:5, v/v/v). A portion of the extract is centrifuged and an aliquot of the supernatant is cleaned by SPE on a reversed phase column. The final determination of is performed by HPLC-MS/MS, monitoring two parent-daughter ion transitions. Matrix-matched calibration solutions are necessary

Recoveries from the internal (LV) and independent laboratory validation (ILV) testing for dithianon in animal commodities based on detection via HPLC-ECD are summarized in Tables 39 and 40.

Table 39 Recoveries for spiked dithianon in animal matrices based on detection via HPLC-ECD

Stability of residues in stored analytical samples

Information was received on the freezer storage stability of dithianon residues in plant commodities. The data are summarized in Table 41. The nominal storage interval is reported in months, if available, the actual storage interval in days is shown in brackets. In general, the values are not corrected for the procedural recovery, except study DT-326-010 (hops), where only corrected values were reported.

In study 2013/1061828, incurred residues were analysed. The samples were stored as whole fruit to exclude degradation in homogenized sample matrix during storage. The stability of the analyte in homogenized samples, the re-analysis of stored homogenized samples were performed. The variability of the results for whole apples in range of 0.15–0.36 mg/kg is caused by the fact that whole apples were stored and reflect the variability of dithianon residues in apples.

Table 41 Freezer storage stability data for dithianon residues in plant matrices

USE PATTERNS

The fungicide dithianon is registered in many countries for control of diseases on a large variety of crops. Dithianon is applied either as solo product or in combinations with other active substances as cymoxanil, dimethomorph, pyraclostrobin and pyrimethanil. The information available to the Meeting on registered uses on citrus fruits, pome fruits, stone fruits, berries and other small fruits, tree nuts and hops is summarized in Table 43 and refers for application rates etc. to dithianon only. Labels were submitted by the manufacturer.

Table 43 Registered uses of dithianon

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received information on supervised field trials for dithianon uses that produced residues on the following commodities:

Crop Group	Commodity	Tables
Citrus fruits	Citrus fruits	44
Pome fruits	Apple	45, 46
	Pear	47
Stone fruits	Cherries	48, 49
	Peaches	50, 51
		52, 53
Berries and other small fruits	Grapes	54, 55
	Currants, black	56

Crop Group	Commodity	Tables
Tree nuts	Almonds	57
Dried herbs	Hops, dry	58

Conditions of the supervised residue trials were generally well reported in detailed field reports. However, some trials conducted in the 1970s and 1980s were reported in summary tables only. Laboratory reports generally included method validation with procedural recoveries from spiking at residue levels similar to those occurring in samples from the supervised trials. Dates of analysis or duration of residue sample storage were provided in most cases, if not, it is indicated in the relevant table.

Because of the age of many trials, the analytical methods used are described in the text and are listed in the tables below. Residue data are recorded unadjusted for recovery. Undetected residues were generally reported lower than the LOQ. Residues and application rates have generally been rounded to two significant figures. Residue values from the trials conducted according to maximum GAP, or, in case of exceeding the ARfD, according to an alternative GAP, have been used for the estimation of maximum residue levels. Those results included in the evaluation are underlined.

In some supervised trials on apples, cherries, peaches, plums and grapes, residues of the parent dithianon and the metabolite 5,6-dicyano-3-(2-hydroxybenzoyl)-1,4-dithiine-2-carboxylic acid (Reg. No. 411094) were analysed.

Citrus fruits

The reports for dithianon residues in citrus fruits conducted in Japan were submitted in the Japanese language but only with a short English explanation. Trials were carried out on mandarins (varieties unshiu, mikan, satsuma), pomelos (natsudaikai, variety amanatsu), citrus sudachi and citrus sphaerocarpa (variety kabosu). Trials were carried out either indoors “G” or outdoors “F”. Peel and pulp samples were analysed separately. The residues in whole fruits were calculated from the weight ratio of peel and pulp.

Samples were analysed using HPLC with UV-detection in parallel in different analytical laboratories: Japan Food Research Laboratories (JFRL), Institute of Environmental Toxicology (IET), Tahara Laboratories, Dainihon Jochugiku or in the Japanese Food Analysis Center (JFAC). Average recoveries in pulp and peel as reported in the English summary, ranged between 77% and 93%; LODs were reported as 0.01–0.02 mg/kg for pulp and 0.02–0.05 mg/kg for peel. The residue trials data are presented in Table 44.

Table 44 Dithianon residues in citrus fruits, scaled residue values are shown in brackets

Apple

During the years 1975–2003, trials were conducted in Northern and Southern Europe. In 2003, different products were tested in three plots side-by-side (Doc ID-No. 2004/1000752). The summary of the residue trials data for apple, whole fruit, is presented in Table 45. The samples were analysed as follows:

Apples from trials conducted during 1975–1985 were analysed by similar methods using HPLC-UV (e.g. RU 107/34/10) or by colorimetry (Merck-Method M 101/67; only for two trials in 1975), all of which were validated at 0.03–0.05 mg/kg and for which procedural recoveries of dithianon were 70–110%.

For trials conducted from 1990–1995, samples were analysed using method FAMS 028-02 for which procedural recoveries of dithianon fortified in fruit at 0.02–1.0 mg/kg were 91–103%; or the samples were analysed using methods similar to FAMS 028-02, such as method FAMS 009-01 and HUK 460/38. Using the latter methods, recoveries of parent obtained from apple fruit fortified at 0.05–1.9 mg/kg were 74–95%.

Most of the samples from the trials conducted in the years 2000 were analysed with method RLA 12616 or further versions, which quantifies dithianon using HPLC with UV detection and an LOQ of 0.01 mg/kg in apple fruit. Procedural recoveries of dithianon fortified in whole fruit at 0.01 mg/kg were 70–110%. HPLC-UV methods similar to RLA 12616 were employed to analyse samples from the remaining trials.

During the 2010 growing season, a total of 11 field trials were conducted in Germany, the United Kingdom, Belgium, the Netherlands, France, Greece, Italy and Spain. Specimens were analysed for dithianon and its metabolite Reg. No. 4110904 using method No. L0152/01 with a LOQ of 0.01 mg/kg. The results for apple, whole fruit are summarized in Table 46.

Pear

Four field trials with pears were conducted in 2004 in Northern France, Denmark, Germany and the Netherlands. The specimens were analysed for residues of dithianon according to method M 3442 (= RLA 12616) with an LOQ of 0.01 mg/kg. The residue trials data for pear, whole fruit are presented in Table 47.

Cherries

Trials on cherries were conducted in Germany in the years 1985, 1986 and 1995. The residue data (whole fruit) are summarized in Table 48. Samples from 1985 and 1986 were analysed for dithianon residues by method CM-RU 107/34/10 (HPLC-UV) with an LOQ of 0.05 mg/kg and a recovery of about 75%. The samples from the trials conducted in the year 1995 were analysed by method FAMS 028-01 (HPLC-UV). The LOQ for dithianon was 0.02 mg/kg in cherry fruit with recoveries at 89%.

In 2009 and 2010, trials with sweet and sour cherries were conducted in France, Germany, Italy, Greece, the Netherlands, the United Kingdom and Spain in order to determine the residues of dithianon and its metabolite Reg. No. 4110904. The results for whole fruits are summarized in Table 49. Samples were analysed with method L0152/01 for dithianon (LOQ 0.01 mg/kg) and its metabolite Reg. No. 4110904 (LOQ 0.01 mg/kg). The recoveries were 93–94% for dithianon and 89–111% for the metabolite Reg. No. 4110904 at fortification levels of 0.01 and 0.1 mg/kg.

Peach

Trials with dithianon on peaches were conducted in 2001 in Southern France. Fruits were analysed with a “GRAPPA in-house” HPLC-method (UV-detection) for dithianon (LOQ 0.05 mg/kg) using extraction with 2N hydrochloric acid and dichloromethane. After some purification steps the extract is further purified by using SPE (Sep-Pak Florisil Plus). The recovery of dithianon in peaches ranged from 78 to 85%. The data are summarized in Table 50.

Trials on peaches were conducted in 2009 and 2010 in Germany, France, Greece, Italy and Spain. Specimens were analysed by method L0152/01 for dithianon and its metabolite Reg. No. 4110904 (LOQ each 0.01 mg/kg). The recoveries were about 81% for dithianon and about 102% for the metabolite Reg. No. 4110904 at fortification levels of 0.01 and 0.1 mg/kg. The results for peaches, whole fruit are summarized in Table 51.

Plums

During the 1996 growing season, three field trials with plums were conducted in France. Dithianon residues in plums were analysed after acetonitrile extraction with an HPLC-UV (LOQ 0.03 mg/kg, recovery 77%, GRAPPA in-house method). Further trials on plums were conducted in 1998 in France. Dithianon residues were analysed with method FAMS 028-02. The results are summarized in Table 52.

^a Residue concentrations calculated for whole fruit including stones.

During the 2009/2010 growing seasons, trials in plums were conducted in Northern France, Italy, Spain and Germany. The results are summarized in Table 53. Shortly before analyses the plum fruits were pitted and the weight ratio of the stones and flesh was determined. Only the flesh was analysed. The residues were calculated for the whole fruit based on the individual ratio stone to flesh. All specimens were analysed for dithianon and its metabolite Reg. No. 4110904 using BASF method number L0152/01 which has a limit of quantitation of 0.01 mg/kg for each of the two analytes.

Grapes

Trials on grapes were conducted in Northern Europe in the 1970s, 1980s and early 1990s. The samples were either analysed for dithianon by HPLC-UV (methods RU 501/02/10, RU 107/34/10, SFS AMS 003-02 and FAMS 028-02), GC-ECD (methods P-14.078.01 and P-14.013.02) or, in one case, by a colorimetric method. The LOQs of all methods applied vary between 0.01 mg/kg and 0.05 mg/kg and the recoveries from 71 to 100%.

Further trials were conducted from 2001 to 2004 in France (North and South), Germany, Greece, Spain and Italy. The fruits were analysed for residues of dithianon using methods M 3442 (RLA 12616) or version RLA 12616.05V with an LOQ of 0.01 mg/kg and mean recovery rates of 70–110%. In the trial FTL/17/03 conducted in Southern France, the harvest was very poor due to extremely dry weather conditions in this area. Because of this, the last sampling was not possible anymore as no more grape samples were left at that time. These extreme conditions also caused considerably higher residues found in this trial compared to all other ones. A summary of the residue trials data is presented in Table 54. The scaled residues according to Slovenian GAP (8×0.35 kg ai/ha) and to Serbian GAP (3×0.35 kg ai/ha) are shown in brackets.

During the growing season of 2010, four trials with grapes were conducted in Greece, Italy and Spain in order to determine the influence of different water volumes on the residue situation. Each field trial consisted of five plots and a control plot. All treated grape specimens were analysed for dithianon and its metabolite Reg. No. 4110904 according to analytical method L0152 (LC-MS/MS, LOQ for each analyte 0.01 mg/kg). The results are summarized in Table 55.

Currants, black

Six field trials with black currants were conducted in 1993/1994 in France (see Table 56). Specimens were analysed after extraction with acetonitrile and liquid-liquid partition with dichloromethane by HPLC-UV with LOQs of 0.05 mg/kg (SICACRO Laboratoire in-house method) or 0.1 mg/kg (no method number, recovery levels were 77% and 85% at 0.1 mg/kg fortification level).

Almonds

Four trials were laid down in France in 1996. The crop growth stage at the final application was “young fruit” in all trials. Almonds without shell were analysed with a “GRAPPA in-house” HPLC-method (UV-detection) for dithianon (LOQ 0.05 mg/kg) using extraction with dichloromethane. Recoveries were in the range of 62% to 92%. The results are summarized in Table 57.

Hops

Trials were conducted in representative hops growing areas in Germany in the growing seasons 1987, 1989–1991 and 1995. The samples from the trials conducted between 1987 and 1991 were either analysed with a GC-ECD method (P-14.005.01 and P-14.005.02). The samples from the trials conducted in 1995 were analysed with method P-14.078 of Dr. Specht & Partner Laboratories. The LOQ for dithianon of all methods is 0.05 mg/kg in hop cones. The recoveries were in the range of 71 to 100% at varying fortification levels. A summary of the residue trials data is presented in Table 58.

FATE OF RESIDUES IN STORAGE AND PROCESSING

In processing - nature of residues

Three studies were provided on hydrolysis of dithianon to assist with identification of the nature of the residues during processing. To estimate the degradation behaviour of dithianon during industrial processing or household preparation, the process of pasteurization (90 °C, 20 min), the process of baking, boiling, brewing (100 °C, 60 min) and the process of sterilization (120 °C, 20 min) was simulated.

Study DT-790-060 (Tsalta, 2001)

The hydrolysis of dithianon was performed using ¹⁴C-dithianon labelled at positions 5, 6, 9 and 10 of the molecule. The test substance had a radiochemical purity of 98.7% (by HPLC) and a specific activity of 42.4 µCi/mg. The experiments were carried out in a closed system under the simulated processing conditions. The hydrolysis of ¹⁴C-dithianon was studied at 90, 100, and 120 °C in sterile buffers at pH 4, 5, and 6, respectively. Radio-labelled test compound was applied at an application rate of 0.13 mg/L. The samples were incubated for 20 to 60 minutes at 90, 100, and 120 °C in the dark. Samples from the test solutions were assayed by liquid scintillation counting at 0-time (immediately after dosing) and after incubation to determine the concentration and recovery. Aliquots of the samples were analysed by reversed phase HPLC directly without sample work-up.

The results for the hydrolysis experiment conducted at pH 4 showed that dithianon was stable under simulated processing conditions of pasteurization. ¹⁴C-dithianon accounted for 94.7% to 97.1% and 90.2% to 94.2% of the recovered radioactivity at 0-time and after 90 °C, 20 minutes incubation, respectively.

The results for the hydrolysis experiment conducted at **pH 5** showed that dithianon was significantly degraded under simulated processing conditions of baking, brewing, and boiling (100 °C, 60 min). ¹⁴C-dithianon accounted for 93.4% to 94.4% of the recovered radioactivity at 0-time.

After incubation at 100 °C for 60 minutes at pH 5, ¹⁴C-dithianon had degraded to a large extent (> 90%) to many mostly polar substances. One major and four minor degradation products were detected. The major degradation product, accounting for 46% to 57% of the recovered radioactivity, was identified by MS and ¹H-NMR as compound Reg. No. 4110904 (CL 1017911) [(1,4-dithiin-2-carboxylic acid, 5,6-dicyano-3-(2-hydroxy-benzoyl)]. The minor degradates formed each accounted for 3.5% to 8.5% of the recovered radioactivity. The MS and ¹H-NMR data revealed that compound Reg. No. 4110904 was formed by cleavage of the quinone ring (under high temperature hydrolytic conditions) resulting in a carboxylic acid. The ¹H-NMR data also showed that the isolated product contained a minor component postulated as CL 1017912 {benzoic acid, 2-[(5,6-dicyano-3-hydroxy-1,4-dithiin-2-yl)carbonyl]} which is probably the positional isomer with the carboxyl and the hydroxy groups in reversed positions.

The results for the hydrolysis experiment conducted at pH 6 showed that dithianon was significantly degraded under simulated processing conditions of sterilization (120 °C, 20 minutes).

The HPLC analysis of the 0-time solutions showed that ¹⁴C-dithianon was degrading rapidly even at room temperature conditions. Dithianon accounted for 75.1% to 77.1% of the recovered radioactivity and compound Reg. No. 4110904 had already started forming at 6.5% to 6.9% of the recovered radioactivity at 0-time. The HPLC analysis of the incubated solutions (20 min) showed no detectable peak corresponding to parent. The major degradation product formed at pH 6, compound Reg. No. 4110904, accounted for 19.8% to 21.2% of the recovered radioactivity. The chromatographic profile of the degradation products was qualitatively very similar to the profile at pH 5. As at pH 5, an additional four degradation products formed, each accounting for an average 6% to 9.5% of recovered radioactivity.

Study 2009/1065632 (Hassink, 2009)

To estimate the degradation behaviour of the test item during industrial processing or household preparation of apple juice, the process of pasteurization was simulated. The test solution containing 0.01 mg dithianon suspended in natural turbid apple juice at pH 3.8 was heated to 90 °C in a round-bottom flask under backflow. The test was performed in duplicate (test A and B). The samples were measured for radioactivity (LSC) and were analysed by HPLC to determine an eventual metabolite pattern. Comparing the overall radioactivity measured by LSC before and after each test it can be seen that no loss of radioactive material occurred.

Test	% Total applied radioactivity (TAR)	
	pH 4, 90 °C, test A	pH 4, 90 °C, test B
Before test (% TAR)	100	100
After test (% TAR)	94.82	98.99

The distribution of radioactivity was determined by HPLC-analysis. Dithianon degraded in both experiments (test A: 24.4% TAR, test B: 31.7% TAR) to a high number of unknown degradation products. In test A about 44 HPLC-peaks could be separated, three of them above 5% TAR (4.9 min: 8.3%; 13.8 min: 6.3%; 46.4 min: 5.9%). In test B 39 peaks occurred, only one of them was quantified above 5% TAR (5.1 min: 5.1%). The quantified peaks consist of several compounds and could not be separated.

Study 2013/1078029 (Class, 2013)

To estimate the degradation behaviour of the test item during industrial processing or household preparation of fruits, the process of pasteurization (90 °C, 20 min), the process of baking, boiling,

brewing (100 °C, 60 min) and the process of sterilization (120 °C, 20 min) was simulated. Apple juice was used as example. ^{14}C -dithianon was diluted with ^{12}C -dithianon in a ratio of about 1:1, in acetonitrile + 1% formic acid as solvent. This dose solution was then added to a commercial naturally turbid apple juice (containing 10% of a pH 4 buffer) to prepare the test solutions. The test solutions were examined by direct LSC for total applied radioactivity (TAR) prior to hydrolysis and after hydrolysis for total radioactive residue (TRR), indicating complete mass balance during hydrolysis. The culture tubes were heated in an oil bath to 90 °C for 20 minutes, 100 °C for 60 minutes or 120 °C for 20 minutes. After hydrolysis the culture tubes were cooled in an ice/water bath, subsequently stored refrigerated (approximately 5 °C). An aliquot of the hydrolysed juice was used for radio-chromatography by RP-HPLC analysis. Additionally, aliquots of the hydrolysed test solutions were dosed with solutions of selected reference compounds for identification by co-chromatography. Selected hydrolysis solutions were re-injected after various storage intervals to establish stable radio-chromatographic patterns. Almost all degradation products identified by RP-HPLC-UV/LSC and found to be $\geq 5\%$ of the TAR was confirmed by HPLC-MS/MS.

Based on the results of the initial high temperature hydrolysis of apple juice at 120 °C for 20 minutes and subsequent refrigerated storage, an additional hydrolysis test was conducted to confirm the presence of component Reg. No. 4107273 (D2) only found immediately after hydrolysis. This sample was dosed with ^{14}C -dithianon, hydrolysed as described above, characterised using HPLC-UV/LSC immediately after hydrolysis and the structure of component Reg. No. 4107273 (D2) confirmed by HPLC-MS/MS immediately following characterisation.

Further hydrolysis tests were conducted with un-buffered apple juice, in order to demonstrate that apple juice available to the consumer would have a similar degradation pattern as that determined in the presence of buffer. In this case, an apple juice sample was dosed with ^{14}C -dithianon, hydrolysed at 120 °C for 20 minutes as described initially, but without buffer, and examined by HPLC-UV/LSC immediately after hydrolysis. Samples were then analysed after 6, 24 and 48 hours, and 7, 14/15, 21 days of room temperature storage until a stable radio-chromatographic pattern was obtained.

All samples of the test solutions were analysed directly without further work-up. Samples were measured for radioactivity (LSC) and were analysed by HPLC-UV/LSC to determine an eventual degradation pattern. Confirmation of almost all degradation products identified in excess of 5% of the TAR was accomplished using HPLC-MS/MS.

The results of initial high temperature hydrolysis tests with ^{14}C -dithianon in buffered apple juice are shown in Table 59.

Table 59 Degradation products observed direct after hydrolysis

The room temperature storage of apple juice samples hydrolysed at 120 °C for 20 minutes showed that the radio-chromatographic pattern/composition of the ¹⁴C-dithianon degradates remained stable from 7 days through 21 days (see Table 63). The degradation pattern is essentially the same with buffer (stored refrigerated for 33 days) and without buffer (stored at room temperature).

In processing – effect on the residue level

The Meeting received information on the fate of dithianon residues during the processing of oranges to juice and pulp, of apple to juice, sauce, pomace and dried fruits, of grapes to juice, must, wine and pomace and of hops to beer. Further studies conducted in 2009/2010 on apples, cherries, plums and

grapes investigated the fate of parent dithianon and of the metabolite Reg. No. 4110904 after processing. The information submitted on processing procedures is summarized below.

RAC, Country, year	Procedure description, remarks	Doc Id-No
Oranges, USA, 1991	No detailed information on the processing procedures of oranges to peel, juice, dry and wet pulp, oil and molasses was submitted.	DT-710-008
Apple, Germany, 1993	A description of processing methods used was not provided.	DT-711-094 DT-711-095
Apple, Italy, 2000	Apples were crushed and pressed to produce <u>juice</u> and <u>wet pomace</u> . Pectolytic enzymes were added to the juice and it was left to settle at least for 12 hours. The juice was filtered, pasteurised by heating to approximately 85 °C for at least one minute, and was then placed in sterilized glass bottles with screw caps. For dried pomace, the wet pomace was placed into an oven and dried at 60 °C for one day. To produce <u>puree</u> , the apples were blanched in hot water (80 °C for 5 minutes) and crushed and sieved to obtain puree. After addition of sugar, heating until a degree Brix of about 24%. The puree was then sterilised at 115-120 °C for 10 minutes and frozen. To produce <u>canned apples</u> the apples were peeled, blanched in hot water (80 °C, for 5 min), core was removed and the apples were cut into pieces.	2002/1011501 2002/1011502
Apple, Italy, Spain, 2001	Apples were processed into apple <u>juice</u> by crushing with a crushing machine. Ascorbic acid (300 mg/kg) was added to prevent oxidation. The crushed apples were immediately pressed in a mechanical wine press. The juice was then poured into a stainless steel vat. Pectolytic enzymes (at a concentration of 5 g/hl) were added to the juice to accelerate the clarification process. A subsample of pomace was taken from each specimen and frozen. After a clarification period of at least 12 hours, the dregs were discarded and only clear juice was bottled, and samples of juice were taken.	2002/1011555
Apple, Germany, 2003	In a first step the apples were filled in a stainless steel tank and washed by hand. The washed apples were transferred into a shredder and subsequently ground. The resulting pulp samples were divided into two parts - the major part was used for juice production; the other part was processed to apple sauce. For the production of <u>juice</u> , an aliquot of the pulp sample was transferred into a tube press. The pressure was increased. The resulting juice was passed through a cloth and a metal sieve. The juice and the <u>fresh pomace</u> were collected separately in tubs. Parts of the fresh pomace were dried at an oven at 90 °C until constant weights were achieved. The other part was used as specimen for analysis. For clarification of the fresh juice, pectinase was added first; in a second step and prior to a filtration step gelatine and Kieselsol were added. The clear juice resulting from the filtration step was subjected to pasteurization (90 °C, 5 min). For the preparation of <u>apple sauce</u> , an aliquot of pulp was filled into a sauce pan and heated up to 85 °C. As soon as the 85 °C was reached (which is sufficient to turn the pulp into mash, duration between 30 and 70 min), the mash was strained using a puree apparatus and filled into sample containers while still hot. Cooling down.	2003/1001126
Apple, Germany, 2010	Preparation of <u>canned apple</u> : Peeling, cutting in small pieces, removal of core and stalk. Addition of water, ascorbic acid, citric acid and glucose syrup. Boiling. Regulation of pH and dry substance. Pasteurisation in jars. Cooling down. Preparation of <u>apple sauce</u> : Cutting in half pieces, removal of stalks. Soft boiling of apple pieces in water. Sieving of cooked apples. Addition of sugar and ascorbic acid. Regulation of pH and dry substance. Pasteurisation in jars. Cooling down. <u>Dried apple</u> preparation: Removal of core and stalks, cutting into rings. Drying in an oven. <u>Juice</u> preparation: Apples were mashed. Pressing to extract the raw juice → wet pomace. The raw juice was pasteurized. Cooling down. Wet pomace dried in an oven → dried pomace.	2011/1135917
Cherries, Germany, 2009	<u>Jam preparation</u> : Washed fruits will be stoned, addition of sugar and glucose syrup to the fruits. Cooking until a dry substance of 63 – 65%. Adding of pectine and citric acid. Cooking until a dry substance of 60 – 62%. Cooling down. Preparation of <u>canned cherries</u> : Addition of water, ascorbic acid, citric acid and sugar to the	2010/1093253

RAC, Country, year	Procedure description, remarks	Doc Id-No
	fruits. Cooking, filling product into cans. Cooling down. Preparation of <u>juice</u> : Washed cherries were mashed in a masher. Pressing to extract the raw juice → wet pomace. The raw juice was pasteurized. Cooling down.	
Plums, Germany, 2009	Preparation of <u>puree</u> : Plums washed, stalks were removed. Fruits will be stoned, cut into small pieces. Addition of sugar, gingerbread, spice, citric acid and glucose syrup to the fruits. Cooking until dry substance > 53%. Cooling down. Preparation of <u>dried prunes</u> : Fruits will be stoned. Dipping in 0.5% ascorbic acid solution. Drying in an oven (65 °C) until a maximal moisture content of 25%.	2011/1031148
Grapes, Germany, 2010	<u>Rose grape variety</u> : The unwashed grapes were crushed. The mesh (stalks, flesh, skin, seed, juice) was pressed to extract the liquid. Before the must was clarified, K ₂ S ₂ O ₅ was added. After the clarification, <u>raw juice</u> was pasteurized (83–87 °C, 2 min). Raw juice was poured into glass vessels, yeast and nutrient salt was added for fermentation. After fermentation, K ₂ S ₂ O ₅ was added. Clarification of the fermentation product. First transfer of wine between vessels. Bentonite was added to absorb proteins. Second transfer of wine and K ₂ S ₂ O ₅ was added. The young <u>wine</u> was filtered after clarification, bottled for maturation and stored at 5–8 °C. <u>Red grape variety</u> : The unwashed grape bunches were crushed. The stalks were removed. K ₂ S ₂ O ₅ was added. The mesh (flesh, skin, seed, juice) was heated up to 60 °C. During heating, mesh was stirred. Subsequent to the cooling down phase, the mesh was pressed to extract the liquid. After the clarification, <u>raw juice</u> was pasteurized (83–87 °C, 2 min.). Raw juice was poured into glass vessels, yeast and nutrient salt was added for fermentation. After fermentation, K ₂ S ₂ O ₅ was added. Clarification of the fermentation product. First transfer of wine between vessels. Bentonite was added to absorb proteins. Second transfer of wine and K ₂ S ₂ O ₅ was added. The young <u>wine</u> was filtered after clarification, bottled for maturation and stored at 5–8 °C. <u>Raisin production</u> : washed grape bunches were put in boiling water for 8–10 sec and afterwards they were manually washed (3 min) with cold tap water. The bunches were dried in a oven (66–74 °C) for 24 hours until a moisture content of 10–14% was achieved. After drying, raisins were removed from the stalks.	2011/1248836
Grapes, Germany, 1986/87	Trials on red grapes (variety Portugieser) and white grapes (variety Müller-Thurgau). A description of processing methods used in the trials was not provided.	DT-713-031
Grapes, Germany, Spain, France, Italy, 2001	<u>White wine production (Germany, Italy)</u> : The grapes were placed directly into the wine press in order to be pressed. Wet pomace and must were separated immediately after the pressing step. Aliquots of the wet pomace sample were dried at about 60 °C in an oven. The resulting must was allowed to settle. After decantation from the must deposits, the alcoholic fermentation took place; it is considered as complete when fermentation has slowed down or stopped (indicated by a density below 1000). For stabilizing and after addition of gelatine / potassium metabisulphite, the young wine was kept under cold storage conditions for at least two weeks. After filtration, the wine was bottled. <u>Red wine production (Spain, France)</u> : The grapes used for red wine processing were crushed and stemmed with an electric crusher/stemmer. The crushed grapes were recovered in a stainless steel tank. The stems were weighed and discarded. Potassium metabisulphite was added to the remaining crushed grapes. Dry active yeasts (0.1 g/L) were added to the must. The progress of the alcoholic fermentation was followed each day by measuring the density, temperature and pH of the must. In case of the French trial, sugar was added to increase the alcohol concentration. The alcoholic fermentation was considered as complete when the density of the must fell below the value 1000 (duration: about one week). The wine was run off to the tank (free-run wine) and the solid part was pressed with a water press in such a manner as to recover the maximum quantity of wine. The pressed wine was added to the free-run wine; wet pomace and young wine sample were taken. Aliquots of the wet pomace sample were dried at about 60 °C in an oven. The malolactic fermentation was carried out in absence of air, at ambient temperatures with a direct inoculation of lactic bacteria. The progress of the malolactic fermentation was followed-up one time each week. After the completion of the malolactic fermentation, potassium metabisulphite was added for natural clarification. After the first clarification step, sediment samples (designated as lees) were taken; subsequently, dry gelatine and further potassium metabisulphite were added to the wine. As for white wine, the young wine was stored in the cold room for stabilization. In order to remove impurities (solid material), the wine was finally filtered and bottled.	2003/1014014

RAC, Country, year	Procedure description, remarks	Doc Id-No
	<u>Juice production:</u> The grapes kept for grape juice processing were crushed and stemmed. The crushed grapes were weighed and, after addition of pectolytic enzymes, placed in plastic jars. The depectinisation of juice took place for two hours at a temperature between 45°C and 60°C (measured by a thermometric probe inside the jar). The glass jars were then removed from the saucepan and their content was pressed in a water press. The wet pomace was then weighed and discarded. The recovered juice was analysed (degree Brix, total acidity, and pH) and then put back in glass jars for clarification. The clarification took place for 5 minutes at a temperature of about 85 °C. This clarification phase was followed by a cold storage of at least 12 hours. After cold storage and racking, only the clear juice (without sediment) was filtered, pasteurized for 1 minute at 85 °C and bottled.	
Hops, Germany, 2001	Besides the hops, malt, yeast and drinking water were used. The brewing process was done at a laboratory scale, but fully comparable to industrial brewing process, including the steps brewing, lautering (→ brewer's grain), wort cooking (→ spent hops), primary fermentation (→ brewer's yeast) and secondary fermentation (→ beer).	2002/1006301

The results of the processing studies on oranges, apples, cherries, plums, grapes and hops for parent dithianon and of the degradation product Reg. No. 4110904 on apples, cherries, plums and grapes are presented in Table 64.

Table 64 Dithianon residues after processing (concentration of Reg. No. 4110904 in brackets)

RESIDUES IN ANIMAL COMMODITIES

Farm animal feeding studies

No data were received.

APPRAISAL

The fungicide dithianon (5,10-dihydro-5,10-dioxonaphtho-[2,3-beta]-1,4-dithiine-2,3-dicarbonitrile) has been evaluated by the JMPR for the first time in 1992 (T, R). The compound was evaluated for toxicology by the 2010 JMPR where an ADI of 0.01 mg/kg bw and an ARfD of 0.1 mg/kg was allocated. The periodic review for residues was scheduled at the 39th session of the CCPR for the 2012 JMPR but postponed to evaluate in 2013.

The Meeting received information from the manufacturer on physical and chemical properties, metabolism studies on plants and animals, analytical methods, supervised residue trials data, processing studies as well as use pattern.

The metabolism and distribution of dithianon in plants and animals as well as the nature of the residue under simulated processing conditions, was investigated using the [5,6,9,10-]¹⁴C-labelled compound or, in some studies, a [5,6,9,10-]¹³C/¹⁴C-labelled compound. The following abbreviations are used for the metabolites or degradation products discussed below.

CL 231509

2-Hydroxy-1,4-naphthoquinone

M216F020

Glucuronic acid conjugate of 1,4-dihydroxy-naphthalene
Reg. No. 4110904

Reg. No. 4005234

Phthalic acid

Reg. No. 4107273

1,4-Naphthoquinone

Reg. No. 31062

Dibenzo-[*b,i*]-thianthrene-5,7,12,14-tetrone

Reg. No. 4110904

5,6-Dicyano-3-(2-hydroxybenzoyl)-1,4-dithiine-2-carboxylic acid

Reg. No- 4110933

4,9-Dihydro-4,9-dioxonaphtho[2,3-*b*]-thiophene-2,3-dicarbonitrile

Reg. No. 4110934

5,10-Dihydro-5,10-dioxo-naphtho[2,3-*b*]-1,4-dithiin-2,3-dicarboxylic acid diamide

Animal metabolism

Metabolism studies on rats reviewed by the 2010 JMPR show that at tested doses of 10 and 50 mg/kg bw orally administered dithianon was about 40–50% absorbed in rats. The majority of the administered dose was recovered in faeces (64–72%) and in urine (27–31%). Dithianon was extensively metabolized according to the following key transformation steps: oxidation of the sulphur atoms, cleavage of the dithiine ring, reduction of the 1,4-naphthoquinone moiety and further glucuronidation, as well as substitution of the carbonitrile moieties by amino and carboxy groups. The only metabolite in rat urine at a level greater than 2% was M216F020.

Two studies were submitted on the metabolism of dithianon in lactating goats. In the first study, one lactating goat each was dosed by capsule at a daily nominal rate of 6 mg (equiv. to 2.5 ppm in the feed) and 60 mg [¹⁴C] dithianon (equiv. to 28 ppm) for five days. The highest radioactive residues (TRR) of the high dose group were detected in kidney (0.49 mg/kg as dithianon equivalents) and in liver (0.17 mg/kg equiv.). Lowest TRR were found in fat (0.013 mg/kg equiv.), in milk (0.018 mg/kg equiv.) and muscle (0.013 mg/kg equiv.). Most of the [¹⁴C] residue was rapidly and constantly excreted via faeces and urine - almost 80% of the applied dose was eliminated at the end of the study.

Further investigation on the nature of radioactive residues was carried out with the high dose (60 mg/day) samples. The TRR (calculated as dithianon equivalents) in muscle and fat were very low

(0.013–0.014 mg/kg equiv.), and no further characterization was possible. For milk and edible tissues, the extracted radioactive residues ranged from 49% of TRR (0.08 mg/kg equiv.) in liver to 77% (0.018 mg/kg equiv.) in milk. The radioactivity in post extraction solids (PES) ranged from 20% (0.005 mg/kg equiv.) in milk to 74% (0.36 mg/kg equiv.) in kidney. Several radioactive components were detected in the extracts but not further identified. Parent dithianon was identified in liver (0.96% of TRR), kidney (2.3% of TRR) and milk (8.2% of TRR).

In the second goat study, after five consecutive daily administrations of [$^{13}\text{C}/^{14}\text{C}$] dithianon at a dose of 60 mg/animal and day (equivalent to 25 ppm in the feed), the highest TRR were detected in kidney (0.48 mg/kg equiv.) and in liver (0.16 mg/kg equiv.). Lower radioactive residues were found in muscle (0.013 mg/kg), in milk (0.018 mg/kg) and fat (subcutaneous 0.074 mg/kg equiv., renal 0.009 mg/kg equiv.). The major route of excretion of radioactivity was via faeces, accounting for 47% of the total administered dose. A further 18% of the total administered radioactivity was excreted via urine.

With the exception of milk, most of the radioactive residues could not be extracted. The PES in liver, kidney, muscle and fat ranged from 59.4% in kidney to 80% in muscle. Neither parent nor any corresponding metabolite was identified. However, in liver, kidney, urine and bile a very complex metabolite profile was noted. More than 20 components were found in the organic phase and at least six components were detected in the aqueous phase at low absolute residue levels (< 0.05 mg/kg) in tissues. In milk, the extracted radioactivity accounted for 78.3% of TRR (0.012 mg/kg equiv.).

The reactivity of dithianon with nucleophiles (commonly thiols in the form of proteins and peptides such as glutathione) was demonstrated *in vitro*. Glutathione and N-acetylcysteine react very quickly with dithianon when incubated in pH 6.5 buffers at 37 °C. It was indicated that the reaction of dithianon with glutathione and protein thiol groups *in vivo* should be virtually instantaneous.

Two groups of laying hens, five hens per group, were treated orally once daily for 5 consecutive days with gelatin capsules containing dithianon. The actual doses of dithianon administered were 0.4 mg/day and 4 mg/day, equivalent to 3.6 ppm and 39 ppm in the feed, respectively.

Over the dosing period, a rapid absorption and excretion of radioactivity occurred. About 90% of the total radioactivity administered was eliminated in excreta by 6 hours after the last dose. There was no indication of accumulation of [^{14}C] dithianon in poultry tissues and eggs.

The highest TRR (in mg/kg as dithianon equiv.) were found in the kidney (0.042 and 0.34–0.38 mg/kg low and high dose, respectively), liver (0.017 and 0.17–0.19 mg/kg), skin with fat (0.005 and 0.039–0.041 mg/kg) and GI Tract (0.14 and 1.5 mg/kg). The lowest concentrations were found in muscle (0.002 and 0.022 mg/kg) and abdominal fat (< 0.002 and 0.014 mg/kg). The highest TRR in egg yolks were 0.005 and 0.075 mg/kg at the end of the study.

Solvent extraction was performed on the high dose group samples and released about of 68% of TRR in muscle (0.008 mg/kg equiv.), 76% of TRR in skin with fat (0.031 mg/kg equiv.), 72% of TRR in liver (0.13 mg/kg equiv.), 74% of TRR in kidney (0.28 mg/kg equiv.) and 47% of the TRR egg yolks (0.037 mg/kg equiv.). The majority of the extracted radioactivity was aqueous/methanol-soluble (35% in egg yolk to 67% of TRR in kidney). The chloroform-soluble radioactivity, containing less polar components, accounted for 6.6% in kidney to 16% of the TRR in liver. Radioactivity in the PES accounted for 25% in liver to 54% of the TRR in egg yolk.

Parent dithianon, detected in minor amounts in the excreta only (1.5% of TRR), was extensively metabolized to yield numerous minor metabolites. The metabolites were profiled by HPLC but were not identified as low concentrations prevented isolation. The organo-soluble metabolites accounted for ≤ 0.003 mg/kg equiv. each in the kidney and liver. One major polar component found in the aqueous/methanol extract accounted for 19% TRR (0.035 mg/kg equiv.) in liver, 11% TRR (0.042 mg/kg equiv.) in kidney, 36% TRR (0.015 mg/kg equiv.) in skin and fat, and 5.7% TRR (0.004 mg/kg equiv.) in egg yolk.

Metabolism studies performed on rats, goats and hens have shown that dithianon is rapidly and intensively metabolized by a number of degradation processes; it was only detected in trace amounts in tissues and/or excreta. As key degradation steps oxidation/reduction and reaction with nucleophiles, commonly R-SH in the form of proteins and peptides such as glutathione are assumed. These reactions result in a huge number of individual metabolites, but also incorporation into natural products. No individual metabolites had been identified; all of them were present in very minor amounts.

Plant metabolism

The metabolism of dithianon has been studied with [^{14}C] dithianon on citrus trees, apple trees, spinach and wheat. The study designs of the plant up-take parts reflect the intended use pattern with several foliar post emergence applications.

Following foliar applications, there was no translocation from the part being directly treated to other parts of the plant. When applied to fruit crops, the dithianon residues remained predominantly associated with the peel. Most of the radioactivity present (> 50% TRR) could be washed off by a surface rinse using acetonitrile/HCl. Neither parent nor any metabolite was translocated to a significant degree into flesh or pulp. Dithianon was identified as the major component of the TRR and ranged from 50.9% in wheat grain up to 96% in spinach leaves.

The parent compound is further metabolized to a large number of polar components. With the exception of spinach, these components could not be identified. None of these metabolites was found in amounts exceeding 5% of the TRR. In spinach, metabolite 4110934, a dicarboxylic acid diamide derivative, 2-hydroxynaphthoquinone (CL 231509) and phthalic acid were found, indicating that the absorbed dithianon was completely metabolised by the plants. All of the individual components of the extracted residues in spinach were between 0.1 and 0.5% of the TRR (0.13–0.8 mg/kg equiv.).

The different functional groups on the dithianon molecule provide multiple sites for chemical and enzymatic attacks resulting in cleavage of the dithiine as well as the quinone ring. The primary products formed are very reactive and could be the target of quite a number of further metabolism and conjugation reactions (e.g. hydroxylation, sulphur oxidation, and reactions with naturally occurring plant constituents), but also incorporation into plant constituents. The Meeting considered parent as the only relevant residue occurring after foliar treatment of plants with dithianon.

Environmental fate

For dithianon, supervised residue trials data were received for foliar spray on permanent crops such as citrus fruits, tree nuts, pome fruits, stone fruits, grapes and hops. Therefore, neither environmental fate nor rotational crops studies are necessary.

Dithianon is not stable in aqueous media. A hydrolysis study showed DT_{50} values of 10.7 days at pH 5, 0.6 days at pH 7 and ca. 10 minutes at pH 9. The photochemical degradation at 20 °C in sterile pH 4 buffer resulted in a DT_{50} value lower than 0.05 days.

Methods of analysis

The Meeting received descriptions and validation data for analytical methods for residues of dithianon in plant and animal commodities. Residue analytical methods for dithianon rely on HPLC with UV-detection or LC-MS/MS for plants and HPLC with electrochemical detection or LC-MS/MS for animal matrices. Typical LOQs achieved for plant and animal commodities fall in the range of 0.01–0.05 mg/kg (except hops, dried, 1 mg/kg). Methods have been subjected to independent laboratory validation.

Descriptions and validation data for analytical methods for residues of the degradation product 4110904 in citrus fruit, apples, grapes, plums and grape wine were received. The analytical methods rely on LC-MS/MS. Typical LOQs achieved for plant commodities were 0.01 mg/kg.

Stability of residues in stored analytical samples

Information was received on the freezer storage stability of dithianon and 4110904 residues in plant commodities.

Older studies from 1992–1994 show that dithianon residues were not stable in spiked samples for a period longer than two months. Newer studies with incurred residues in apples (testing period 2 years) and wine grapes (testing period 14 months) show that dithianon residues were apparently stable at freezer temperature for the intervals tested. Residues of dithianon were not stable in wine, declining on average by 86% of the original fortification after 26 weeks of frozen storage.

The storage stability studies with 4110904 demonstrate that the compound is stable under freezer conditions in plant matrices for about two years in apples, plums and wine. Residues of 4110904 were not stable in grapes, declining by ca. 65% of the fortification level after 3 months, and in lemons, declining by ca. 55% after a week.

Definition of the residue

Animal metabolism studies were performed in lactating goats and laying hens. The parent compound dithianon is rapidly and intensively metabolized and was only detected in trace amounts in tissues and excreta. There was no bioaccumulation in tissues, milk and eggs. No individual metabolites had been identified; all of them were present in very minor amounts (< 0.05 mg/kg and also $< 10\%$ TRR).

Dithianon has a log P_{OW} of 3.2. In animal metabolism studies, the TRR in muscle and fat were comparable (dithianon *per se* could not be detected). The Meeting decided that the residue of dithianon is not fat-soluble.

In plant metabolism studies performed on fruits (oranges, apples), leafy crops (spinach) and cereals (wheat) the same metabolic behaviour was observed. The parent compound dithianon is the dominant component of the residue in plant commodities and ranged from 50.9% of the TRR in wheat grain up to 96% of the TRR in spinach leaves. No individual metabolite occur at relative amounts $> 10\%$ of TRR and of absolute concentrations of > 0.05 mg/kg in the same matrix.

Therefore, from the metabolism studies on plants and animals presented, the proposed definition of the residue is parent dithianon only.

The Meeting took into account the possibility of the formation of two hydrolysis products (Reg. No. 31062 and 4110904) in significant concentrations during industrial or household processing of dithianon treated fruits. Based on their dietary risk assessment, the Meeting concluded that there is no need to include both degradates in the residue definition for estimation of the dietary intake.

Definition of the residue (for compliance with the MRL and for estimation of dietary intake) for plant and animal commodities: *Dithianon*.

The residue is not fat-soluble.

Results of supervised residue trials on crops

The Meeting received supervised residue trials data for citrus fruits, apple, pear, cherries, peaches, plums, grapes, currants, almonds and hops. If two field samples were taken or results of two replicate plots were submitted, the mean value was calculated. For HR estimation, the highest single value of the trials according to GAP was used. From two or more trials carried out side-by-side the higher residue was chosen.

Citrus fruits

In Japan, dithianon is registered for foliar spray use on citrus fruits at a maximum application rate of 3×0.5 kg ai/hL with a PHI of 30 days. Supervised trials with 3×0.5 – 0.7 kg ai/hL with a PHI of 28–30 days were available from Japan: four on mandarins (four for whole fruit, six for pulp), two on pomelo, as well as one each on the small citrus fruits sudachi and kabosu (citrus sphaerocarpa).

The Meeting agreed to use the proportionality approach and scaled the residue data of the overdosed trials according to an application rate of 0.5 kg ai/hL.

The scaled dithianon residue values were in:

mandarins 0.46, 0.7, 0.82, 2.2 mg/kg (whole fruit) and < 0.018, < 0.018, < 0.018, < 0.021, 0.05, 0.07 mg/kg (pulp). The highest single value in pulp was 0.09 mg/kg.

pomelos 1.05, 1.45 mg/kg (whole fruit) and 0.02, 0.05 mg/kg (pulp)

sudachi and kabosu 0.84, 2.5 mg/kg (whole fruit).

The Meeting noted that only four residue trials on mandarin, two on pomelo and two on the small citrus varieties (sudachi/kabosu) are insufficient to estimate a maximum residue level for the whole group of citrus fruits.

The Meeting considered that six residue trials were available for mandarin. It was noted that in four trials data for whole fruit and in six trials pulp data were submitted. The Meeting agreed that only four trials on mandarin (whole fruit) are insufficient to estimate a maximum residue level for the subgroup mandarins. The previous recommendations of 3 mg/kg for mandarin, shaddocks or pomelos should be withdrawn.

Pome fruits

Dithianon is registered for foliar spray treatment on pome fruit in Germany with 12 treatments per season of 0.035 kg ai/hL and 0.18 kg ai/ha per m crown height (equivalent to 0.54 kg ai/ha for 3 m crown height) and a PHI of 21 days.

During the years 1975–2000, 21 trials on apples were conducted in Germany (12), France (3), Greece (1), Italy (3) and Spain (2). Foliar applications were made from 12 to 14 times to apple trees at application rates of 0.51–0.63 kg ai/ha. At a PHI of 21 days, the residues were < 0.03, < 0.05, 0.12, 0.13, 0.20, 0.24, 0.36, 0.38, 0.43, 0.48, 0.48, 0.59, 0.62, 0.76, 0.86, 1.0, 1.3, 1.5, 1.7, 1.7 and 1.7 mg/kg.

Four trials on pears were conducted in 2004 in Germany, The Netherlands, Northern France and Denmark with foliar spray by 12×0.53 kg ai/ha. The dithianon residues were at a PHI of 21–22 days 0.19, 0.37, 0.39 and 0.87 mg/kg.

The rank order of the combined dithianon residues on apple and pear were ($n = 25$): < 0.03, < 0.05, 0.12, 0.13, 0.19, 0.20, 0.24, 0.36, 0.37, 0.38, 0.39, 0.43, 0.48, 0.48, 0.59, 0.62, 0.76, 0.86, 0.87, 1.0, 1.3, 1.5, 1.7, 1.7 and 1.7 mg/kg.

The Meeting noted that the ARfD of 0.1 mg/kg bw is exceeded for apple by the IESTI for children (120% of ARfD) using 1.7 mg/kg as HR and decided that the dataset is not appropriate to estimate a maximum residue level for pome fruit.

An alternative GAP is an Italian use of 4×0.3 kg ai/ha on apple and of 3×0.3 kg ai/ha on pear with a PHI of 35 days. In Macedonia, dithianon is registered in apples with 4×0.24 –0.30 kg ai/ha and in pear with 4×0.32 –0.4 kg ai/ha. The PHI is 35 days also.

Five apple trials were conducted in 2003 with 4×0.3 –0.35 kg ai/ha. The dithianon residues were 34–35 days after treatment 0.11, 0.14, 0.35, 0.39 and 0.43 mg/kg.

Eleven apples trials were carried out in 2010 in Germany (1), the UK (1), Belgium (1), the Netherlands (1), France (2), Greece (1), Italy (2) and Spain (2) with 4×0.36 kg ai/ha. The dithianon residues were after a PHI of 35 days < 0.01, 0.02, 0.02, 0.06, 0.10, 0.14, 0.16, 0.21, 0.27, 0.34 and 0.65 mg/kg.

The combined dithianon residue data after application of 4×0.3 –0.36 kg ai/ha from 2003 and 2010 were ($n = 16$): < 0.01, 0.02, 0.02, 0.06, 0.10, 0.11, 0.14, 0.14, 0.16, 0.21, 0.27, 0.34, 0.35, 0.39, 0.43 and 0.65 mg/kg.

The Meeting agreed to extrapolate from apple to the whole group and estimated a maximum residue level of 1 mg/kg for dithianon residues in pome fruits to replace the previous recommendation (5 mg/kg). An STMR and an HR value of 0.15 mg/kg and 0.65 mg/kg were estimated.

Stone fruits

The GAP for stone fruits in Hungary is 2–3 times foliar spray treatment of 0.053–0.066 kg ai/hL, 0.53 kg ai/ha and a PHI of 21 days. Supervised trials were available for cherries, peaches and plums.

On cherries, sour, seven trials were carried out in Germany from 1985 to 1995 by an application of 3×0.53 kg ai/ha and a PHI of 21 days. The dithianon residues were 0.17, 0.26, 0.28, 0.34, 0.41, 0.49 and 0.80 mg/kg.

Further trials on cherries (sweet and sour) were conducted in 2009/2010 in the UK (2), France (3), Germany (2), Greece (2), Italy (3), The Netherlands (2) and Spain (1) with 3×0.53 kg ai/ha and a PHI of 20–21 days. The dithianon residues were 0.04, 0.09, 0.19, 0.19, 0.21, 0.38, 0.43, 0.45, 0.50, 0.57, 0.59, 0.69, 0.82, 0.90 and 1.0 mg/kg.

The Meeting concluded to combine the dithianon residues on cherries from both datasets. The dithianon residues on cherries were in rank order ($n = 22$): 0.04, 0.09, 0.17, 0.19, 0.19, 0.21, 0.26, 0.28, 0.34, 0.38, 0.41, 0.43, 0.45, 0.49, 0.50, 0.57, 0.59, 0.69, 0.80, 0.82, 0.90 and 1.0 mg/kg.

On plums, twelve trials were conducted in 2009/2010 in France (3), Belgium (1), Germany (4), Italy (2) and Spain (2) with 3×0.53 kg ai/ha and a PHI of 20–22 days. The dithianon residues were 0.04, 0.05, 0.06, 0.10, 0.10, 0.18, 0.21, 0.25, 0.27, 0.32, 0.40 and 0.45 mg/kg.

On peaches, twelve trials were conducted in 2009/2010 in France (4), Germany (2), Greece (2), Italy (2) and Spain (2) with 3×0.53 kg ai/ha and a PHI of 20–21 days. The dithianon residues were 0.17, 0.18, 0.24, 0.36, 0.38, 0.43, 0.44, 0.45, 0.56, 0.60, 1.0 and 1.6 mg/kg.

The Meeting noted that the Hungarian GAP is for the stone fruit group, and considered a group maximum residue level. To consider a group maximum residue level, residues in individual commodities should be similar (e.g. medians should not differ by more than five times). The Meeting agreed to estimate a maximum residue level for the group stone fruit.

In deciding whether to combine the datasets for the different crops for use in the statistical calculator or to only utilise the data from the commodity with the highest residues, the Meeting recognised the similarity of the datasets of cherries and peaches (confirmed by the Mann-Whitney U-test). The Meeting agreed to combine these datasets for the purposes of determining a group maximum residue level for stone fruit.

The rank order of the combined dataset of cherries and peaches is ($n = 34$): 0.04, 0.09, 0.17, 0.17, 0.18, 0.19, 0.19, 0.21, 0.24, 0.26, 0.28, 0.34, 0.36, 0.38, 0.38, 0.41, 0.43, 0.43, 0.44, 0.45, 0.45, 0.49, 0.50, 0.56, 0.57, 0.59, 0.60, 0.69, 0.80, 0.82, 0.90, 1.0, 1.0 and 1.6 mg/kg.

The Meeting estimated a maximum residue level of 2 mg/kg, an STMR of 0.43 mg/kg and an HR of 1.6 mg/kg for dithianon residues in stone fruits. The previous recommendation of 5 mg/kg for dithianon in cherries was withdrawn.

Grapes

Dithianon is registered for foliar spray treatment on grapes in Slovenia with $1\text{--}8 \times 0.35$ kg ai/ha and a PHI of 42 days.

Trials on grapes were available from Germany (24). The plants were treated eight times during the growing season with 0.23–0.68 kg ai/ha; the last applications were in a range of 0.44–0.68 kg ai/ha. The Meeting agreed to use the proportionality approach to scale the residues of a PHI of 41–43 days according an application rate of 0.35 kg ai/ha. The rank order of scaled residues was ($n = 24$): 0.15, 0.19, 0.29, 0.34, 0.36, 0.43, 0.44, 0.44, 0.48, 0.50, 0.54, 0.60, 0.61, 0.72, 0.75, 0.76, 0.80, 0.92, 1.0, 1.05, 1.2, 1.2, 1.4 and 2.5 mg/kg.

Further trials were conducted in France (3), Germany (1), Greece (1), Italy (4) and Spain (4). Grapes were treated with 8×0.56 kg ai/ha. The PHI was 41–42 days. The rank order of the scaled dithianon residues on the application rate of 0.35 kg ai/ha were ($n = 13$): 0.21, 0.28, 0.33, 0.37, 0.63, 0.69, 0.69, 0.81, 0.81, 0.88, 0.94, 2.1 and 4.6 mg/kg.

The rank order of the combined scaled residue data was ($n = 37$): 0.15, 0.19, 0.21, 0.28, 0.29, 0.33, 0.34, 0.36, 0.37, 0.43, 0.44, 0.44, 0.48, 0.50, 0.54, 0.60, 0.61, 0.63, 0.69, 0.69, 0.72, 0.75, 0.76, 0.80, 0.81, 0.81, 0.88, 0.92, 0.94, 1.0, 1.05, 1.2, 1.2, 1.4, 2.1, 2.5 and 4.6 mg/kg.

The Meeting estimated a maximum residue level of 5 mg/kg for dithianon residues in grapes. Because the ARfD of 0.1 mg/kg bw is exceeded by the IESTI of dithianon for grapes using 4.6 mg/kg as HR (310% for children, 150% for general population), the Meeting decided that the maximum residue level of 5 mg/kg is not suitable for table grapes and should be apply to wine grapes only. For calculation of residues in processed commodities (juice, wine), a median residue level of 0.69 mg/kg was estimated.

The Meeting agreed to search for an alternative GAP to estimate a maximum residue level, an STMR and an HR for table grapes.

Another registration exists in Serbia of 3×0.35 kg ai/ha and a PHI of 35 days for grapes. Trials on grapes treated with 3×0.53 kg ai/ha and a PHI of 35 days from Germany (4), France (7), Spain (2), Italy (1) and Greece (1) were submitted. The Meeting agreed to use the proportionality approach to estimate a separate maximum residue level, an STMR and HR for table grapes. The scaled residue values according to Serbian application rate were ($n = 15$): 0.29, 0.39, 0.48, 0.50, 0.56, 0.57, 0.59, 0.63, 0.64, 0.73, 0.86, 0.99, 1.1, 1.2 and 1.3 mg/kg.

The Meeting estimated a maximum residue level of 2 mg/kg for dithianon residues in table grapes. The previous recommendation for grapes of 3 mg/kg was withdrawn. An STMR of 0.63 mg/kg and an HR of 1.3 mg/kg were estimated.

Currants

In France, dithianon may be used as foliar spray on currants with an application rate of 2×0.49 kg ai/ha and a PHI of 14 days.

Six trials on black currants according to the French GAP (2×0.53 kg ai/ha, PHI 14 days) were submitted. The dithianon residues were < 0.05 , < 0.05 , ≤ 0.1 , 0.11, 0.61 and 0.89 mg/kg.

The Meeting agreed to extrapolate from black currants to currants, black, red, white and estimated a maximum residue level of 2 mg/kg, an STMR of 0.105 mg/kg and an HR of 0.89 mg/kg for dithianon residues in currants.

Almonds

The registered use of dithianon in almonds in France is foliar spray treatment of 2×0.35 kg ai/ha and a PHI of 58 days. Four French trials in line with French GAP were available. The dithianon residues were in almonds (without shell) < 0.05 mg/kg (4).

The Meeting considered four trials as sufficient for the estimation of a maximum residue level in almonds because dithianon is located on the surface of the shell and no residues are to be expected in the nutmeat and estimated a maximum residue level of 0.05* mg/kg, and an STMR and an HR of 0 mg/kg.

Hops, dry

In Austria and Germany, dithianon is registered for use on hops at 10×0.63 –1.4 kg ai/ha (depending from growth stage) and a PHI of 14 days. German trials in line with GAP (10 – 12×0.3 –1.5 kg ai/ha, PHI 14 days) were submitted. The residues were in dried cones 4.1, 16, 17, 21, 22, 32, 58, 70, 82, 88, 89, 94, 96 and 242 mg/kg.

The Meeting estimated for dithianon residues in hops, dry a maximum residue level of 300 mg/kg and an STMR of 64 mg/kg. The previous recommendation of 100 mg/kg should be replaced.

Fate of residues during processing

Nature of residues

Three studies on the nature of the residue under simulated processing conditions, performed with [¹⁴C] dithianon at higher temperatures, were received.

In the first study, hydrolysis was conducted in buffers solutions whereas in the second study, [¹⁴C] dithianon was incubated in apple juice under the conditions of pasteurization (pH 4, incubation for 20 minutes at 90 °C). In both studies, at pH 4, the parent molecule formed the major part of the radioactivity. In addition, a multiple number of unknown degradation products was formed; each of them < 10% of the total applied radioactivity (TAR). At high temperature conditions and pH 5 (simulated processing conditions of baking, brewing and boiling) or pH 6 (simulated processing conditions of sterilization) the hydrolytic degradation of dithianon was fast and resulted in many degradation products. The degradation product 4110904 was found at pH 5 and pH 6 in concentrations exceeding the level of 10% the total applied radioactivity (TAR) accounting for 46–57% of TRR at pH 5 and for about 20% of TRR at pH 6.

A third hydrolysis study on the degradation of dithianon in apple juice at 90 °C, 100 °C and 120 °C was conducted for further characterization of the components formed. The initial high temperature hydrolysis tests with [¹⁴C] dithianon in apple juice resulted in the rapid disappearance of dithianon. Between 44 and 47% of the TAR remained as dithianon after hydrolysis at 90 °C for 20 minutes, 0.9–1% of the TAR remained as dithianon after hydrolysis at 100 °C for 60 minutes and less than 1% of the TAR remained as parent after hydrolysis at 120 °C for 20 minutes. The results of the identification of the degradation products are as follows:

The initial high temperature hydrolysis tests resulted in the formation of naphthoquinone (4107273) at greater than 10% of the TAR upon 20 minutes of hydrolysis at 120 °C. Formation of 4107273 was not observed in the lower temperature hydrolysis samples. 4107273 was also no longer found after refrigerated storage (21 days/33 days) of the apple juice sample hydrolysed at 120 °C. The compound was only found immediately after hydrolysis.

Phthalic acid (4005234) and compound 4110933 were both observed in hydrolysed apple juice, but always at less than 5% of the TAR.

Compounds 4110904 and 31062 were formed at 9.4% and 10.5% of TAR, respectively, upon 60 minutes of hydrolysis at 100 °C. At 20 minutes of hydrolysis at 120 °C, 4110904 was formed at 5.8% and 31062 at 10% of TAR. Both compounds appear to be stable in hydrolysed apple juice stored refrigerated.

Level of residues

The Meeting received information on the fate of dithianon residues during the processing of oranges to juice, oil and dry pulp, of apples to juice, sauce, dried apple and wet pomace, of cherries to juice, canned cherries and jam, of plums to puree and dried prunes, of grapes to juice, must, wine, raisins and wet pomace and of hops to beer.

The processing factors obtained in the processing studies and estimated STMR-P and HR-P values are summarized below.

Raw agricultural commodity (RAC)			Processed commodity			
Name	STMR (mg/kg)	HR (mg/kg)	Name	Processing factor (median or best estimate)	STMR-P (mg/kg)	HR-P (mg/kg)
Apples	0.15		Juice	< 0.03 (median)	0.0045	
			Sauce	< 0.03 (median)	0.0045	

Raw agricultural commodity (RAC)			Processed commodity			
Name	STMR (mg/kg)	HR (mg/kg)	Name	Processing factor (median or best estimate)	STMR-P (mg/kg)	HR-P (mg/kg)
			Syrup	< 0.04 (median)	0.006	
			Canned apple	< 0.06 (median)	0.009	
			Dried apple	0.1 (median)	0.015	
			Wet pomace	2.2 (median)	0.33	
Cherries	0.43		Juice	< 0.055 (median)	0.024	
			Canned cherries	< 0.055 (median)	0.024	
			Jam	< 0.055 (median)	0.024	
Plums	0.43		Puree	0.035 (median)	0.015	
			Dried prunes	0.515 (median)	0.22	
Wine-grapes	0.69		Juice	< 0.0025 (median)	0.002	
			Must	0.024 (median)	0.017	
			Wine	< 0.003 (median)	0.002	
			Wet pomace	0.93 (median)	0.64	
Table-grapes	0.63	1.3	Raisins	1.64 (median)	1.03	2.13
Hops	64		Beer	< 0.0003 (median)	0.019	

The Meeting noted that dithianon concentrated during processing in apple pomace, wet and in raisins. Because apple pomace is not a commodity in trade, no maximum residue level is estimated.

Based on the recommended MRL of 2 mg/kg for dithianon residues in table grapes and the processing factor of 1.64, the Meeting estimated a maximum residue level of 3.5 mg/kg for dried grapes ($2 \times 1.64 = 3.28$). An STMR-P of 1.03 mg/kg and an HR-P of 2.13 mg/kg were estimated for raisins.

The Meeting discussed the relevance of the hydrolysis products 411094 and 31062 for the residue definition for industrial or household preparations of dithianon treated fruits and made the following assumptions to estimate their dietary intake:

According to the results of the hydrolysis studies, both degradation products accounted for about 10% of the TAR.

In addition to dithianon, the degradation product 4110904 was investigated in the processing studies for dithianon on apples, cherries, plums and grapes. No residues of 4110904 above the LOQ of 0.01 mg/kg were detected in the RAC. The degradate was not detected in must, wine and juice, but in raisins where the residues were lower than 1% of the dithianon residue. The Meeting agreed to use the LOQ for must, wine and juice or the highest real measured value for raisins to estimate the dietary intake of 4110904. For hops, because no data for 4110904 were available, 10% of the STMR for dithianon in hops adjusted by the molecular weight of 4110904 (330.3) was used.

Because no residue data for the degradate 31062 in RAC and the related processed products were submitted, the estimated dietary intake is based on 10% of the STMR of parent dithianon. The Meeting noted that 31062 was formed by dimerization, resulting in the doubling of the radioactivity per molecule. Therefore the stoichiometric factor to extrapolate from dithianon to 31062 residues is 0.635 [$376.1 \div (2 \times 296.3)$]. The 31062 concentrations are calculated as follows:

$$\text{RESIDUE}_{31062} = \text{STMR}_{\text{Dithianon}} \times 0.635 \div 10.$$

The following concentrations of the degradates 4110904 and 31062 were estimated for chronic and acute dietary intake purposes:

Name	Name	4110904, mg/kg	Basis	31062, mg/kg	Basis
Apples,	Juice	0.01	LOQ ₄₁₁₀₉₀₄	0.0095	STMR _{Dithianon}
Pears	Sauce	0.01	LOQ ₄₁₁₀₉₀₄	0.0095	STMR _{Dithianon}
	Canned	0.01	LOQ ₄₁₁₀₉₀₄	0.0095	STMR _{Dithianon}
	Dried	0.01	LOQ ₄₁₁₀₉₀₄	0.0095	STMR _{Dithianon}
Currants	Juice	0.012	STMR _{Dithianon}	0.007	STMR _{Dithianon}
Stone fruits	Juice	0.01	LOQ ₄₁₁₀₉₀₄	0.0273	STMR _{Dithianon}
	Canned	0.01	LOQ ₄₁₁₀₉₀₄	0.0273	STMR _{Dithianon}

Name	Name	4110904, mg/kg	Basis	31062, mg/kg	Basis
	Jam	0.01	LOQ ₄₁₁₀₉₀₄	0.0273	STMR _{Dithianon}
	Plum puree	0.01	LOQ ₄₁₁₀₉₀₄	0.0273	STMR _{Dithianon}
	Dried prunes	0.01	LOQ ₄₁₁₀₉₀₄	0.052	HR _{Dithianon}
Wine-grapes	Juice	0.01	LOQ ₄₁₁₀₉₀₄	0.044	STMR _{Dithianon}
	Must	0.01	LOQ ₄₁₁₀₉₀₄	0.044	STMR _{Dithianon}
	Wine	0.01	LOQ ₄₁₁₀₉₀₄	0.044	STMR _{Dithianon}
Table-grapes	Raisins	0.11	4110904 measured value	0.135	HR _{Dithianon}
Hops	Beer	7.1	STMR _{Dithianon}	4.06	STMR _{Dithianon}

Conservative estimates of long-term exposure of the degradation products Reg. No. 31062 and Reg. No. 4110904 after industrial or household processing were calculated for the 13 GEMS/Food cluster diets using residue concentrations estimated above. The maximum long-term daily intake was 4.7 µg per person (0.00008 mg/kg bw). Applying this intake to the TTC approach (threshold value 0.0015 mg/kg bw, Cramer Class III), the calculated exposures were up to 5% of the TTC.

Conservative estimates of short-term exposure of the degradation products Reg. No. 31062 and Reg. No. 4110904 were calculated using the residue concentrations estimated above. The maximum short-term daily intake was 115 µg per person (0.00192 mg/kg bw). Applying this intake to the TTC approach (threshold value 0.005 mg/kg bw, Cramer Class III), the maximum calculated exposure was 40% of the TTC.

The Meeting concluded that the long-term and short-term intake of residues of Reg. No. 31062 and Reg. No. 4110904 arising of dithianon, when used in ways that have been considered by the JMPR, is unlikely to present a public health concern.

Farm animal dietary burden

The 2013 JMPR evaluated residues of dithianon in apple pomace wet and grape pomace wet which are listed under by-products in the OECD feeding table for beef and dairy cattle but not for poultry.

Estimated maximum and mean dietary burdens of farm animals

Dietary burden calculations based on the feed items evaluated for beef cattle and dairy cattle as presented in Annex 6. The calculations were made according to the livestock diets from Australia, the EU, Japan and US-Canada in the OECD Table. Because the calculation based on the STMR-P values of the processed by-products, the maximum and mean burden is identical. The table below shows the values calculated.

Because apple pomace wet and grape pomace wet are no feed items for poultry, the livestock dietary burden for broiler and layer is zero.

	Livestock dietary burden, dithianon, ppm of dry matter diet							
	US-Canada		EU		Australia		Japan	
	Max	Mean	Max	Mean	Max	Mean	Max	Mean
Beef cattle	0	0	0.165	0.165	0.853 ^a	0.853 ^a	0	0
Dairy cattle	0.083	0.083	0.090	0.090	0.853 ^a	0.853 ^a	0	0
Poultry—broiler	0	0	0	0	0	0	0	0
Poultry—layer	0	0	0	0	0	0	0	0

^a Highest mean and maximum beef or dairy cattle dietary burden suitable for MRL and STMR estimates for mammalian meat, edible offal and milk.

Farm animal feeding and metabolism studies

No animal feeding studies of dithianon were submitted. The Meeting agreed to extrapolate the residue levels to be expected in ruminant tissues and milk from the goat metabolism studies.

The metabolism studies in lactating goats were performed at actual dose levels of 2.5 and 28 ppm in the first study and of 25 ppm in the feed of the second study. The overdosing factors are calculated as about 2.9 (2.5 ppm ÷ 0.853 ppm), 33 (28 ppm ÷ 0.853 ppm) and 29 (25 ppm ÷ 0.853 ppm), respectively.

Animal commodity maximum residue levels

The expected total residues in milk and edible tissues of ruminants can be extrapolated from the highest TRR found in the goat metabolism studies as follows:

Commodity	Feeding level, ppm	TRR from metabolism study, mg/kg	TRR extrapolated from actual dietary burden, mg/kg
Milk	2.5	< 0.01	< 0.003
Liver		0.07	0.024
Kidney		0.04	0.014
Muscle		Not detected	–
Fat		< 0.01	< 0.003
Milk	28	0.030	0.0009
Liver		0.174	0.0053
Kidney		0.489	0.0149
Muscle		0.013	0.0004
Fat		0.014	0.0004
Milk	25	0.016	0.0006
Liver		0.157	0.0054
Kidney		0.475	0.0162
Muscle		0.014	0.0005
Fat		0.074	0.0025

The extrapolated TRR are for milk, muscle and fat are lower than the LOQ of 0.01 of dithianon in animal products. In case of liver and kidney, the extrapolated TRR range from 0.005–0.02 mg/kg and 0.01–0.02 mg/kg, respectively.

The Meeting noted that the results from metabolism studies on rats, goats and hens show that dithianon is intensively metabolized. In the goat, parent dithianon was detected at low levels (≤ 0.01 mg/kg) and no single metabolite in the extracts was detected > 0.05 mg/kg. Therefore, it is not expected that the calculated TRR in cattle tissues and milk arising from a burden of 0.853 ppm would account for 100% of dithianon or a related metabolite. In case of poultry, the dietary burdens for broiler and layer are zero. The Meeting concluded that the contribution of dithianon arising residues in animal products to the dietary intake is negligible.

The Meeting estimated maximum residue levels of 0.01* mg/kg for meat of mammals, other than marine mammals, edible offal (mammalian), milk, poultry meat, poultry edible offal and eggs. The STMR for milk and the STMR/HR values for mammalian and poultry meat, mammalian and poultry edible offal as well as for eggs are zero.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of the residue (for compliance with the MRL and for estimation of dietary intake) for plant and animal commodities: *Dithianon*.

The residue is not fat-soluble.

MRL recommendations and dietary intake

	Commodity	MRL, mg/kg		STMR or STMR-P	HR or HR-P

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Dietary Intakes (IEDIs) of dithianon were calculated for the 13 GEMS/Food cluster diets using STMRs and STMR-Ps estimated by the current Meeting (Annex 3 of the 2013 JMPR Report). The ADI is 0–0.01 mg/kg bw and the calculated IEDIs were 1–7% of the maximum ADI. The Meeting concluded that the long-term intake of residues of dithianon resulting from the uses considered by the current JMPR is unlikely to present a public health concern.

Short-term intake

The International Estimated Short Term Intake (IESTI) for dithianon was calculated for food commodities and their processed fractions for which maximum residue levels were estimated and for which consumption data were available. The results are shown in Annex 4 of the 2013 JMPR Report.

The Meeting noted that for apples and grapes the IESTI calculated according to the maximum GAP exceeded the ARfD of 0.1 mg/kg bw and used an alternative GAP.

For the commodities considered by the JMPR, the IESTI represented 0–40% of the ARfD for the general population and 0–90% of the ARfD for children. The Meeting concluded that the short-term intake of residues of dithianon, when used in ways that have been considered by the JMPR, is unlikely to present a public health concern.

FENBUCONAZOLE (197)

First draft prepared by Mr Makoto Irie, Ministry of Agriculture, Forestry and Fisheries, Tokyo, Japan

APPRAISAL

Fenbuconazole was first evaluated for residues and toxicology by the JMPR in 1997, and then evaluated for residues in 2009 and for toxicology in 2012. The 1997 JMPR allocated an ADI of 0–0.03 mg/kg bw. The 2012 JMPR established an ARfD of 0.2 mg/kg bw.

The Meeting recommended a number of maximum residue levels in 1997 and 2009. Those maximum residue levels were adopted by the Codex Alimentarius Commission in 1999, 2000 and 2013 as Codex MRLs.

The 2009 JMPR received the residue trial data on citrus fruits (grapefruit, oranges and lemons). However, it could not estimate a maximum residue level for fenbuconazole in citrus fruits as the residue trials submitted did not match the available GAP.

Fenbuconazole was scheduled by the Fourt-fourth Session of the CCPR for the residue evaluation of citrus fruits. The “Principles and guidance for application of the proportionality concept for estimation of maximum residue limits for pesticides” were adopted by the Codex Alimentarius Commission in 2013.

Results of supervised residue trials on crops

Information on GAP and supervised trial data were submitted to the 2009 JMPR for lemons and oranges and to the 1997 JMPR for grapefruit and oranges.

Citrus fruits

The GAP on citrus fruit in the USA is a maximum of three foliar applications at a rate of 0.14 kg ai/ha with a PHI of 0 day. Nine trials for grapefruit, sixteen trials for oranges and five trials for lemons were conducted in the USA (3×0.28 kg ai/ha, PHI 0 day). As the application rate of those trials submitted to the 1997 and 2009 JMPR was 2 times the GAP rate, the Meeting decided to use the principle of proportionality to select data for estimating a maximum residue level, an STMR value and an HR value for citrus fruit.

The Meeting considered the result from one trial on grapefruit was not appropriate for use in estimating a maximum residue level as the residue concentration in pulp was higher than in the whole fruit.

Scaled residues in the whole fruit of grapefruit were (scaling factor 0.5: 0.28→0.14 kg ai/ha): 0.05, 0.06, 0.07, 0.08 (2), 0.10, 0.17 and 0.24 mg/kg.

Scaled residues in the whole fruit of oranges were (scaling factor 0.5: 0.28→0.14 kg ai/ha): 0.06 (2), 0.07, 0.08, 0.09 (4), 0.10, 0.14, 0.15 (2), 0.17, 0.22, 0.26 and 0.33 mg/kg.

Scaled residues in the whole fruit in lemons were (scaling factor 0.5: 0.28→0.14 kg ai/ha): 0.26, 0.29 (2), 0.35 and 0.42 mg/kg.

To consider a maximum residue level for a crop group, residues in individual crops should be similar (e.g., medians should not differ by more than 5×). The Meeting agreed to estimate a maximum residue level for the group of citrus fruits. In considering whether to combine data to estimate a maximum residue level, the Meeting recognized that the residue populations from trials on grapefruit, oranges and lemons were significantly different according to statistical test (Kruskal-Wallis H-test): the residue population from trials on lemons was different from those on grapefruit and oranges, while the residue populations from trials on grapefruit and oranges were not different according to statistical test (Mann-Whitney U-test). Therefore, the Meeting decided to combine the grapefruit and oranges data sets to estimate a maximum residue level for citrus fruits (except lemons and limes).

The combined residues in the whole fruit of grapefruit and oranges, in rank order, were (n=24): 0.05, 0.06 (3), 0.07 (2), 0.08 (3), 0.09 (4), 0.10 (2), 0.14, 0.15 (2), 0.17 (2), 0.22, 0.24, 0.26 and 0.33 mg/kg.

Scaled residues in pulp of grapefruit were (scaling factor 0.5): < 0.01 (4) and 0.01 mg/kg.

Scaled residues in pulp of orange were (scaling factor 0.5): < 0.01 (5) mg/kg.

The combined residues in pulp of grapefruit and orange were in rank order (n=10): < 0.01 (9) and 0.01 mg/kg.

Based on the scaled residues in the whole fruit of grapefruit and oranges, the Meeting estimated a maximum residue level of 0.5 mg/kg and an STMR value for processing of 0.09 mg/kg for fenbuconazole in citrus fruit (except lemons and limes). Based on the scaled residues in pulp of grapefruit and orange, the Meeting estimated an STMR value of 0.01 mg/kg and an HR value of 0.01 mg/kg for fenbuconazole in citrus fruit (except lemons and limes).

Scaled residues in pulp of lemon were (scaling factor 0.5): < 0.01, 0.016, 0.018, 0.033 and 0.085 mg/kg.

Based on the scaled residues in the whole fruit of lemon, the Meeting estimated a maximum residue level of 1 mg/kg and an STMR for processing of 0.29 mg/kg for fenbuconazole in lemons and limes. Based on the scaled residues in pulp of lemon, the Meeting estimated an STMR value of 0.018 mg/kg and an HR value of 0.085 mg/kg for fenbuconazole in lemons and limes.

Fate of residues during processing

The Meeting received information on the fate of incurred residues of fenbuconazole during the processing of citrus whole fruit (grapefruit and oranges) to juice, dried pulp and cold press oil conducted in the USA in 2009. Based on processing factors for grapefruit and oranges, in combination with STMR for processing estimated for citrus fruits (except lemons and limes) and lemons and limes, the STMR-Ps for juice, dried pulp and oil were calculated as follows.

Processing factors, STMR-P and HR-P for food and feed

Processed commodity	Calculated processing factors*	PF (Mean or best estimate)	Raw agricultural commodity (RAC) STMR		STMR-P (mg/kg)
			mg/kg	RAC	
Juice	< 0.204, < 0.256	< 0.23	0.09	Citrus fruit (except lemons and limes)	0.021
			0.29	Lemons and limes	0.067
Cold press oil	49.0, 66.7	58	0.09	Citrus fruit (except lemons and limes)	5.2
			0.29	Lemons and limes	17
Dried pulp	6.31, 7.74	7.0	0.09	Citrus fruit (except lemons and limes)	0.63

* Processing factors were derived from the two processing studies each on grapefruit or orange. The factor is the ratio of the residue in processed commodity divided by the residue in the RAC.

The Meeting estimated the maximum residue levels of 4 mg/kg ($0.5 \text{ mg/kg} \times 7.0 = 3.5 \text{ mg/kg}$) for deried citrus pulp, 30 mg/kg ($0.5 \text{ mg/kg} \times 58 = 29 \text{ mg/kg}$) mg/kg for citrus oil (except lemons and limes) and 60 mg/kg ($1 \text{ mg/kg} \times 58 = 58 \text{ mg/kg}$) for oil of lemons and limes based on the maximum residue levels of citrus fruit (except lemons and limes) and of lemons and limes.

Residues in animal commodities

Farm animal feeding studies

A lactating dairy cattle feeding study and a laying hen feeding study were submitted to the 1997 JMPR.

Animal commodity maximum residue levels

Dried citrus pulp may be fed to beef cattle, dairy cattle, broilers and layers. But the STMP-P of dried citrus pulp was low at 0.63 mg/kg not contributing significantly to animal dietary burden. The calculated maximum and mean dietary burdens, with addition of dried citrus pulp, to be used for estimating maximum residue levels for commodities of animal origin (both mammals and poultry) were identical to those calculated by the 2009 JMPR.

The Meeting, therefore, confirmed the previous recommendations of the maximum residue levels for fenbuconazole in animal commodities.

RECOMMENDATIONS

On the basis of the data from supervised trials, the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for dietary intake assessment.

Definition of the residue (for compliance with the MRL and for estimation of dietary intake, for plant and animal commodities): *fenbuconazole*

The residue is not fat soluble.

Commodity		Recommended MRL, mg/kg		STMR or STMR-P, mg/kg	HR or HR-P, mg/kg
CCN	Name	New	Previous		
FC 0001	Citrus fruit (except Lemons and Limes)	0.5	-	0.01	0.01
OR 0001	Citrus oil, edible (except Lemons and Limes)	30	-	5.2	-
AB 0001	Citrus pulp, dry	4	-	0.63	-
FC 0002	Lemons and Limes (including Citron)	1	-	0.018	0.085
	Oil of Lemons and Limes	60	-	17	-

Commodity name	STMR or STMR-P, mg/kg	HR or HR-P, mg/kg
Citrus juice (except lemons and limes)	0.021	-
Juice of lemons and limes	0.067	-

DIETARY RISK ASSESSMENT***Long-term intake***

In the current evaluation STMRs were estimated for 7 food commodities. Where consumption data were available these STMRs were used in the estimates of dietary intake together with previous MRL recommendations for other food commodities. The results are shown in Annex 3 of the 2013 JMPR Report.

The ADI is 0–0.03 mg/kg bw and the calculated IEDIs were 0–2% of the maximum ADI (0.03 mg/kg bw). The Meeting concluded that the long-term intake of residues of fenbuconazole, resulting from the uses considered by current JMPR, is unlikely to present a public health concern.

Short-term intake

The International Estimated Short Term Intake (IESTI) for fenbuconazole was calculated for 7 food commodities (including processed fractions) for which maximum residue levels were estimated at the present meeting and for which consumption data were available. The results are shown in Annex 4 of the 2013 JMPR Report.

The ARfD is 0.2 mg/kg bw and the calculated IESTI were a maximum of 0% of the ARfD for all population groups. The Meeting concluded that the short-term intake of residues of fenbuconazole, when used in ways that have been considered by the JMPR, is unlikely to present a public health concern.

FENPYROXIMATE (193)

*First draft prepared by Dr Yukiko Yamada, Ministry of Agriculture, Forestry and Fisheries,
Tokyo, Japan*

EXPLANATION

Fenpyroximate is a pyrazole non-systemic acaricide. It was first evaluated by JMPR in 1995 and then in 1999 and 2010 for maximum residue levels, and in 2004 and 2007 for toxicology. The currently standing recommendations of JMPR are as follows:

ADI: 0–0.01 mg/kg bw (1995)

ARfD: 0.02 mg/kg bw (2007)

Residue definition—Fenpyroximate for compliance with the MRL and for estimation of dietary intake (both for animal and plant commodities). The residue is fat soluble. (1999)

A number of maximum residue levels have been recommended by the 1995, 1999 and 2010 JMPR including those for citrus fruits, pome fruits, grapes, fruiting vegetables other than cucurbits (except sweet corn and mushroom), cucumber, melon (except water melon), tree nuts, dry hops, dried grapes, dried chilli pepper, and cattle liver meat and milk.

The current Meeting received information on the latest use pattern and the supervised residue trials on stone fruits, strawberry, avocado, cucumber, common bean (pods and/or immature seeds and bean fodder), potato, and mints conducted in the USA.

USE PATTERNS

The authorized uses relevant to the supervised trials data submitted to the current Meeting are summarized in Table 1. They can be applied when pests are immature or at a susceptible stage and populations are building, before crop damage occurs.

Table 1 Registered use of fenpyroximate in the USA relevant to the residue evaluation by the current Meeting

Crop	Form g ai/L	F or G	Application						PHI days
			Method	Rate kg ai/ha	Water L/ha	Seasonal kg ai/ha	No.	Interval days	
Stone fruits (Cherry (sweet and tart), peach & plum)	50 EC	F	Foliar	0.117	≥ 748 (ground only)	≤ 0.234	≤ 2	14	7
Low-growing berry (Strawberry)	50 EC	F	Foliar	0.058–0.117	≥ 234 (ground only)	≤ 0.234	≤ 2	14	1
Avocado	50 EC	F	Foliar	0.058–0.117	≥ 889 (ground) ≥ 468 (air)	≤ 0.234	≤ 2	14	1
Cucumber	50 EC	F	Foliar	0.058–0.117	≥ 374 (ground) ≥ 93.5 (air)	≤ 0.234	≤ 2	14	1
		G ^a	Foliar	0.117	≥ 374	≤ 0.117	≤ 1	14	7
Snap beans ^b	50 EC	F	Foliar	0.117	≥ 281 (ground) ≥ 47 (air)	≤ 0.234	≤ 2	14	1
Potato	50 EC	F	Foliar	0.117	≥ 187 (ground) ≥ 47 (air)	≤ 0.234	≤ 2	7	7
Mint (Peppermint, spearmint)	50 EC	F	Foliar	0.058–0.117	≥ 234 (ground only)	≤ 0.234	≤ 2	7	1

^a Do not apply in ultra-low volume equipment

^b Common beans in the Codex Classification.

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting considered residue data from supervised field trials conducted in the USA on stone fruits, strawberry, avocado, cucumber, common bean (pods and/or immature seeds and bean fodder), potato, and mints with foliar applications of the fenpyroximate emulsion concentrate (EC) formulation (50 g ai/L nominal concentration).

Application rates and residue concentrations were reported as fenpyroximate. Residue concentrations are recorded unadjusted for recoveries or for residue values in control samples. Where multiple samples were taken from a single plot, individual results are reported, and the calculated average concentration (in parentheses) is used for estimation of maximum residue level. Where trials were conducted in the same location, with the same or similar varieties, same or similar formulations, and same equipment, and at the same or similar timing, they are not regarded as independent and only one result from these trials was chosen for the estimation of a maximum residue level.

Residues from the trials conducted according to maximum GAP have been used for the estimation of maximum residue levels and they are underlined.

Crop Group	Commodity	Table No.
Stone fruits	Cherry	Table 2
	Peach	Table 3

Stone fruits

Cherry

A total of eight supervised trials on cherries were conducted in California (one), Colorado (one), Michigan (three), New York (one), and Washington (two) in the USA in 2010 (Samoil, 2012a).

In each trial, two foliar applications of the fenpyroximate EC formulation (56 g ai/L) were made at a rate of approximately 0.11 to 0.12 kg ai/ha per application. An adjuvant (e.g. Induce, Silwet L-77, Activator 90, Ad Wet 90, JMS Stylet oil, Nu-Film 17, or Dyne-Amic) was added to the spray solutions, as appropriate. Applications were made on a 13- to 14- day interval, and the cherries were harvested 7 to 8 days after the last treatment.

Two samples of cherries were collected from each treated plot and untreated plot. Specimens were stored frozen and shipped frozen to the analytical laboratory. Samples were processed with dry ice in a Robot Coupe RSI 10U. Processed samples were stored frozen until analysis.

The method of analysis was based LC-MS/MS using multiple reaction monitoring (MRM) in +ESI mode. The LOQ was 0.05 mg/kg for each analyte. Average recovery of cherries at all fortifications was $96.0 \pm 8.8\%$ and $92.8 \pm 6.0\%$ for fenpyroximate and M-1, respectively (n=18). No control samples contained residues at or above the LOQ of the method.

Table 2 Residues of fenpyroximate in cherries from supervised trials conducted with foliar spray in the USA in 2010

Peach

A total of ten supervised trials on peaches were conducted in Arkansas (one), California (three), Michigan (one), North Carolina (two), New Jersey (two), and Texas (one) in the USA in 2010 (Samoil, 2012b).

In each trial, two foliar applications of the fenpyroximate EC formulation (56 g ai/L) were made at a rate of approximately 0.11 to 0.12 kg ai/ha per application. An adjuvant (Silglow, Induce, Silwet L-77, Pro 90, Agri-Dex, Super Spread 7000, Tricard Silicone, Attach, or Spreader 90) was added to the spray solutions, as appropriate. Applications were made on a 13- to 15- day interval, except for the trials located in Winters, California in which the applications were made on a 7- day interval. The peaches were harvested 6 to 8 days after the last treatment, except for the trials located in Winters, California where samples were collected on DALTs of 2, 7, 11, and 14 days.

Two samples of peaches were collected from each treated plot and untreated plot. Specimens were stored frozen and shipped frozen to the analytical laboratory. Samples were processed with dry ice in a Robot Coupe RSI 10B. Processed samples were stored frozen until analysis.

The method of analysis was based on LC-MS/MS. The LOQ was 0.05 mg/kg for each analyte. Average recovery of peaches at all fortifications was $97.2 \pm 15.5\%$ and $99.8 \pm 10.9\%$ for fenpyroximate and M-1, respectively (n=21). No control samples contained residues at or above the LOQ of the method.

Plum

A total of six supervised trials on plums were conducted in California (four), Michigan (one), and Oregon (one) in the USA in 2010 (Samoil, 2012c).

In each trial, two foliar applications of the fenpyroximate EC formulation (56 g ai/L) were made at a rate of approximately 0.11 to 0.12 kg ai/ha per application, except the CA97 trial in California where an additional treated plot received two foliar applications made at a rate of approximately 0.57 kg ai/ha, 5× exaggerated rate. An adjuvant (Latron B-1956, Induce, Silglow, Pro 90, Super Spread 7000, or Preference) was added to the tank mix, as appropriate. Applications were made 13 to 15 days apart and the plums were harvested 7 days after the last treatment, except that in the trial in Oregon (OR23 trial), plums were collected 6 days after the last treatment.

Two samples of plums were collected from each treated plot and untreated plot. Specimens were stored frozen and shipped frozen to the analytical laboratory. Samples were processed with dry ice in a Robot Coupe RSI 10B. Processed samples were stored frozen until analysis.

The method of analysis was based on LC-MS/MS. The LOQ was 0.05 mg/kg for each analyte. Average recovery of all fortifications for fenpyroximate was 87.2 ± 10.1 (n=17). Average recovery of all fortifications for M-1 was 87.7 ± 7.4 (n=17). No control samples contained residues at or above the LOQ of the method.

^a Same location^b Average in parentheses*Berries and other small fruits**Strawberry*

A total of three supervised trials on strawberries were conducted in California (two) and Florida (one) in the USA in 2008 (Hattermann, 2008). In each trial, two foliar applications of the fenpyroximate SC or EC formulation (50 g ai/L nominal) were made at a rate of approximately 0.11 to 0.12 kg ai/ha per application. Applications were made 14 to 15 days apart and the strawberries were harvested 1 day after the last treatment.

Two samples of strawberries were collected from each treated plot and one untreated plot. Specimens were stored frozen and shipped frozen to the analytical laboratory and were processed with dry ice in a HCM-61 Food Processor. Processed samples were stored frozen until analysis.

The method of analysis was based on gas chromatography with nitrogen/phosphorous detection (GC-NPD). The LOQ was 0.01 mg/kg for each analyte. Average recovery of all fortifications was $91.9 \pm 12.0\%$ for strawberry (n=14). No control samples contained residues at or above the LOQ of the method.

A total of five supervised trials on strawberry were conducted in New York (one), North Carolina (one), Minnesota (one), California (one), and Oregon (one) in the USA in 2010 (Carringer, 2011). In each trial, two foliar applications of the fenpyroximate EC formulation (56 g ai/L) were made at a rate of approximately 0.11 to 0.12 kg ai/ha per application. An adjuvant (Induce, Dyne-Amice, or Silwet) was added to the spray solutions, as appropriate. Applications were made 14 to 15 days apart and the strawberries were harvested 1 day after the last treatment.

Two samples of strawberries were collected from each treated plot and one sample of strawberries was collected from each untreated plot. Specimens were stored frozen and shipped frozen to the analytical laboratory and were processed with dry ice in a Hobart food processor equipped with a 1/8 inch plate or a Robot Coupe RSI 45B grinder. Processed samples were stored frozen until analysis.

The method of analysis was based on LC-MS/MS. The LOQ was 0.01 mg/kg and the LOD was 0.003 mg/kg. Average recovery of all fortifications was $88.9 \pm 9.6\%$ for strawberry (n=37). No control samples contained residues at or above the LOQ of the method.

Avocado

A total of five supervised trials on avocados were conducted in California (four) and Florida (one) in the USA in 2008 and 2009 (Samoil, 2011b).

In each trial, two foliar applications of the fenpyroximate EC formulation (52 g ai/L) were made at a rate of approximately 0.10 to 0.12 kg ai/ha per application. An adjuvant, Omni Supreme Spray (petroleum oil) or First Choice Narrow Range 415 Spray Oil, was added to the tank mix, as appropriate. Applications were made 13 to 17 days apart and the avocados were harvested 1 day after the last treatment.

Two samples each of avocado were collected from each treated plot and untreated plot. Specimens were stored frozen and shipped frozen to the analytical laboratory. Samples were

processed with dry ice in a Hobart food processor. Processed samples were stored frozen until analysis.

The method of analysis was based on gas chromatography coupled to a Mass Selective Detector (MSD) operating in selective ion monitoring (SIM) mode. The LOQ was 0.05 mg/kg. Average recovery of all fortifications was $104.3 \pm 7.3\%$ for avocado (n=18). No control samples contained residues at or above the LOQ of the method.

Cucumber

The 2010 Meeting reviewed the data from supervised trials on cucumbers conducted indoor in European countries following GAP for cucumber (indoor) in the USA with PHI of 7 days. The current Meeting received data from supervised trials on cucumber conducted outdoor following US GAP for cucumber (outdoor) with PHI of 1 day.

A total of nine supervised trials on cucumber were conducted in North Carolina (one), South Carolina (two), Georgia (two), Ohio (two), Texas (one), and California (one) in the USA in 2009 (Leonard, 2011a).

In each trial, two foliar applications of the fenpyroximate EC formulation (56 g ai/L) were made at a rate of approximately 0.11 kg ai/ha per application. An adjuvant, Induce, Activator 90, UAP 80/20, Top Surf, or Kinetic, was added to the tank mix, as appropriate. Applications were made on a 13- to 16-day interval and the cucumbers were harvested 1 day after the last treatment.

Two samples of cucumber were collected from each treated plot and untreated plot. Specimens were stored frozen and shipped frozen to the analytical laboratory. Samples were processed with dry ice in a Hobart food processor. Processed samples were stored frozen until analysis.

The method of analysis was based on LC-MS/MS. The LOQ was 0.05 mg/kg for each analyte, and the LOD was 0.01 mg/kg. Average recovery of all fortifications was $109.7 \pm 8.2\%$ and $96.4 \pm 10.4\%$ for fenpyroximate and M-1, respectively, for cucumber (n=19). No control samples contained residues at or above the LOQ of the method.

DALT: days after the last application

Legume vegetables

Common beans (pods and/or immature seeds)

A total of eight supervised trials on common beans were conducted in California (one), Florida (one), Georgia (one), New York (one), Ohio (two), Washington (one), and Wisconsin (one) in the USA in 2008 (Samoil, 2011a).

In each trial, two foliar applications of the fenpyroximate EC formulation (52 g ai/L) were made at a rate of approximately 0.11 kg ai/ha per application. An adjuvant (Crop Oil COC, Chemnut 80-20 NIS, UAP Surfactant 80/20, Induce, Top Surf, 90 Plus, or Liberate) was added to the spray solutions, as appropriate. Applications were made 13 to 15 days apart and the unshelled immature

beans were harvested 1 day after the last treatment, except for the CA38 trial in which unshelled beans were harvested additionally on 3, 8 and 10 days after the last treatment.

Two samples of unshelled beans were collected from each treated plot and untreated plot; at the CA38 trial, two additional samples were collected from each of the treated plots on each day of harvest. Specimens were stored frozen and shipped frozen to the analytical laboratory. Samples were processed with dry ice in a Hobart Food Chopper. Processed samples were stored frozen until analysis.

The method of analysis was based on LC-MS/MS. The LOQ was 0.05 mg/kg for each analyte. Average recovery of all fortifications was 100.1±12.1% bean (n=38). No control samples contained residues at or above the LOQ of the method.

DALT: days after the last application

^a Average in parentheses

*Root and tuber vegetables**Potato*

A total of sixteen supervised trials on potatoes were conducted in the USA: in New York (two), North Carolina (one), Ohio (one), Michigan (one), Wisconsin (two), New Mexico (one), California (one), Washington (four), and Idaho (two) in 2009 and in Florida (one) in 2010 (Leonard, 2011b).

In each trial, two foliar applications of the fenpyroximate EC formulation (56 g ai/L) were made at a rate of approximately 0.11 to 0.13 kg ai/ha per application. In the ID12 trial, an additional treated plot received two foliar applications made at the 5× exaggerated rate. An adjuvant (Induce, Chem Nut 80/20, Top Surf, Activator 90, Ad Wet 90, or 90 Plus) was added to the spray solutions, as appropriate. Applications were made on a 6- to 8-day interval and the potatoes were harvested 6-7 days after the last treatment, except that in the MI11 and NC18 trials, potatoes were harvested on 0, 3, 7, 11, and 14 or 0, 3, 6, 9, and 12, respectively after the last treatment.

Two samples of potato were collected from each treated plot and untreated plot. In the two decline trials, two additional samples were collected from the treated plot on each day of harvest. Specimens were stored frozen and shipped frozen to the analytical laboratory. Samples were processed with dry ice in a Hobart food processor. Processed samples were stored frozen until analysis.

The method of analysis was based on LC-MS/MS. The LOQ was 0.05 mg/kg for each analyte. Average recovery of all fortifications was $98.3 \pm 6.2\%$ for potatoes (n=58). No control samples contained residues at or above the LOQ of the method.

Herbs

Mints

A total of six supervised trials on mint were conducted in the USA: Washington (three), and Idaho (one) in 2002 (Dorschner, 2005 PR No. 08452), and Wisconsin (two) in 2004 (Dorschner, 2007 PR No.A8542).

In each trial, two foliar applications of the fenpyroximate EC formulation (52 g ai/L) were made at a rate of approximately 0.11 to 0.13 kg ai/ha per application. Applications were made 6 to 8 days apart and the mint was harvested 1 day after the last treatment.

Two samples of mint were collected from each treated plot and untreated plot. Specimens were stored frozen and shipped frozen to the analytical laboratory. Samples were processed with dry ice in a Hobart food processor. Processed samples were stored frozen until analysis.

The method of analysis was based on GC-NPD. The LOQ was 0.05 mg/kg for combined residues of fenpyroximate and M-1. Average recovery of all fortifications was $107.0 \pm 10.4\%$ for mint (n=25). No control samples contained residues at or above the LOQ of the method.

As the method analyses fenpyroximate and M-1 as M-1, no information was available on the concentrations of fenpyroximate alone.

FATES OF RESIDUES IN STORAGE AND PROCESSING

In processing

Plum

A processing study was conducted using fresh plum samples taken 7 days after the last treatment in one field trial in Parlier, California, with two applications of fenpyroximate at a rate of 0.57 kg ai/ha each, 5× the GAP rate (Samoil, 2012c). Dried plums were prepared from fresh plums simulating commercial practices by pitting and placing them in dryers set at around 57 °C to 60 °C for 15 to 17 hours until the moisture level reached around 25 to 26%. Fresh and dried samples were shipped frozen to the laboratory, where the samples remained frozen until analysis.

Residues of fenpyroximate and M-1 were analysed in the different plum matrices were determined by LC-MS/MS. The method was validated prior to analysis with a LOQ of 0.05 mg/kg for

fenpyroximate and M-1 in fresh and dried plums. The recoveries of fenpyroximate were 72–107% in fresh plums, and 92–118% in dried plums.

As shown in Table 12, residues of fenpyroximate concentrated during the processing of dried plums.

Table 12 Residues of fenpyroximate in fresh and dried plums

Commodity	Fenpyroximate mg/kg	Processing factor for Fenpyroximate	M-1 mg/kg
Fresh plum	1.84	–	0.208
Dried plum	3.18	1.73	0.316

Potato

A processing study was conducted using potato samples taken 7 days after the last treatment in one field trial in Kimberly, Idaho, with two applications of fenpyroximate at a rate of 0.57 kg ai/ha each, 5× the GAP rate. (Leonard 2011b). Potatoes were processed into flakes, chips, and wet peels by steam peeling, scrubbing, pressing, trimming, cutting, rinsing free starch, precooking in a steam jacketed kettle, cooling, cooking in a steam jacketed kettle, mashing, mixing with additives, drying in a drum dryer, breaking in a mill, and drying, using a procedure that simulated commercial practice. Processed samples and a retained whole potato sample were shipped frozen to the laboratory, where the samples remained frozen until analysis.

Residues of fenpyroximate and M-1 were determined by LC-MS/MS. The method was validated prior to analysis with a LOQ of 0.05 mg/kg for fenpyroximate and M-1 in all matrices. The recoveries for fenpyroximate were 110% in potato tubers, 83% in potato flakes, 90% in potato chips, and 99% in potato wet peels.

The results of the processing study are summarized in Table 13. As residues in fresh and processed potato samples are all less than the LOQ, it was not possible to calculate processing factors.

Table 13 Residues of fenpyroximate in potatoes and their processed commodities

Commodity	Fenpyroximate mg/kg	M-1 mg/kg
Potato (RAC)	< 0.05, < 0.05	< 0.05, < 0.05
Potato flakes	< 0.05, < 0.05	< 0.05, < 0.05
Potato chips	< 0.05, < 0.05	< 0.05, < 0.05
Potato wet peels	< 0.05, < 0.05	< 0.05, < 0.05

Mint

A processing study was conducted using mint samples taken 1 day after the last application in two field trials (one in Prosser, Washington, and the other in Portage, Wisconsin) with two applications of fenpyroximate at a rate of 0.11 to 0.12 kg ai/ha each complying with the GAP rate (Dorschner 2005 and Dorschner 2007). Samples were processed into oil by distilling using a mint still, a procedure that simulated commercial practice. Processed samples and a retained whole mint sample were shipped frozen to the laboratory, where the samples remained frozen until analysis.

Residues of fenpyroximate and M-1 in the different mint matrices were analysed as M-1 by GC with a nitrogen phosphorous detector. The method was validated prior to analysis with a LOQ of 0.05 mg/kg for mint leaves and 0.10 mg/kg for mint oil. The recoveries were 108% and 100% for mint leaves and 97% and 106% for mint oil as reported in Dorschner 2005 and Dorschner 2007, respectively.

The results of the processing study are summarized in Table 14. Although it was not possible to calculate a processing factor for fenpyroximate alone as no concentrations of fenpyroximate alone were reported, the sum of fenpyroximate and M-1 decreased during processing into oil.

Table 14 Residues of fenpyroximate in mint leaves and mint oil

Commodity	Fenpyroximate +M-1 mg/kg	Processing factor for Fenpyroximate +M-1	Reference
Fresh mint	1.1	–	Dorschner 2005 (PR No. 08452)
Mint oil	< 0.10	< 0.09	
Fresh mint	1.01, 1.05	–	Dorschner 2007 (PR No. A8452)
Mint oil	0.254, 0.206	0.25, 0.20	
	Best estimate	0.20	

APPRAISAL

Fenpyroximate is a pyrazole non-systemic acaricide. It was first evaluated by JMPR in 1995 and then in 1999 and 2010 for maximum residue levels, and in 2004 and 2007 for toxicology. The currently standing recommendations of JMPR are as follows:

ADI: 0–0.01 mg/kg bw (1995)

ARfD: 0.02 mg/kg bw (2007)

Residue definition: Fenpyroximate for compliance with the MRL and for estimation of dietary intake (both for animal and plant commodities). The residue is fat soluble. (1999)

The current Meeting received information on the latest use pattern and the supervised residue trials on stone fruits, strawberry, avocado, cucumber, common bean (pods and/or immature seeds and bean fodder), potato and mints conducted in the USA.

Results of supervised residue trials on crops

The Meeting received supervised trial data for fenpyroximate conducted in the USA on stone fruits, strawberry, avocado, cucumber, common bean (pods and/or immature seeds; and bean fodder), potato and mints with foliar applications of the fenpyroximate emulsion concentrate (EC) formulation.

For estimating HR or highest residue, the highest individual residue concentration from the trials conducted in accordance with GAP was used.

Stone fruits

The approved use of fenpyroximate on stone fruits in the USA consists of up to two foliar spray applications with an interval of 14 days at a maximum rate of 0.117 kg ai/ha and a minimum of 748 L/ha of water, the PHI is 7 days. In supervised residue trials, various adjuvants were used with the result that there were no significant difference or trend found between the different adjuvants.

A total of eight supervised trials on cherries were conducted in the USA in 2010. The residues of fenpyroximate in cherries from six independent trials in accordance with US GAP were in rank order: 0.27, 0.34, 0.46, 0.69, 0.81 and 0.87 mg/kg.

The Meeting estimated an STMR of 0.57 mg/kg for cherries.

A total of ten supervised trials on peach were conducted in the USA in 2010. The residues from seven trials in accordance with US GAP were in rank order: 0.08, 0.08, 0.12, 0.13, 0.13, 0.15 and 0.18 mg/kg.

The Meeting estimated an STMR of 0.13 mg/kg for peach.

A total of six supervised trials on plum were conducted in the USA in 2010. The residues from five trials in accordance with US GAP were in rank order: < 0.05, 0.09, 0.13, 0.20 and 0.27 mg/kg.

The Meeting estimated an STMR of 0.13 mg/kg for plum.

The GAP in the USA covers the group of stone fruits; and the STMRs for cherries, peach and plum were within five-fold difference. However, the Meeting decided to estimate two maximum

residue levels, one for cherries and the other for stone fruits except cherries, in order to avoid probability of IESTI for children calculated for peach exceeding the ARfD.

The Meeting therefore estimated a maximum residue level, STMR and HR of 2, 0.57 and 0.90 mg/kg, respectively for cherries.

As the residue populations of peach and plum were similar according to the Mann-Whitney U test, the Meeting decided to combine the data to recommend a maximum residue level for stone fruits except cherries. The combined residues were in rank order (n=12): < 0.05, 0.08, 0.08, 0.09, 0.12, 0.13, 0.13, 0.13, 0.15, 0.18, 0.20 and 0.27 mg/kg.

The Meeting estimated a maximum residue level, STMR and HR at 0.4, 0.13 and 0.29 mg/kg, respectively, for stone fruits, except cherries.

Strawberry

The approved use of fenpyroximate on strawberry in the USA consists of up to two foliar spray applications with an interval of 14 days at a maximum rate of 0.117 kg ai/ha and a minimum of 234 L/ha of water. PHI is 1 day.

A total of three supervised trials on strawberry were conducted in the USA in 2008. In a trial in Porterville, California, the water volume was less than the minimum specified in GAP. However, as the Meeting considered that difference in spray volume would have little impact on terminal residues, the Meeting used the residue data from this trial for the estimation of maximum residue level.

A total of five supervised trials on strawberry were also conducted in the USA in 2010.

The residues of fenpyroximate in strawberry from eight independent trials in accordance with US GAP were in rank order: 0.07, 0.08, 0.19, 0.19, 0.24, 0.24, 0.28 and 0.53 mg/kg.

The Meeting estimated a maximum residue level, STMR and HR at 0.8, 0.215 and 0.59 mg/kg, respectively for strawberry.

Avocado

The approved use of fenpyroximate on avocado in the USA consists of up to two foliar spray applications with an interval of 14 days at a maximum rate of 0.117 kg ai/ha and a minimum of 889 L/ha of water (for ground spray). PHI is 1 day.

A total of five supervised trials on avocado were conducted in the USA in 2008 and 2009. The residues of fenpyroximate in avocado from four independent trials in accordance with US GAP were in rank order: < 0.05 (2), 0.06 and 0.10 mg/kg.

The Meeting estimated a maximum residue level, STMR and HR at 0.2, 0.055 and 0.10 mg/kg respectively for avocado.

Cucumber

The current approved use of fenpyroximate on field grown cucumber in the USA consists of up to two foliar spray applications with an interval of 14 days at a maximum rate of 0.117 kg ai/ha and a minimum of 374 L/ha of water (for ground spray). PHI is 1 day.

A total of nine supervised trials on cucumber were conducted outdoor in the USA in 2009. The residues of fenpyroximate in cucumber from nine independent trials in accordance with US GAP were in rank order: < 0.05 (2), 0.06, 0.07, 0.07, 0.08, 0.08, 0.11 and 0.17 mg/kg.

The Meeting estimated a maximum residue level, STMR and HR at 0.3, 0.07 and 0.19 mg/kg respectively for cucumber. The new recommendation replaces that of the 2010 JMPR (maximum residue level of 0.03 mg/kg).

Common beans (pods and/or immature seeds)

The approved use of fenpyroximate on common beans (US GAP for snap beans) in the USA consists of up to two foliar spray applications with an interval of 14 days at a maximum rate of 0.117 kg ai/ha and a minimum of 281 L/ha of water (for ground spray). PHI is 1 day.

A total of eight supervised trials on common beans were conducted in the USA in 2008. The residues of fenpyroximate in common beans (pods and/or immature seeds) from seven independent trials in accordance with US GAP were in rank order: < 0.05, 0.09, 0.09, 0.09, 0.15, 0.18 and 0.19 mg/kg.

The Meeting estimated a maximum residue level, STMR and HR at 0.4, 0.09 and 0.19 mg/kg respectively for common beans (pods and/or immature seeds).

Potato

The approved use of fenpyroximate on potato in the USA consists of up to two foliar spray applications with an interval of 7 days at a maximum rate of 0.117 kg ai/ha and a minimum of 187 L/ha of water (for ground spray). PHI is 7 days.

A total of sixteen supervised trials on potato were conducted in the USA. The residues of fenpyroximate in potato from fourteen independent trials in accordance with US GAP were in rank order: < 0.05 (14) mg/kg. The residues of fenpyroximate from one trial in which the application rate was 5 times the GAP rate were also < 0.05 mg/kg.

The Meeting estimated a maximum residue level, STMR and HR at 0.05 *, 0 and 0 mg/kg respectively for potato.

Mints

The approved use of fenpyroximate on mint in the USA consists of up to two foliar spray applications with an interval of 7 days at a maximum rate of 0.117 kg ai/ha and a minimum of 234 L/ha of water (for ground spray). PHI is 1 day.

A total of six supervised trials on mint were conducted in the USA. As the method used analyses fenpyroximate and M-1 as M-1, no information was available on the concentrations of fenpyroximate alone. In general, the concentrations of M-1 in food commodities were much lower than those of fenpyroximate but the data from supervised residue trials provided to JMPR so far indicate that M-1 can be present up to 30% of fenpyroximate. The Meeting considered that the information was insufficient to estimate a maximum residue level for mints.

Legume animal feeds*Bean forage*

Common bean plants with pods were sampled by cutting the whole plant at soil level.

The residues of fenpyroximate in foliage of common bean plant from seven independent trials in accordance with US GAP were in rank order: < 0.05, 0.90, 1.87, 1.92, 2.45, 3.42 and 5.80 mg/kg on a fresh weight basis.

The Meeting estimated a median residue and highest residue at 1.92 and 6.50 mg/kg respectively for bean forage (on a fresh weight basis) for the purpose calculating livestock dietary burdens.

Fate of residues during processing

The Meeting received information on the processing of plum into dried plums; potato into potato flakes, chips and wet peels; and mint into mint oils.

As concentration of fenpyroximate was observed in the processing of plums, there was a need to estimate a maximum residue level for dried plum. Using the processing factor of 1.73 shown below, a maximum residue level for dried plum was estimated to be 0.7 mg/kg.

Commodity	Fenpyroximate mg/kg	Processing factor for Fenpyroximate	STMR-(P)	HR-(P)
Fresh plum	1.84	-	0.11	0.29
Dried plum	3.18	1.73	0.18	0.50

As for processing of potato, no processing factors could be calculated as the residues of fenpyroximate were all below the LOQ of 0.05 mg/kg in fresh potato and processed potato products (flakes, chips and wet peels).

As for processing of mint, since no information was available for the concentration of fenpyroximate alone was available, processing factor of fenpyroximate could not be calculated. The best estimate of processing factor for the sum of fenpyroximate and M-1 in the processing of mint to mint oil was 0.20.

Residues in animal commodities

Estimation of dietary burdens

Among commodities reviewed by the 1999, 2010 and the current JMPR, apple wet pomace (STMR-P, 0.05 mg/kg), dry citrus pulp (STMR-P, 0.64 mg/kg), wet grape pomace (STMR-P, 0.06 mg/kg), wet tomato pomace (STMR-P, 0.03 mg/kg), bean forage (median residue, 1.89 mg/kg; and highest residue, 3.415 mg/kg on a fresh weight basis) and potato wet peel (STMR-P, 0.05 mg/kg) can be fed to beef and dairy cattle. There have been no feed items for poultry.

The maximum and mean dietary burdens were calculated using the highest residue and STMR/median residue of fenpyroximate in the above-mentioned commodities on a basis of the OECD Animal Feeding Table. The summary of calculated dietary burdens of fenpyroximate is shown in the following table.

Summary of livestock dietary burdens (ppm of dry matter diet)

	US-Canada		EU		Australia		Japan	
	max	mean	max	Mean	max	mean	Max	mean
Beef cattle	0.15	0.15	0.18	0.18	11.35	3.50	-	-
Dairy cattle	0.07	0.07	3.90 ^a	1.28 ^b	13.21	4.05	-	-

^a Suitable for estimating maximum residue levels for meat, fat, edible offal and milk of cattle (see below).

^b Suitable for estimating STMRs for meat, fat, edible offal and milk of cattle (see below).

Residues in milk and mammalian tissues

The 1999 JMPR reviewed a cattle feeding study conducted at levels equivalent to 1, 3 and 10 ppm in the feed. In the study, fenpyroximate in milk or tissues was measured together with M-1. No information was available on the concentration of fenpyroximate alone. Nonetheless, the 1999 JMPR and 2010 JMPR used the results of this study as the dietary burdens were lower than 1 ppm and the residue concentrations in the tissues and milk were also very low.

In the animal metabolism study, residues of M-1 in tissues and milk were < 0.001 mg/kg and less than fenpyroximate except in the case of liver in which M-1 was present at much higher concentrations. In the animal feeding study, the sum of fenpyroximate and M-1 in kidney was higher than that in liver, and as such, the residue in kidney would be the basis for a maximum residue level for edible offal. In kidney, the concentration of fenpyroximate was significantly higher than that of M-

1. Therefore, the Meeting decided to use the results of animal feeding study recognizing that it would lead to some overestimate of maximum residue level.

The maximum and mean dietary burdens in cattle were 13.21 and 4.05 ppm of dry matter diet respectively. The Meeting noted that the highest maximum dietary burden in cattle, based on animal feed ration in Australia, was higher than the highest feeding level of 10 ppm in feed in the cattle feeding study by about 30%.

As fenpyroximate has not been authorized for use for common beans in Australia, and bean forage is not generally traded internationally, the Meeting decided to use the second highest maximum dietary burden based on the animal feed ration in Europe, where use of fenpyroximate for common bean has been authorized, together with residue levels in tissues and milk at 1, 3 and 10 ppm dose groups. The maximum dietary burden calculated for cattle using the feed ration in Australia without bean forage was 0.21 ppm in dry matter diet.

	Feed level (ppm) for milk residues	Fenpyroximate+M-1 (mg/kg) in milk	Feed level (ppm) for Tissue residues	Fenpyroximate+M-1 (mg/kg) in			
				Muscle	Liver	Kidney	Fat
Maximum residue level beef or dairy cattle							
Feeding study ^a	3	0.0062	3	0.017	< 0.003	< 0.01	0.073
	10	0.013	10	0.049	0.011	0.019	0.159
Dietary burden and highest residue	3.90	0.007	3.90	0.021	0.004	0.011	0.084
STMR beef or dairy cattle							
Feeding study ^b	1	-	1	< 0.01	< 0.003	< 0.003	0.015
	3	0.0062	3	0.015	< 0.003	< 0.003	0.056
Dietary burden and mean residue	1.28	< 0.005	1.28	0.011	< 0.003	< 0.003	0.021

^a highest residues for tissues and mean residue for milk

^b mean residues for tissues and mean residue for milk

The Meeting estimated STMR of 0.005, 0.011, 0.003, 0.003 and 0.021 mg/kg for milk, muscle, liver, kidney and fat, respectively; and HR of 0.021, 0.004, 0.011 and 0.084 mg/kg for muscle, liver, kidney and fat, respectively.

The Meeting estimated maximum residue levels of 0.01* mg/kg for milks, 0.02 mg/kg for edible offal (mammalian) and 0.2 mg/kg (fat) for meat (from mammals other than marine mammals) and withdrew the existing CXLs for cattle milk, kidney, liver and meat.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of the residue for both plant and animal commodities (for compliance with the MRL and for estimation of dietary intake): *fenpyroximate*.

The residue is fat soluble.

Commodity		Recommended MRL, mg/kg		STMR/STMR-P mg/kg	HR/HR-P mg/kg
CCN	Name	New	Previous		
FI 0326	Avocado	0.2	-	0.055	0.10
MO 1280	Cattle kidney	W	0.01*		
MO 1281	Cattle liver	W	0.01*		

Commodity		Recommended MRL, mg/kg		STMR/STMR-P	HR/HR-P

For calculating animal dietary burden

Commodity		Recommended MRL, mg/kg		STMR/STMR-P	HR/HR-P
CCN	Name	New	Previous	mg/kg	mg/kg
AL 1030	Bean forage			1.92 ^a	5.80 ^a

^a for the purpose of calculating animal dietary burdens. Expressed on an “as received” basis.

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Dietary Intakes (IEDIs) of fenpyroximate were calculated for the 13 GEMS/Food cluster diets using STMRs and STMRPs estimated by the 1999, 2010 and current Meetings, see Annex 3 of the 2013 JMPR Report. The ADI is 0–0.01 mg/kg bw and the calculated IEDIs were 1–7% of the maximum ADI. The Meeting concluded that the long-term intake of residues of fenpyroximate resulting from the uses considered by the JMPR is unlikely to present a public health concern.

Short-term intake

The International Estimated Short-Term Intakes (IESTI) of fenpyroximate were calculated for commodities and their processed commodities using STMRs/STMR-Ps estimated by the current Meeting, see Annex 4 of the 2013 JMPR Report. The ARfD is 0.02 mg/kg and the calculated IESTIs were 0–80% of the ARfD. The Meeting concluded that the short-term intake of residues of fenpyroximate, when used in ways that have been considered by the JMPR, is unlikely to present a public health concern.

FLUDIOXONIL (211)

The first draft was prepared by Professor Eloisa Dutra Caldas

University of Brasilia, Brasilia/DF, Brazil

EXPLANATION

Fludioxonil is a phenylpyrrole fungicide that was reviewed by the JMPR in 2004 (T, R), 2010 (R) and 2012 (R). The compound was listed by the Forty-fourth Session of CCPR for the evaluation by the 2013 JMPR. Residue studies were submitted for pineapple, tomato, fresh peas, dry beans and potato, and processing studies on pineapple, tomato and potato. Additionally, a farm hen feeding study and analytical method to analyse fludioxonil and its metabolites in poultry tissues and eggs were also submitted.

Definition of residue for compliance with the MRLs and estimation of dietary intake in plant commodities: fludioxonil. Definition of residue for compliance with the MRLs and estimation of dietary intake: sum of fludioxonil and its benzopyrrole metabolites, determined as 2,2-difluorobenzo[1,1]dioxole-4-carboxylic acid and expressed as fludioxonil. The residue is fat-soluble.

METHODS OF RESIDUE ANALYSIS

Method GRM025.03A determines fludioxonil and its metabolites oxidisable to CGA192155 (2,2-difluorobenzo[1,3]dioxole-4-carboxylic acid) in poultry tissues and eggs (Sole 2008, 2008a). Samples of muscle, liver and kidney are homogenised and extracted by refluxing with ammonium hydroxide:acetonitrile (80:20 v/v). After filtration, the aqueous phase is acidified and partitioned with toluene following addition of sodium chloride. Conversion of fludioxonil and its metabolites to CGA192155 is carried out by heating in the presence of potassium permanganate and aqueous sodium hydroxide; the oxidation is then quenched with sodium metabisulfite, the extracts are filtered, acidified, and partitioned into dichloromethane:ethyl acetate (80:20 v/v). After evaporation, the residues are dissolved in acetonitrile:water (50:50 v/v) and determined as total fludioxonil by LC-MS/MS. A molecular weight correction factor of 1.23 is applied when calculating procedural recovery values and quantifying residues of CGA192155. The recoveries obtained are shown in Table 1.

Table 1 Recovery of CGA192155 (2,2-difluorobenzo[1,3]dioxole-4-carboxylic acid) expressed as fludioxonil obtained during method validation

Matrix effects (enhancement or suppression) were greater than 10% for several matrices, and the use of matrix-matched standards is recommended. Standard solutions containing CGA192155 at concentrations ranging from 0.0005 to 0.05 µg/mL (equivalent to 5 to 500 pg of analyte injected on column based on a 10 µL injection) were analysed. The response of the LC-MS/MS system was shown to be linear for CGA192155 primary transition (201.0>157.0 m/z) and the confirmatory transition (201.0>91.0 m/z) over the concentration range tested. The relative standard deviations (RSDs) of recoveries at each fortification level and overall for each matrix tested during method validation were < 20% and therefore according to the EU Guidance (SANCO 3029/99 rev 4. 11/07/00) demonstrate the method has satisfactory repeatability.

The validated limit of quantification for fludioxonil and metabolites as CGA192155 in animal tissues was 0.01 mg/kg for fludioxonil (= 0.0081 mg/kg for CGA192155) when measured as CGA192155 for all animal matrices tested. The stability of CGA192155 was assessed by storing the extracts of representative animal matrices (eggs and liver) refrigerated at 0-9°C and re-analysing them (in quintuplet) after 7 and 9 days of storage. The results showed that the residues were stable in the extracts over these time periods.

USE PATTERNS

All the supervised trials submitted by the manufacturer were conducted in the United States or in Canada. Table 2 shows the registered uses of fludioxonil in USA for the crops relevant to this submission.

Table 2 Use patterns of fludioxonil in USA

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

Supervised residue trials (149) conducted with fludioxonil in Canada and USA were submitted to the Meeting. Studies were conducted according to GLP, and specified concurrent determination of residues in untreated crops gave residues < LOQ. Residues of fludioxonil arising from use patterns where rate or PHI or $\pm 25\%$ of GAP are underlined and considered for estimation of maximum residue levels and STMRs. In the tables, DAT means days after treatment. In all trials, unless specified, two samples were analysed and the mean residues reported.

Lemon

Five supervised residue trials were conducted in the USA during the 2004-2005 growing season. After harvest, samples were dried and stored deep-frozen for less than 22 months. The results are summarized in Table 3.

Table 3 Residues resulting from fludioxonil application to lemon in USA and Canada (Report: IR-4 PR No. 08297) ^a

Pineapple

Eight supervised residue trials were conducted in the USA (Hawaii) in 2009. From each site, pineapple fruit were treated twice post-harvest with the test substance in either a dip plus wax followed by a spray directed to the peduncle or a drench plus wax followed by a spray directed to the peduncle. The fruit was allowed to air dry between applications, and samples of pineapple fruit without crowns were collected following the second application, after the test substance had dried. Samples were stored deep-frozen for a maximum of 18 months. The results are summarized in Table 5.

Table 5 Residues of fludioxonil in pineapple after post-harvest treatment (Report: IR-4 PR No. 10203)

Potato

Five post-harvest trials were conducted in the United States and Canada during 2009 and 2010. From each site, potato tubers were treated as a spray directed to tubers falling from a conveyor belt or moving along a roller table. Samples were stored deep-frozen for a maximum of 11.3 months before analysis. The results are summarized in Table 11.

^a. potato samples were cut in half in the field;

^b. spray directed to tubers falling from conveyor belt or moving along a roller table;

^c. spray directed to tubers placed on a flat surface (i.e. tarp) close together, allowed to dry, turned over, and sprayed again;

^d. spray directed to tubers placed close together inside a spray chamber, allowed to dry, turned over, and sprayed again;

^e. spray directed to tubers placed on a brush table that rolled the potatoes under the spray.

Radish

Six supervised residue trials were conducted in USA in 2004. The results from analysis of treated samples are summarized in Table 12.

RESIDUES IN PROCESSED COMMODITIES

Pineapple

The trial 10203.09-HI05 shown in Table 4 included a processing study. Pineapple fruit (5.62 mg/kg fludioxonil) was processed to juice, that contained residue of 5.40 mg/kg, with a processing factor of 0.96.

Tomato

In one processing study, tomato plants received four foliar applications of fludioxonil (0.24 kg ai/ha), and samples were processed simulating commercial practices (Thompson, 2005; IR-4 PR No. 08124). After washing, the tomatoes were placed in a grinder and the crush was pumped into a hot break system. The crush was heated and processed through a finisher to remove peel and seeds. The resulting juice was concentrated to puree with a vacuum evaporator. After puree sample collection, the remaining puree was condensed into paste. Residues was 0.14 mg/kg in RAC, 0.05 mg/kg in pure (PF=0.36) and 0.15 mg/kg in paste (PF=1.1).

Potato

The trial 09-ID19 shown in Table 8 included a processing study. Residues in tubers were 0.472 mg/kg, in wet peel 0.797 mg/kg (PF=1.69), 0.01 mg/kg in flakes (PF=< 0.02) and 0.018 mg/kg in chips (PF=0.04).

RESIDUES IN ANIMAL COMMODITIES

Farm Animal Feeding Studies

Hen feeding study

A residue transfer study in poultry was carried out with four dosing level groups following a 28-day repeat dose regime via a gelatin capsule (Leslie, 2009; Report No. 1983/108-D2149). Dose levels were 1.54, 4.64 and 15.4 mg/kg feed (AR). Each of the four dosed groups was further sub divided into three sub-groups. Collection of eggs was made in the afternoon following dosing and the following morning immediately prior to dosing, which comprised a single day's sample. Following sacrifice, samples of tissue were homogenised to a fine powder in the presence of dry ice and stored frozen prior to analysis. Samples from the 10× dose group were analysed initially and then those from the lower dose group analysed if residues of fludioxonil were found to be above LOQ. The maximum storage period for eggs and tissues samples was 58 days. Residue levels (sum of fludioxonil and its benzopyrrole metabolites, determined as 2,2-difluorobeno[1,1]dioxole-4-carboxylic acid and expressed as fludioxonil) in eggs as a function of time from the three dosed groups are shown in Table 19.

Table 19 Fludioxonil residue level in eggs (sum of fludioxonil and its benzopyrrole metabolites, determined as 2,2-difluorobeno[1,1]dioxole-4-carboxylic acid and expressed as fludioxonil)

Days after dosing	Equivalent Fludioxonil Residue Level (mg/kg)					
	1.54 ppm		4.64 ppm		15.4 ppm	
	Average	Max	Average	Max	Average	Max
0	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01
1	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01
3	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01
5	< 0.01	< 0.01	0.010	0.013	0.024	0.036
7	< 0.01	< 0.01	< 0.01	< 0.01	0.026	0.032

28	< 0.01	< 0.01	0.011	0.013	0.040	0.052

Residue levels in tissues as a function of feeding level from the three dosed groups are summarised in Table 20. Muscle samples from animals treated at 15.4 ppm per day exhibited residues <LOQ and so further analysis of samples from the lower dose groups was not considered necessary.

Table 20 Fludioxonil residue level in tissues (sum of fludioxonil and its benzopyrrole metabolites, determined as 2,2-difluorobeno[1,1]dioxole-4-carboxylic acid and expressed as fludioxonil)

		Equivalent Fludioxonil Residue Level (mg/kg)

	Average	< 0.01	0.035	0.020	0.283

na = not analysed

One of the highest dosed group of animals remained on the study after the cessation of dosing to monitor the elimination of fludioxonil from eggs and tissues after dosing had been withdrawn – depuration phase. Commensurate with the dosing phase, egg samples were collected twice daily until twelve days after dosing ceased. From this final group, the three sub groups were sacrificed at three, seven, and eleven days after cessation of dosing and edible tissue samples were retained as for the dosing period. The results are shown in Table 21.

Table 21 Summary of equivalent fludioxonil residue levels in egg samples across sub groups during depuration phase.

Number Days after end of dosing	Equivalent Fludioxonil Residue Level (mg/kg)		
	Sub Group A	Sub Group B	Sub Group C
0	0.024	0.035	0.032
1	0.029	0.032	0.028
3	0.024	0.023	0.022
4	Na	< 0.01	< 0.01
6	Na	< 0.01	< 0.01
8	Na	< 0.01	< 0.01
10	Na	na	< 0.01
11	Na	na	< 0.01

na = not available for analysis – animals sacrificed

Fludioxonil was not detected in any of the muscle, fat and liver samples from the depuration study (< LOQ), suggesting rapid elimination of fludioxonil following completion of dosing.

APPRAISAL

Fludioxonil was reviewed by the JMPR in 2004, 2006, 2010 and most recently in 2012. The ADI for fludioxonil is 0–0.4 mg/kg bw and an ARfD was considered unnecessary. Residue studies were submitted by the manufacturer for various crops, in addition to a hen feeding study and analytical method for poultry tissues and eggs.

The residue definition for fludioxonil for plant commodities for compliance with the MRL and estimation of dietary intakes is fludioxonil. For animal commodities the residue is the sum of fludioxonil and its benzopyrrole metabolites, determined as 2,2-difluoro-benzo[1,3]dioxole-4-carboxylic acid and expressed as fludioxonil. The residue is considered fat-soluble.

Methods of analysis

Method GRM025.03A, not previously evaluated by the JMPR, determines fludioxonil and its metabolites oxidisable to 2,2-difluorobenzo[1,3]dioxole-4-carboxylic acid (CGA192155) in poultry tissues and eggs. Samples of muscle, liver and kidney are homogenized, extracted by refluxing with ammonium hydroxide:acetonitrile and the aqueous phase is acidified and partitioned with toluene. Fludioxonil and its metabolites are converted to CGA192155 by heating in the presence of potassium permanganate and sodium hydroxide; the oxidation is quenched with sodium metabisulfite, the extracts are filtered, acidified, and partitioned into dichloromethane:ethyl acetate (80:20 v/v). Residues are determined as total fludioxonil by LC-MS/MS. A molecular weight correction factor of 1.23 is applied when calculating procedural recovery values and quantifying residues of CGA192155. The LOQ for fludioxonil and metabolites as CGA192155 in animal tissues was 0.01 mg/kg for fludioxonil (=0.0081 mg/kg for CGA192155). Residues of CGA192155 were shown to be stable at 0–9 °C for at least 7–9 days of storage.

Data evaluated by the 2004 JMPR showed that fludioxonil and CGA192155 are stable for at least 12 months in frozen muscle and for at least 18 months in frozen liver, milk and eggs.

Results from supervised residue trials on crops

Lemon

Five foliar supervised residue trials were conducted in the USA in lemons in 2004–2005 matching US GAP (1×0.245 kg ai/ha; 0 day PHI). Residues were 0.12 (3) and 0.16 (2) mg/kg.

Residues on lemons from foliar application are covered by the previous recommendation of maximum residue level of 10 mg/kg (Po) for fludioxonil on citrus

Avocado

Six supervised residue trials were conducted in USA in avocado in 2003 complying with US GAP (4×0.245 kg ai/ha; 0 day PHI). Residues were 0.02 (2), 0.04, 0.06, 0.11 and 0.19 mg/kg.

The Meeting estimated a maximum residue level of 0.4 mg/kg and a STMR of 0.05 mg/kg for fludioxonil in avocado.

Pineapple

Fludioxonil is registered in the USA for use in pineapple as a post-harvest high volume drench and/or directed peduncle spray at 1×0.06 kg ai/hL. Eight supervised residue trials were conducted in the USA (Hawaii) in 2009 using a dip plus wax or drench application at 0.06 kg ai/hL followed by a spray directed to the peduncle at 0.87 kg ai/hL. Residues ranged from 4.8 to 6.6 mg/kg (n=8).

As no trials were conducted according to GAP, the Meeting could not estimate a maximum residue level for fludioxonil in pineapple.

Fruiting vegetables, Cucurbits

Eighteen supervised residue trials were conducted in the USA in 2004 complying with the US GAP for cucurbits (4×0.245 kg ai/ha; 1 day PHI).

Residues in cantaloupe were (n=6) 0.02, 0.07, 0.09, 0.13, 0.20 and 0.36 mg/kg.

Residues in cucumber were: (n=7) 0.03, 0.04 (2), 0.05, 0.06, 0.09 and 0.13 mg/kg.

Residues in summer squash were: (n=5) 0.01, 0.04 (2) and 0.08 (2) mg/kg

The median residues found in the three individual commodities were within a 5 times range, allowing a recommendation to be made for the cucurbits crop group.

As the residue populations are not statistically different, the Meeting agreed they could be combined as (n=18) 0.01, 0.02, 0.03, 0.04 (4), 0.05, 0.06, 0.07, 0.08 (2), 0.09 (2), 0.13 (2), 0.20 and 0.36 mg/kg.

The Meeting recommended a maximum residue level of 0.5 mg/kg and a STMR of 0.065 mg/kg for fludioxonil in fruiting vegetables, cucurbits.

The Meeting withdrew its previous recommendation of 0.03 mg/kg for Melons, except watermelon, and of 0.3 mg/kg for summer squash.

Tomato

Fludioxonil is registered in the USA for use on tomatoes as a post-harvest in line dip/drench at 1×0.06 kg ai/hL or high volume spray at 0.0044kg ai/1000 kg tomatoes (combined with propiconazole in a tank mix).

Residues in tomatoes from six trials at GAP using the dip or drench application were: 0.28, 0.43, 0.48, 0.73, 0.77 and 1.1 mg/kg (if drench and drip was used in one trial, only the highest residue was selected). Three trials conducted at GAP using spray application gave residues of 0.18, 0.66 and 1.8 mg/kg.

Residue data from the two application types were similar and could be combined for residues of 0.18, 0.28, 0.43, 0.48, 0.66, 0.73, 0.77, 1.1 and 1.8 mg/kg (n=9).

The Meeting estimated a maximum residue level of 3 mg/kg and a STMR of 0.66 mg/kg for fludioxonil in tomato (Po).

The Meeting withdrew its previous maximum residue level recommendation for fludioxonil in tomato of 0.5 mg/kg.

Peppers (Bell & Non-Bell)

Currently, there is a MRL of 1 mg/kg for fludioxonil in Peppers, sweet, based European trials matching the GAPs of Italy and Austria.

The GAP of the USA consists of 4×0.245 kg ai/ha; 0 day PHI. The current Meeting received 14 supervised field residue trials on bell (sweet pepper) and non-bell peppers (including chili pepper) from the USA and Canada and five greenhouse trials matching US GAP.

Residues in the field trials for sweet peppers were < 0.02 (2), 0.08, 0.09, 0.12, 0.13 (2), 0.16 (2) and 0.28 (2) mg/kg. Residues for non-bell peppers were 0.06, 0.07, 0.12 and 0.14 mg.

Residues found in the greenhouse trials were 0.10, 0.20, 0.21 and 0.22 mg/kg for sweet pepper and 0.20 mg/kg for non-bell peppers.

These data indicate that the current MRL of 1 mg/kg would accommodate the expected fludioxonil residues resulting in non-bell peppers when applied according to US GAP. The Meeting agreed to extend the previous recommendation of 1 mg/kg to peppers.

Based on the data on non-bell peppers (0.06, 0.07, 0.12, 0.14 and 0.20 mg) and a factor of 10, the Meeting estimates a maximum residue level of 4 mg/kg and a STMR of 1.2 mg/kg for dried chili peppers.

Leafy vegetables

Currently, there is a MRL of 10 mg/kg in Head lettuce, based on indoor trials matching the Italian GAP, and a MRL of 10 mg/kg in Mustard greens based on trials matching the GAP of the USA.

In the USA, GAP in leafy greens is 4×0.245 kg ai/ha; 0 day PHI. Twenty five trials were conducted in USA in 2001 in lettuce and spinach according to GAP were submitted to this Meeting. Additionally, trials evaluated by the 2004 JMPR according to GAP were also considered. Six trials conducted in USA in 2004 in radish tops were not at GAP.

Residue in head lettuce (with wrapper leaves) were (n=8) 0.42, 1.2, 1.4, 2.0 (2), 2.2, 2.8 and 4.6, mg/kg.

Indoor trials conducted in Europe in head lettuce at Italian GAP evaluated by the 2004 JMPR gave residues (n=11) ranging from 0.72 to 6 mg/kg, median of 2.7 mg/kg.

Residues in leafy lettuce were (n= 6) 4.8, 6.5, 6.7, 10, 16 and 22 mg/kg.

Residues in spinach were (n= 11) 1.9, 3.4, 4.6, 4.9 (2), 5.8, 7.5, 8.3, 9.8, 12 and 16 mg/kg.

Residues in watercress from trials evaluated in 2004 (USA GAP) were 4.2 and 4.5 mg/kg.

Residues in mustard greens from trials evaluated in 2004 (USA GAP) ranged from 0.06 to 7.1 mg/kg, median of 1.2 mg/kg (n=9).

The median residues found in the individual commodities from trials conducted matching USA GAP were outside the 5 times range, not allowing a recommendation for leafy vegetable group.

The Meeting therefore, estimated a maximum residue level of 40 mg/kg and a STMR of 8.3 mg/kg for fludioxonil in leafy lettuce

The Meeting estimated a maximum residue level of 30 mg/kg and a STMR of 5.8 mg/kg for fludioxonil in spinach.

The Meeting agreed that there were insufficient trials to estimate a maximum residue level for watercress.

The Meeting confirmed its previous recommendation of 10 mg/kg for fludioxonil in head lettuce and mustard greens.

Potato

Currently, there is a MRL of 0.02 mg/kg for potato, based on the Australian GAP as a seed treatment.

Fludioxonil is registered in the USA for use in potatoes as a post-harvest in line spray at 0.0045 kg ai/1000 kg tubers. Five trials were conducted in the USA and Canada in 2009/2010 matching the US GAP, giving residues of 0.66, 1.1, 1.5, 1.7 and 2.9 mg/kg.

The Meeting estimated a maximum residue level of 5 mg/kg and a STMR of 1.5 mg/kg for fludioxonil in potato (Po).

The Meeting withdrew its previous recommendation for fludioxonil in potatoes of 0.02 mg/kg.

Radish

Six supervised residue trials were conducted in the USA in 2004 matching US GAP (2×0.245 kg ai/ha; 7 days PHI). Residues in the radish tops were: < 0.02 (2), 0.04, 0.08, and 0.10 (2) mg/kg.

The Meeting estimated a maximum residue level of .3 mg/kg and a STMR of 0.06 mg/kg for fludioxonil in radish.

Legume vegetables

Currently, there is a MRL of 0.3 mg/kg for beans, except broad beans and soya beans and for peas (pods and succulent=immature seeds), based on the GAP of France.

The GAP in USA for beans (dried and succulent, except cow beans) is 4×0.245 kg ai/ha; 7 days PHI). In eight trials conducted in snap beans (common beans) from the USA, matching US GAP, residues in snap beans pods were: < 0.02, 0.03 (2), 0.04 (2), 0.05 (2) and 0.38 mg/kg.

Based on the US data on snap beans, the Meeting estimated a maximum residue level of 0.6 mg/kg and a STMR of 0.04 mg/kg for fludioxonil in Beans, except broad bean and soya bean. The Meeting withdrew its previous recommendation of 0.3 mg/kg for beans, except broad bean and soya bean.

In seven trials conducted in lima beans in the USA according to US GAP, residues in succulent shelled beans were: < 0.02 (4), 0.03, 0.04 and 0.21 mg/kg.

The Meeting estimated a maximum residue level of 0.4 mg/kg and a STMR of 0.02 mg/kg for fludioxonil in Beans, Shelled. The Meeting agreed to withdraw its previous recommendation of 0.03 mg/kg for Beans, Shelled.

Fludioxonil is registered in USA to be used in peas as a seed treatment at 0.005 kg ai/100 kg seed. Five trials conducted at US GAP gave residues in mature fresh peas with pods of < 0.01 (5) mg/kg. Fifteen trials conducted at higher or lower GAP rate gave the same results.

The Meeting confirms its previous recommendation of 0.3 mg/kg for peas (pods and succulent=immature seeds).

Beans (dry)

Currently, there is a Codex MRL of 0.07 mg/kg for beans (dry) based on Spanish GAP.

Seven trials were conducted in USA in 2001 according to US GAP (4×0.245 kg ai/ha; 7 days PHI) gave residues in dry beans of 0.02 (2), 0.04 (2), 0.06, 0.12 and 0.23 mg/kg. In two trials harvested earlier or with 6 applications gave residues in the same range.

The Meeting estimated a maximum residue level of 0.5 mg/kg and a STMR of 0.04 mg/kg for fludioxonil in beans (dry) The Meeting withdrew its previous recommendation of 0.07 mg/kg for Beans (dry).

Herbs

Currently, there is a Codex MRL of 10 mg/kg for fludioxonil in fresh basil and chives and of 50 mg/kg for dried basil and chives.

The Meeting received four supervised residue trials in parsley from the USA matching US GAP in herbs (4×0.245 kg ai/ha; 7 days PHI). Residues in fresh parsley were 1.6, 2.3, 3.2 and 3.9 mg/kg and in dry parsley 8.9, 15, 18 and 23 mg/kg.

Data submitted to the 2004 JMPR matching US GAP showed residue of 1.8 and 3.9 mg/kg on fresh chives and 1.9 and 3.0 mg/kg on fresh basil, 14 and 31 mg/kg on dry chives and 15 and 24 mg/kg on dry basil.

The residues found in the individual fresh or dried commodities from trials conducted according to USA GAP are in the same range, and they are combined for allowing recommendations for herbs, fresh and dried.

The residues of fludioxonil in fresh parsley, basil and chives were considered similar and could be combined giving residues of 1.6, 1.8, 1.9, 2.3, 3.0, 3.2 and 3.9 (2) mg/kg.

The Meeting recommended a maximum residue level of 9 mg/kg and a STMR of 2.65 mg/kg for fludioxonil in herbs.

The residue data sets of fludioxonil from dried parsley, basil and chives were also considered similar and could be combined giving residues of 8.9, 14, 15 (2), 18, 22, 24 and 31 mg/kg.

The Meeting recommended a maximum residue level of 60 mg/kg and a STMR of 16.5 mg/kg for fludioxonil in dried herbs, except dried hops.

The Meeting agreed to withdraw its previous recommendations for chives and basil of 10 mg/kg and for dried chives and basil of 50 mg/kg.

Ginseng

Four supervised residue trials were conducted in the USA and Canada from 2005 to 2006 according to GAP (4×0.245 kg ai/ha; 14 days PHI). Residues were 0.16, 0.18, 0.40 and 1.7 mg/kg.

The Meeting recommends a maximum residue level of 4 mg/kg and a STMR of 0.29 mg/kg for fludioxonil in ginseng.

Residues in processed commodities

Pineapple fruit (5.62 mg/kg fludioxonil) processed to juice contained a residue of 5.40 mg/kg, with a processing factor (PF) of 0.96. However, as no maximum residue level recommendation on the raw commodity was made, the Meeting could not make an assessment of residues for pineapple juice.

Tomatoes containing 0.14 mg/kg of fludioxonil were processed to paste (0.15 mg/kg), giving a PF of 1.1. Processing factors estimated by the 2004 JMPR were 1.1, 1.4, 1.5 and 1.6. The best estimated processing factor for tomato paste is 1.4. Based on a STMR of 0.66 mg/kg for tomato, the Meeting estimated a of STMR-P of 0.924 mg/kg for tomato paste

Tomatoes was also processed to puree (0.05 mg/kg) giving a PF of 0.36. The Meeting estimated a STMR-P of 0.236 mg/kg for tomato puree.

The best estimate PF for tomato juice (2004 JMPR) was 0.22. The Meeting estimated a STMR-P of 0.145 mg/kg for fludioxonil.

Potato tubers containing 0.472 mg/kg fludioxonil were processed into chips. Residues were 0.797 mg/kg in wet peel (PF=1.69), 0.01 mg/kg in flakes (PF < 0.02) and 0.018 mg/kg in chips (PF of 0.04).

The Meeting estimated a STMR-P of 0.06 mg/kg for fludioxonil in potato chips (STMR in potato is 1.5 mg/kg).

Residues in animal commodities

Farm animal dietary burden

Dietary burden calculations for beef cattle, dairy cattle, broilers and laying poultry are provided in Appendix IX of the FAO manual. The calculations were made according to the animal diets from US-Canada, EU, Australia and Japan in the Table (Appendix IX of the FAO manual). The STMR, STMR-Ps were estimated at the present Meeting. Dietary burden calculations are provided in Annex 5 of the 2013 JMPR Report.

Livestock dietary burden for fludioxonil, ppm of dry mater diet

Commodity	US-Canada		EU		Australia		Japan	
	Max	Mean	Max	Mean	Max	Mean	Max	Mean
Beef cattle	0.029	0.018	0.56 ^a	0.27 ^c	0.24	0.13	0.017	0.017
Dairy cattle	0.39	0.18	0.57 ^{a,b}	0.27 ^d	0.24	0.11	0.02	0.018
Poultry-broiler	0.017	0.017	0.38 ^e	0.19 ^f	0.035	0.035	0.002	0.002
Poultry-layer	0.017	0.017	0.38	0.19	0.035	0.035	0.002	0.002

^a Highest maximum beef or dairy cattle dietary burden suitable for maximum residue level estimated for mammalian tissues

^b Highest maximum dairy cattle dietary burden suitable for maximum residue level estimated for mammalian milk

^c Highest mean beef or dairy cattle dietary burden suitable for STMR estimated for mammalian tissues.

^d Highest mean dairy cattle dietary burden suitable for STMR estimated for milk.

^e Highest maximum poultry dietary burden suitable for maximum residue level estimated for poultry tissues

^f Highest mean poultry dietary burden suitable for maximum residue level estimated for poultry tissues

Animal feeding study

A feeding study on poultry submitted to the current Meeting was conducted with fludioxonil at 1.54, 4.64 and 15.4 mg/kg feed on a 28-day daily dose regime via gelatine capsules.

Residues in eggs from the 15.4 ppm dose level hens were < 0.01 mg/kg 3 days after the initiation of dosing, increased to 0.024 mg/kg fludioxonil eq. (max. of 0.036 mg/kg), and reached 0.04 mg/kg at day 28. The Mean level during the study was 0.025 mg/kg and a maximum of 0.052 mg/kg fludioxonil eq. Eggs from the 4.64 ppm group had a mean and a maximum residue of 0.01 and 0.013 mg/kg fludioxonil eq., respectively. No residues were found in eggs from the 1.54 ppm dose group.

Only liver samples from the 1.54 ppm group were analysed, giving a mean of 0.05 mg/kg eq. (0.03 to 0.08 mg/kg).

In the 4.64 ppm group, residues in skin/fat (including abdominal fat) ranged from < 0.01 to 0.01 mg/kg eq. and residues in liver ranged from 0.06 to 0.21 mg/kg eq. (mean of 0.12 mg/kg).

In the 15.4 mg/kg ppm group, residues in muscle were < 0.01, from 0.01 to 0.04 mg/kg eq. in skin and fat (mean of 0.03 mg/kg) and 0.28 mg/kg eq. in liver.

A depuration study conducted at 15.4 ppm dosing level demonstrated that residues in the eggs ranged from 0.02 to 0.04 mg/kg eq. up to 3 days after termination of the study and were not detected further. Fludioxonil was not detected in any of the muscle, fat or liver samples, suggesting rapid elimination of fludioxonil following completion of dosing.

Animal commodity maximum residue levels

A feeding study in cattle evaluated by the 2004 JMPR showed that residues of fludioxonil and its metabolites found in the highest feeding level dose group (5.5 ppm) were 0.014–0.017 mg/kg in liver, 0.022–0.025 mg/kg in kidney (LOQ of 0.05 mg/kg) and none was detected in fat (< 0.05 mg/kg) or muscle (< 0.01 mg/kg). The highest and median residues in milk were 0.019 and 0.01 mg/kg, respectively (LOQ of 0.01 mg/kg). The feeding level in this study is about 10 times higher than the highest dietary burden estimated for cattle at this Meeting (0.57 ppm).

The Meeting confirmed its maximum residue level recommendation of 0.05* mg/kg for edible offal (mammalian), and 0.01* mg/kg for meat (from mammals other than marine mammals) and milks.

Based on an estimated dietary burden for poultry of 0.07 ppm and a metabolism study, the 2004 JMPR had estimated that residues of fludioxonil and metabolites were unlikely to be found in poultry commodities and recommended maximum residue levels of 0.05* mg/kg for eggs, 0.01* mg/kg for poultry meat and 0.05* mg/kg for poultry edible offal and STMRs of 0 mg/kg for eggs, poultry meat and poultry edible offal.

The highest calculated poultry dietary burden calculated by the current Meeting was 0.38 ppm. As the feeding study showed that no residues are expected at a dietary burden of 1.54 ppm (lowest dose tested), the Meeting confirmed that no residues are expected in poultry commodities.

The Meeting recommended a maximum residue level of 0.01* mg/kg and a STMR of 0 for fludioxonil in poultry edible offal and eggs.

The Meeting confirmed its previous recommendation of 0.01* mg/kg for poultry meat.

RECOMMENDATION

The residue definition: for plant commodities for compliance with the MRL and estimation of dietary intakes: *fludioxonil*.

For animal commodities the residue is the sum of fludioxonil and its benzopyrrole metabolites, determined as 2,2-difluoro-benzo[1,3]dioxole-4-carboxylic acid and expressed as fludioxonil.

The residue is fat-soluble.

DIETARY RISK ASSESSMENT

Long-term intake

The IEDI of fludioxonil based on the STMRs estimated by this and previous Meetings for the 13 GEMS/Food regional diets were 2–6% of the maximum ADI of 0–0.4 mg/kg bw (see Annex 3 of the 2013 Report). The Meeting concluded that the long-term dietary intake of residues of fludioxonil is unlikely to present a public health concern.

Short-term intake

The 2004 JMPR decided that an ARfD for fludioxonil is unnecessary. The Meeting therefore concluded that the short-term dietary intake of fludioxonil residues is unlikely to present a public health concern.

FLUTOLANIL (205)

*First draft prepared by Dr Yukiko Yamada, Ministry of Agriculture, Forestry and Fisheries,
Tokyo, Japan*

EXPLANATION

Flutolanil is a systemic fungicide with protective and curative actions. It was evaluated by JMPR in 2002 for the first time for toxicologically and for residues. The 2002 JMPR allocated an ADI of 0–0.09 mg/kg bw, and ARfD unnecessary. It also determined that the definition of residues should be flutolanil for plant commodities (for compliance with MRLs and for estimation of dietary intake) and flutolanil and transformation products, (containing the 2-trifluoromethylbenzoic acid moiety), expressed as flutolanil, for animal commodities (for compliance with MRLs and for estimation of dietary intake). It recommended a maximum residue level for rice, husked; rice, polished; rice bran, unprocessed; rice straw and fodder, dry; tissues of cattle goats, pigs, sheep and poultry; milks; and eggs.

The current Meeting received information on analytical methods, storage stability, use patterns and supervised trials to support estimation of maximum residue levels for broccoli, cabbage and mustard greens.

RESIDUE ANALYSIS

Analytical methods

The Meeting received information on the analytical method used for the determination of flutolanil which is based on the method XAM-65, LC-MS method, and which was originally developed for analysis of flutolanil and its metabolite M-4 in cotton seed and corn grain. It has been modified for the determination of flutolanil and its metabolite M-4 in Brassica vegetables (Corley, 2009a, b and c).

Flutolanil was extracted from broccoli or mustard green samples with acetone. Samples were partitioned twice with ethyl acetate:dichloromethane (1:9). The top layers were dried down and reconstituted in acetone. Following clean-up on a Florisil column, eluates were dried down and reconstituted in mobile phase. Flutolanil in cabbage samples was extracted with methanol:water (1:1, v/v). The analysis was carried out using LC-MS/MS (electro-spray ionization mode; molecular ion of 324 (m+H⁺) m/z and product ion of 282 m/z).

The modified XAM-65 method was validated for the determination of residues of flutolanil in broccoli, cabbage and mustard greens at three different fortification levels, 0.05, 0.5 and 5 mg/kg. Recoveries were 96–110%, 97–106% and 83–110% for broccoli, cabbage and mustard greens, respectively. These were all within the acceptable range of 70–110%, with the relative standard deviation below 10% (Table 1).

Table 1 Recovery results obtained for the determination of flutolanil by the modified method XAM65

Matrix	Fortification level (mg/kg)	N	Recoveries (%)				Mean (%)	RSD (%)
Broccoli	0.05	3	109,	110,	97		105	6.9
	0.5	3	103,	101,	96		100	3.6
	5	3	97,	103,	108		103	5.4
Cabbage	0.05	3	105,	102,	103		103	1.5
	0.5	3	102,	104,	106		104	1.9
	5	3	98,	100,	97		98	1.6
Mustard greens	0.05	4	98,	88,	88,	83	89	7.0
	0.5	4	94,	99,	101,	109,	101	6.2
	5	3	92,	103,	100,	110	101	7.4

The calculated limit of detection (LOD), limit of quantification (LOQ) and lowest level of method validation (LLMV) are shown in Table 2.

Table 2 LOD, LOQ and LLMV of the modified method XAM65 for flutolanil in the matrices relevant to the current review

Matrix	LOD (mg/kg)	LOQ (mg/kg)	LLMV (mg/kg)
Broccoli	0.01	0.03	0.05
Cabbage	0.005	0.015	0.05
Mustard greens	0.008	0.02	0.05

Stability of pesticide residues in stored analytical samples

Storage stability studies were conducted on broccoli in conjunction with supervised trials. Flutolanil in the frozen condition was stable up to 569 days at -22–4 °C (102–114% remaining) in broccoli, 297 days at -29–10 °C (95–101% remaining) in cabbage and 519 days at -22–4 °C (107–114% remaining) in mustard greens. The concurrent recovery spike extracted and analysed along with the storage stability samples showed 95% and 111% recoveries for flutolanil. In the supervised residue trial studies, samples were stored frozen for periods shorter than the respective period tested for the storage stability studies. The storage stability data indicate that the compound was stable under the conditions that the samples were held between sampling and analyses (Corley, 2009a, b and c).

Table 3 Stability of flutolanil in frozen Brassica vegetables

Matrix	Fortification level (mg/kg)	Storage (days)	% Remaining		Concurrent recovery (%) ^a
			Actual	Average	
Broccoli	0.5	569 (-22–4 °C)	114, 102, 104	107 ± 6	111 (at 0.05 mg/kg) 103 (at 5 mg/kg)
Cabbage	0.5	297 (-29–10 °C)	101, 97, 95	98 ± 5	111 at 0.5 mg/kg
Mustard greens	0.5	519 (-22–4 °C)	114, 107, 112	111 ± 4	98 (at 0.05 mg/kg) 95 (at 5 mg/kg)

^a Analyses conducted on the same day

USE PATTERNS

The authorized uses relevant to the supervised trials data submitted to the current Meeting are summarized in Table 4.

Table 4 Registered uses of flutolanil in the USA relevant to the residue evaluation by the current Meeting

Crop	Form g ai/L	Application					PHI days
		Method	Rate kg ai/ha	Water L/ha	Timing	No.	
Brassica leafy vegetables (Head and stem Brassica) (Brassica leafy greens) (Turnip greens)	WP 700	In-furrow or Directed spray	0.863	> 28	At planting	1	–
		Soil drench			At planting	1	45
		Banded application directed at plant bases		281–468	Immediately after transplanting	1	

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting considered residue data from supervised field trials conducted in the USA on broccoli, cabbage and mustard greens with flutolanil WP formulation (700 g ai/kg nominal concentration).

Application rates and residue concentrations were reported as flutolanil. Residue concentrations are recorded unadjusted for recoveries or for residue values in control samples. Where multiple samples were taken from a single plot, individual results are reported, and the calculated average concentration (in parentheses) is used for estimation of maximum residue levels. Where trials were conducted in the same location, with the same or similar varieties, same or similar formulations,

and the same equipment, and at the same or similar timing, they are not regarded as independent and only one result from these trials was chosen for the estimation of a maximum residue level.

Residues from the trials conducted according to maximum GAP have been used for the estimation of maximum residue levels and they are underlined.

Crop Group	Commodity	Table No.

Brassica vegetables

Broccoli

A total of eleven field trials were conducted across the USA. Each field trial site consisted of one untreated control plot and one treated plot. Common cultural practices were followed to maintain the broccoli crop. Additional maintenance pesticides and fertilizers were used at all of the sites (except CA66) to produce a commercial quality crop. No adjuvants were used in any of the trials. At all the trials, a single ground application directed in a narrow band at the base of the transplants or over the seed furrow was made at the time of seeding or immediately after transplanting. All applications were made using appropriate equipment, and the carrier volume was sufficient to provide adequate dispersal of the test substance. At the NJ34 trial, the treated area was calculated using the narrow band into which the test substance was sprayed instead of using the entire row width. This resulted in an under-application of the test substance by 45% at the NJ34 trial. At all the trials, the untreated samples were harvested before or simultaneously with the treated samples by different people. Samples were harvested using techniques simulating commercial practices. The commercially mature broccoli heads (including stems and jacket leaves) were harvested 56–106 days after the application.

The samples were analysed using the modified XAM-65 method for both Flutolanil (parent) and its metabolite M-4. No detectable residues of flutolanil or M-4 above the lowest level of method validation (0.05 mg/kg) were found in any of the untreated samples. An apparent flutolanil residue of approximately 0.02 mg/kg was found in the untreated control sample from the OH*11 trial. Also, apparent flutolanil residues of approximately 0.01 mg/kg and 0.009 mg/kg (at or below the calculated LOD) were found in the treated samples from the same trial. All other apparent peaks occurring at or around the retention times for flutolanil and M-4 were below the calculated limit of detection for both compounds and well below the lowest calibration standard.

DAT: days after treatment

^a Average residue concentration in parentheses

Leafy vegetables

Mustard greens

A total of ten field trials were conducted across the USA. Each field trial site consisted of one untreated control plot and one treated plot. Common cultural practices were followed to maintain the greens (mustard) crop. Additional maintenance pesticides and fertilizers were used at all of the sites to produce a commercial quality crop. No adjuvants were used in any of the trials. At all the trials, a single ground application directed in a narrow band over the seed furrow was made at the time of seeding. All applications were made using appropriate equipment, and the carrier volume was sufficient to provide adequate dispersal of the test substance. At the NC11 & NJ16 trials, the treated area was calculated using the narrow band into which the test substance was sprayed instead of using the entire row width as specified by the protocol. This resulted in an under-application of the test substance by 34% and 74% at the NC11 & NJ16 trials respectively. At all the trials, the untreated samples were harvested before the treated samples. Samples were harvested using techniques simulating some commercial practices. The commercially mature mustard greens were harvested 31–63 days after the application.

The samples were analysed using the modified XAM-65 method. The samples were analysed for both Flutolanil (parent) and its metabolite M-4. The two treated samples from the CA67 trial showed residues of 0.06 and 0.05 mg/kg of flutolanil. Residues of flutolanil and/or M-4 ranging from approximately 0.01 to 0.03 mg/kg were detected in treated samples from some of the trials. However, these residues were well below the LLMV and around or below the calculated LOQ making the

numbers unquantifiable. No detectable residues of flutolanil or M-4 above the lowest level of method validation (0.05 mg/kg) were found in any of the untreated control samples.

DAT: days after treatment

^a Average residue concentration in parentheses

APPRAISAL

Flutolanil was evaluated by JMPR in 2002 for the first time toxicologically and for residues. The 2002 JMPR allocated an ADI of 0–0.09 mg/kg bw and ARfD unnecessary. It also determined that the definition of residues should be flutolanil for plant commodities (for compliance with MRLs and for estimation of dietary intake) and flutolanil and transformation products containing the 2-trifluoromethylbenzoic acid moiety, expressed as flutolanil for animal commodities (for compliance with MRLs and for estimation of dietary intake) and recommended a maximum residue level for rice, husked; rice, polished; rice bran, unprocessed; rice straw and fodder, dry; tissues of cattle goats, pigs, sheep and poultry; milks; and eggs.

The current Meeting received information on analytical methods, storage stability, use patterns and supervised trials to support estimation of maximum residue levels for broccoli, cabbage and mustard greens.

Methods of analysis

The Meeting received information on the analytical method used for the determination of flutolanil. Flutolanil in broccoli or mustard green was extracted with acetone and flutolanil in cabbage was extracted with methanol:water (1:1, v/v). Acetone extract or methanol extract was partitioned with ethyl acetate:dichloromethane (1:9) and the top layer was dried down and reconstituted in acetone. Following clean up on a Florisil column, eluates were dried down, reconstituted in mobile phase. The analysis is carried out using LC-MS/MS (electro-spray ionization mode; molecular ion of 324 ($m+H^+$) m/z and product ion of 282 m/z).

This method was found to be suitable for the determination of residues of flutolanil in broccoli, cabbage and mustard greens with recoveries of 83–110%, 97–106% and 83–110%, respectively, for these matrices at fortification levels 0.05–5 mg/kg.

The LOQ was 0.05 mg/kg for broccoli, cabbage and mustard green.

Stability of pesticide residues in stored analytical samples

Storage stability studies were conducted on broccoli in conjunction with supervised trials.

Flutolanil in the frozen condition was stable up to 569 days at -22 to -4 °C (102–114% remaining) in broccoli, 297 days at -29 – -10°C (95–101% remaining) in cabbage and 519 days at -22 to -4 °C (107–114% remaining) in mustard green.

In the supervised residue trial studies, samples were stored frozen for periods shorter than the respective periods tested for the storage stability studies.

Results of supervised residue trials on crops

The Meeting considered residue data from supervised field trials conducted in the USA on broccoli, cabbage and mustard green with a flutolanil WP formulation (700 g ai/kg nominal concentration).

Brassica vegetables

The approved use of flutolanil in the USA on the crop group Brassica leafy vegetables (including Brassica vegetables) consists of one application at a rate of 0.863 kg ai/ha either as an in-furrow or directed spray (minimum of 28 L/ha) or as soil drench at planting (PHI of 45 days), or, when transplanted, as a banded application directed at plant bases immediately after transplanting (281–468 L/ha).

According to the review of information on environmental fate by the 2002 JMPR, flutolanil is strongly adsorbed to most soils and is classified as low mobility through soil.

Broccoli

A total of eleven field trials were conducted across the USA. At all the trials, a single ground application directed in a narrow band at the base of the transplants or over the seed furrow was made at the time of seeding or immediately after transplanting. The commercially mature broccoli heads (including stems, and jacket leaves) were harvested 56–106 days after the application.

Residues of flutolanil in broccoli from trials in accordance with US GAP were all < 0.05 mg/kg (9). The Meeting estimated a maximum residue level of 0.05 * mg/kg. As flutolanil is applied at the time of planting or immediately after transplanting and flutolanil is unlikely to be taken up from soil by crops, the Meeting estimated an STMR of 0 mg/kg.

Cabbages, Head

A total of nine field trials were conducted across the USA. At all the trials, a single ground application directed in a narrow band at the base of the plant or over the seed furrow was made at the time of transplanting or seeding. The commercially mature cabbage heads were harvested 62–138 days after the application.

Residues of flutolanil in head cabbages from trials in matching US GAP were all < 0.05 mg/kg (9). The Meeting estimated a maximum residue level of 0.05* mg/kg. Applying the same rational as for broccoli on soil uptake, the Meeting estimated an STMR of 0 mg/kg. The Meeting also estimated a highest residue of 0 mg/kg for the purpose of calculating livestock dietary burdens.

Leafy vegetables

Mustard greens

A total of ten field trials were conducted across the USA. At all the trials, a single ground application directed in a narrow band over the seed furrow was made at the time of seeding. The commercially mature mustard greens mustard were harvested 31–63 days after the application.

Residues of flutolanil in mustard greens from trials matching US GAP were < 0.05 (7) and 0.055 mg/kg. The Meeting estimated a maximum residue level of 0.07 mg/kg. The Meeting estimated an STMR of 0.05 mg/kg.

Brassica (cole or cabbage) vegetables, Head cabbages, Flowerhead Brassicas; and Brassica leafy vegetables

The GAP in the USA covers the crop group Brassica leafy vegetables, including head and stem Brassica, Brassica leafy vegetables and turnip greens. As this GAP involves one application at planting or immediately after transplanting, residues in commodities in this group harvested at their maturity are expected to be very low, as was observed in the trials on broccoli, cabbage and mustard greens.

Consequently, the Meeting decided to extend the recommendations for maximum residue levels of 0.05* mg/kg and STMRs of 0 mg/kg for broccoli and head cabbage to the group Brassica (cole or cabbage) vegetables, Head cabbages, Flowerhead Brassicas (VB 0040); and the recommended maximum residue level of 0.07 mg/kg and STMRs of 0.05 mg/kg for mustard greens to Brassica leafy vegetables (VL 0054).

Residues in animal commodities

Estimation of dietary burdens

The Meeting noted that in addition to rice grain, rice bran, rice hulls and rice straw from which dietary burdens were calculated by the 2002 JMPR, cabbages can also be fed to beef and dairy cattle and laying hens. Although both the STMR and highest residue of head cabbages were estimated to be 0 mg/kg and therefore not impacting on animal dietary burden, as the OECD Animal Feeding Table had been revised since the last evaluation, the maximum and mean dietary burdens were re-calculated using the highest residue and STMR/median residue of the above-mentioned commodities on a basis of the updated OECD Animal Feeding Table. The summary of calculated dietary burdens is shown in the following table.

Summary of livestock dietary burdens (ppm of dry matter diet)

	US-Canada		EU		Australia		Japan	
	max	Mean	max	Mean	max	mean	Max	mean
Beef cattle	0.372	0.372	0.822	0.411	5.83 ^a	3.37 ^b	4.90	2.64
Dairy cattle	0.372	0.372	0.789	0.584	2.78 ^c	1.96 ^d	2.24	1.22
Broiler	0.278	0.278	0.189	0.189	0.599	0.599	0.094	0.094
Layer	0.278	0.278	0.094	0.094	0.599 ^e	0.599 ^f	0.378	0.378

^a Suitable for estimating maximum residue levels for meat, fat and edible offal of cattle.

^b Suitable for estimating STMRs for meat, fat and edible offal of cattle.

^c Suitable for estimating maximum residue level for milk of cattle.

^d Suitable for estimating STMR for milk of cattle.

^e Suitable for estimating maximum residue levels for meat, fat, edible offal of poultry.

^f Suitable for estimating STMRs for meat, fat, edible offal of poultry.

Residues in milk and mammalian tissues

The 2002 JMPR reviewed a cattle feeding study conducted at levels equivalent to 39, 116 and 388 ppm in the feed.

The maximum and mean dietary burdens in cattle were 2.78 and 1.96 ppm of dry matter diet respectively for estimating a maximum residue level and STMR for milk; and 5.83 and 3.37 ppm respectively for estimating maximum residue levels and STMRs for tissues. The maximum residue levels, STMRs and highest residues for relevant commodities of animal origin were estimated using the residue levels in tissues and milk at 39 ppm feeding group.

	Feed level (ppm) for milk residues	Flutolanil* (mg/kg) in milk	Feed level (ppm) for tissue residues	Flutolanil * (mg/kg) in			
				Muscle	Liver	Kidney	Fat
Maximum residue level beef or dairy cattle							
Feeding study ^a	39	< 0.05	39	< 0.05	2.0	0.79	0.06
Dietary burden and highest residue	2.78	< 0.004	5.83	< 0.007	0.299	0.118	0.009
STMR beef or dairy cattle							
Feeding study ^b	39	< 0.05	39	< 0.05	1.7	0.42	0.05
Dietary burden and mean residue	1.96	< 0.003	3.37	< 0.004	0.147	0.036	0.004

^a highest residues for tissues and mean residue for milk

^b mean residues for tissues and mean residue for milk

* From the common moiety method

The Meeting estimated STMRs of 0.147 and 0.036 mg/kg for liver and kidney respectively. As the residues in meat were < 0.05 mg/kg in any of feeding groups, the Meeting confirmed the existing STMR for meat at 0 mg/kg. Since the calculated STMR for milk was less than one tenth of the LOQ, the Meeting decided to use the existing STMR of 0 mg/kg.

The Meeting confirmed the previous maximum residue level recommendations of 0.05* and 0.05* mg/kg for milks and meat (from mammals other than marine mammals), and estimated a maximum residue level of 0.5 mg/kg for edible offal (mammalian) and withdrew the previous recommendations for liver and kidney.

Residues in eggs and poultry tissues

The 2002 JMPR reviewed a chicken feeding study conducted at levels equivalent to 0.78, 2.4 and 7.8 ppm in the feed. The maximum of calculated poultry dietary burden was 0.60 ppm.

At the lowest feeding level in the feeding study, residues from the common moiety method were all < 0.05 mg/kg in the eggs and all tissues tested. As a result the Meeting confirmed the existing maximum residue levels for eggs, poultry meat and poultry, edible offal of 0.05 * mg/kg.

At all feeding levels, residues did not exceed the LOQ of 0.05 mg/kg in eggs, muscle, fat or skin. The Meeting therefore confirmed the previously estimated STMRs of 0 mg/kg for these commodities.

Residues in the liver were below 0.05 mg/kg in the lowest and middle feeding groups but were detected at 0.08, 0.10 and 0.20 mg/kg in the highest feeding group. The Meeting, therefore also confirmed the STMR of 0.05 mg/kg for poultry, edible offal of.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of the residue for plant commodities (for compliance with MRLs and for estimation of dietary intake): flutolanil.

Definition of the residue for animal commodities (for compliance with MRLs and for estimation of dietary intake): flutolanil and transformation products containing the 2-trifluoromethylbenzoic acid moiety, expressed as flutolanil.

The residue is not fat-soluble.

Commodity		Recommended MRL, mg/kg		STMR/STMR-P
CCN	Name	New	Previous	mg/kg
VL 0054	Brassica leafy vegetables	0.07	-	0.05
VB 0040	Brassica (cole or cabbage) vegetables, Head cabbages, Flowerhead brassicas	0.05*	-	0
MO 0105	Edible offal (mammalian)	0.5	-	Liver, 0.147 Kidney, 0.036
MO 0098	Kidney of cattle, goats, pigs and sheep	W	0.1	
MO 0099	Liver of cattle, goats, pigs and sheep	W	0.2	

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Dietary Intakes (IEDIs) of flutolanil were calculated for the 13 GEMS/Food cluster diets using STMRs estimated by the 2002 and current Meetings (Annex 3). The ADI is 0–0.09 mg/kg bw and the calculated IEDIs were 0–1% of the maximum ADI. The Meeting concluded that the long-term intake of residues of flutolanil resulting from the uses considered by the current JMPR is unlikely to present a public health concern.

Short-term intake

The 2002 JMPR decided that an ARfD is unnecessary. The Meeting therefore concluded that the short-term intake of residues of flutolanil is unlikely to present a public health concern.

GLYPHOSATE (158)

First draft prepared by Dr Dugald MacLachlan, Department of Agriculture, Fisheries and Forestry, Australia

EXPLANATION

Glyphosate was listed in the Periodic Re-evaluation Programme of the Thirty-fourth Session of the CCPR for residue review by 2005 JMPR. It has been reviewed by the JMPR in 1986 (TR), 1987 (R), 1988 (R), 1994 (R), 1997 (TR), 2004 (T), 2005 (R) and 2011 (R).

For the current evaluation the Meeting received critical data required for the estimation of MRLs for glyphosate tolerant rape (with the *gat* trait).

The glyphosate tolerant crops with the *gat* trait have been inserted with a glyphosate N-acetyltransferase gene which inactivates glyphosate by converting it to N-acetylglyphosate, making it the main metabolite in plant commodities. The Meeting received data on glyphosate metabolism in glyphosate tolerant rape crops, methods of residue analysis, storage stability, use patterns (USA and Canada), data from supervised residue trials and processing studies.

Trivial and systematic chemical names of all glyphosate related compounds referenced in the study reports submitted for the evaluation of the use of glyphosate on maize and soya bean with the *gat* trait are shown below in Table 1. These genetically modified crops lead to a different metabolic pathway of glyphosate in plants than in conventional crops or crops genetically modified to contain the CP4-EPSPS gene making them tolerant for glyphosate.

Table 1 List of reference compounds used in various study reports, including reports evaluated in previous JMPR reports

Abbreviation	Trivial and systematic chemical names Other abbreviations used in study reports	Found as or in
Gly	metabolite 1/parent glyphosate N-(phosphonomethyl)glycine C ₃ H ₈ NO ₅ P DPX-B2856	Rat, goat, hen
AMPA	metabolite 2 AMPA (aminomethyl)phosphonic acid H ₂ NCH ₂ PO ₃ H IN-YB726	Rat, goat, hen
NA-AMPA	metabolite 6 N-acetyl AMPA [(acetylamonio)methyl]phosphonic acid CH ₃ C(O)NHCH ₂ PO ₃ H ₂ IN-EY252	Rat, goat, hen
NA-Gly	metabolite 9 N-acetylglyphosate N-acetyl-N-(phosphonomethyl)glycine IN-MCX20	Rat, goat, hen

METABOLISM AND ENVIRONMENTAL FATE

Plant metabolism

The Meeting received information on the fate of glyphosate after single pre-emergence application followed by three foliar applications on rape crops containing the *gat* gene. Studies were conducted with [phosphonomethyl- ^{14}C] glyphosate under glasshouse conditions at a total rate of approximately 7.5 kg ai/ha.

The metabolism of [^{14}C] glyphosate was investigated in 0827 rape plants containing the *gat* gene [Chapleo & McLachlan, 2010, DuPont-26109]. A single pre-emergence soil application (4.5 kg ai/ha) followed by three foliar applications (each 1.0 kg ai/ha at the 2 and 5 leaf stage and 1 week before maturity) were made of an aqueous solution containing [^{14}C] glyphosate (SL formulation and 2% ammonium sulphate salt). The intervals between the four applications were 48, 9 and 83 days, respectively. Rape plants were harvested as immature foliage (midway between the 2nd and 3rd foliar applications), immediately prior to the last application (pods with seeds, foliage) and finally at maturity whereupon plants were separated into seeds and foliage fractions. After homogenization tissues were extracted with 0.1% formic acid (aqueous):methanol (96:4, v/v) followed by enzyme (α -amylase then amyloglucosidase and cellulase), alkaline (NaOH, 0.1 N, 60 °C, 6 hours) then acid (HCl, 1.0 N, 60 °C, 6 hours) digestion. Extracts containing ≥ 0.01 mg/kg were analysed by HPLC and the identification of residues accomplished with reference to authenticated reference standards.

Table 2 Identification of radioactivity in plants and seed

	Harvest 1		Harvest 2			Harvest 3

RESIDUE ANALYSIS

Analytical methods

The Meeting received information on methods for the determination of glyphosate and some of its metabolites in rape commodities (DuPont 27816 Rev 1). The methods were similar to those reviewed by the 2011 JMPR and are suitable for measuring residues in rape commodities.

Residues of glyphosate, N-acetylglyphosate, N-acetyl AMPA, and AMPA were extracted from forage, seed, and meal in 96% aqueous 0.1% formic acid/4% methanol. Clean-up included partitioning with methylene chloride and passage through a C₁₈ SPE cartridge. A portion of the C₁₈ purified sample was further cleaned-up on an anion exchange cartridge before analysis for glyphosate, N-acetylglyphosate and N-acetyl AMPA with glyphosate internal standard. Another aliquot of the C₁₈ purified extract was further cleaned-up on a cation exchange cartridge before analysis for AMPA with AMPA internal standard.

Residues of glyphosate, N-acetylglyphosate, N-acetyl AMPA, and AMPA were extracted from oil via direct partition into 0.02 M phosphoric acid, with methylene chloride present to retain the oily components. An aliquot of the aqueous sample was diluted prior to analysis for glyphosate, N-acetylglyphosate, N-acetyl AMPA, and AMPA after addition of both glyphosate and AMPA internal standards to each sample. The sample was injected twice, once for analysis of glyphosate, N-acetylglyphosate and N-acetyl AMPA and a second time for AMPA. The LOQ was 0.05 mg/kg for each analyte (glyphosate and metabolites). Mean recoveries for forage, seed, refined oil and meal samples fortified at levels that ranged from 0.05 to 30 mg/kg were acceptable ranging from 78 ± 9.7% to 97 ± 14% for the various analytes.

Stability of pesticide residues in stored analytical samples

The 2005 and 2011 JMPR meetings evaluated data on the storage stability of glyphosate residues (and metabolites) in plant commodities that included commodities with high oil content (corn and soya bean), and in animal commodities. The studies concluded residues in high oil commodities are stable for more than 12 months freezer storage. The longest storage interval in the current trials was 302 days.

USE PATTERNS

Glyphosate is registered as an herbicide on a wide variety of crops. Information on registered uses was made available to the Meeting and those uses of relevance to this evaluation, which are supported by supervised residue trials and based on label information provided by the manufacturers, are summarized in Table 3.

Table 3 Table of use patterns

Crop	Country	Method	Growth stage	Rate kg ai/ha	No.	L/ha	PHI (days)	Comment
Rape seed tolerant varieties, <i>gat</i> gene	Canada	Broadcast spray (ground or aerial)	Pre-emergence	0.68	–		na	
		Broadcast spray (ground or aerial)	0–6 leaf stage	0.3–0.68	–	50–100	7	
		Broadcast spray (ground or aerial)	Pre-harvest	0.9	–	50–100	7 ^a	
Rape seed tolerant varieties, <i>gat</i> gene	USA (pending)	Broadcast spray (ground or aerial)	pre-emergence (A)	≤ 1.7 (seasonal max 1.7 kg/ha pre-emergence)	≥ 1			The combined total per year for pre- and post-emergent (A+B) = (1.7 + 0.84) =
		Broadcast	from crop	≤ 0.84	–single or		60	

Crop	Country	Method	Growth stage	Rate kg ai/ha	No.	L/ha	PHI (days)	Comment
		spray, in crop (over-the- top), ground or aerial	emergence to 6 leaf stage (B)	If two applications 0.42 at the 1–3 leaf stage + 0.42 at < 6 leaf stage but > 10 days apart.	split			2.5 kg ai/ha. The combined total max of post emergence applications = 0.84 kg ai/ha/year

^a Pods are green to yellow; most seeds are yellow to brown. Apply when crop has < 30% grain moisture, typically 7–14 days before harvest

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received information on supervised residue trials of foliar treatments of glyphosate for the following crops:

Application rates were reported as glyphosate acid equivalents (parent). Unquantifiable residues are shown as below the reported LOQ (e.g. < 0.05 mg/kg). Residues, application rates and spray concentrations have been rounded to two figures. Residue data are recorded unadjusted for percentage recoveries or for residue values in control samples. Where multiple analyses were conducted on a single sample, the average value is reported. Where results from separate plots with distinguishing characteristics such as different formulations, varieties or treatment schedules were reported, results are listed for each plot.

Residues from the trials conducted according to critical GAP have been used for the estimation of maximum residue levels, STMR and HR values. Those results are underlined.

The Meeting received supervised residue trials on glyphosate tolerant rape containing the *gat* trait. Supervised residue trials on glyphosate tolerant rape (containing the *gat* trait) were conducted in the USA and Canada in 2009 (DuPont 27816 Rev 1). Residues in seeds are shown in Table 5. The maximum frozen storage interval was 302 days. Oil and meal processing samples were stored for 34 and 46 days, respectively.

Table 4 Summary of sprayers, plot sizes and field sample sizes in the supervised trials

Crop	Location	Year	Sprayer	Plot size	Sample size

For additional containment, tents were used to cover the field plots at the Canadian locations. The tents were a white mesh material that reflected some light, resulting in taller, thinner plants than typical. The tents also created a warmer, more humid environment which served to prolong flowering and to delay maturity beyond what was normal for un-tented canola in the area. Consequently, the trials ran late into the season, it was harder to determine staging and timing, and in some provinces the crops were affected by frost before sampling occurred, despite efforts to protect the plants from frost damage by re-covering the plots with the tents following the third application. The use of mesh tents is unlikely to significantly affect residues in seed or forage.

Samples of forage were collected at times after planting typical for use of the crop as forage.

Table 6 Residues of glyphosate and its metabolites in forage of glyphosate tolerant rape (containing the *gat* trait). All residue concentrations are expressed in glyphosate equivalents (DuPont 27816 Rev 1).

For additional containment, tents were used to cover the field plots at the Canadian locations. The tents were a white mesh material that reflected some light, resulting in taller, thinner plants than typical. The tents also created a warmer, more humid environment which served to prolong flowering and to delay maturity beyond what was normal for un-tented canola in the area. Consequently, the trials ran late into the season, it was harder to determine staging and timing, and in some provinces the crops were affected by frost before sampling occurred, despite efforts to protect the plants from frost damage by re-covering the plots with the tents following the third application. The use of mesh tents is unlikely to significantly affect residues in seed or forage.

Processing studies on grain

A processing study was undertaken in rape seed from rape plants containing event DP-Ø73496-4 modified with the *gat* gene (Shepard, 2013; DuPont-27816 Rev 1). Rape plots were treated with

approximately 5.85 kg ai/ha, as applications of 0.68, 0.68 and 4.5 kg ai/ha, with application timings pre-emergence, 6 leaf stage (BBCH 16) and 7 days pre-harvest. Two different processing procedures (cold-pressing and solvent extraction) were trialled and samples of refined oil and meal collected for analysis.

Cold pressing

Rape seed samples were pressed in an expeller to mechanically remove a portion of the crude oil. Resulting products were meal (cold press) and expelled crude oil. Cold press meal was collected and placed in frozen storage. Crude oil was filtered and processed in the same manner as the combined crude oil from the solvent extraction procedure described below. Cold press refined oil was collected separately and placed into frozen storage.

Solvent Extraction Procedure

Rape seed/kernel was flaked in a flaking roll with a gap setting of 0.28 to 0.38 mm. Flakes were heated to 82–99 °C and held for 10 to 15 minutes in the temperature range. Flakes were then pressed (expelled) in an expeller to mechanically remove a portion of the crude oil. Resulting products were presscake and expelled crude oil. Residual crude oil remaining in the solid material (presscake) exiting the expeller was extracted with hexane.

Presscake was placed in stainless steel batch extractors and submerged in 49–60 °C solvent (hexane). After 30 minutes, the miscella (hexane and crude oil) was drained and fresh hexane added to repeat the cycle two more times. The final two washes were for 15–30 minutes each. After the final draining, the solvent was removed from extracted presscake (meal) using a stream of warm air. Meal was collected and placed into frozen storage.

Miscella was passed through a laboratory vacuum evaporator to separate the crude oil and hexane. Crude oil was heated to 91–96 °C for hexane removal.

Crude oil samples recovered from the expeller and solvent extraction were filtered and combined into a container. Percent free fatty acid (FFA) of the crude oil was determined. Oil was placed in a water bath after pre-treatment with 85% phosphoric acid. Oil was mixed for 29–31 minutes at 40–44 °C. After the pre-treatment, an amount of 12 N baumé sodium hydroxide was added to the oil. Samples were mixed for 19 to 21 minutes at 40–44 °C and then for 9–11 minutes at 65–70 °C. Neutralized oil was then centrifuged to separate the refined oil and soapstock. Refined oil was decanted and filtered. Refined oil was collected and placed in frozen storage.

There was marked reduction in canola oil to non-detectable levels from the residues on the raw agricultural commodity. There was concentration in meal up to 1.8× for glyphosate and N-acetylglyphosate residues. Concentration and reduction of residues was the similar for both cold press and solvent extraction processes. Average meal processing factors were 0.787 and 0.563 for cold press and solvent extraction processes for glyphosate residues and 1.45 and 1.10 for N-acetylglyphosate residues.

Residues in the edible portion of food commodities

No data submitted.

National residue definition

Not applicable.

APPRAISAL

Glyphosate is an herbicide with uses on many crops, conventional and glyphosate tolerant. Glyphosate has been evaluated several times with the initial evaluation in 1986 and the latest in 2011 where the use of glyphosate on glyphosate tolerant crops was reviewed.

The 2011 JMPR established a residue definition for compliance with MRLs for plant commodities as the sum of glyphosate and N-acetyl-glyphosate, expressed as glyphosate in the case of soya bean and maize and glyphosate for other crops. The definition of the residue for compliance with MRL for animal commodities is the sum of glyphosate and N-acetyl-glyphosate, expressed as glyphosate. For estimation of dietary intake it is the sum of glyphosate, AMPA, N-acetyl-glyphosate

and N-acetyl AMPA, expressed as glyphosate. The toxicology of glyphosate was re-evaluated by the 2011 JMPR which estimated group ADI of 0–1 mg/kg bw for the sum of glyphosate, N-acetyl-glyphosate, AMPA and N-acetyl-AMPA. The same Meeting confirmed that an ARfD was unnecessary.

For the current evaluation data have been submitted covering the use on genetically modified rape crops containing the *gat* trait (glyphosate-N-acetyl transferase or GAT gene). These crops inactivate glyphosate by converting it to N-acetyl-glyphosate. The Meeting received information on glyphosate metabolism in genetically modified rape containing the *gat* trait, methods of residue analysis, GAP information, supervised residue trials on *gat* rape crops and the fate of residue during storage and processing.

To assist uniform interpretation of GAP application rates have been expressed in terms of glyphosate acid equivalents (ae), unless indicated otherwise.

Metabolites referred to in the appraisal were addressed by their common names:

N-acetyl-glyphosate	N-acetyl-N-(phosphonomethyl)glycine
AMPA	aminomethyl phosphonic acid
N-acetyl-AMPA	[(acetylamino)methyl]phosphonic acid.

Plant metabolism

The metabolic fate of [¹⁴C] glyphosate in *gat* rape plants was examined following a single pre-emergence soil application of 4.5 kg ae/ha, followed by three foliar applications at 1.0 kg ae/ha at three different growth stages (2 and 5 leaf stage and 1 week before harvest). Rape plants were harvested as immature foliage, immediately prior to the final application and at maturity (PHI 7 days).

N-acetyl-glyphosate was the major metabolite in immature foliage (90% TRR; 5.4 mg/kg glyphosate equivalents). Glyphosate, AMPA and N-acetyl-AMPA were also detected accounting for 3.0, 1.4 and 3.4% of TRR respectively. At the intermediate harvest prior to the final application the only glyphosate related compound detected in foliage and immature pods (with seeds) was N-acetyl-glyphosate representing 93% TRR in foliage and 80% TRR in immature pods (with seeds). The residue in seeds at harvest, seven days after the final application, comprised glyphosate (21% TRR; 0.45 mg/kg), N-acetyl-glyphosate (51% TRR; 1.1 mg/kg), AMPA (1.9% TRR; 0.04 mg/kg) and N-acetyl-AMPA (15% TRR; 0.32 mg/kg).

The proposed pathway of glyphosate in rape plants with the *gat* trait is deactivation to N-acetyl-glyphosate which can be further metabolized to N-acetyl-AMPA and AMPA. The metabolism is similar to that observed for maize and soya bean crops with the *gat* trait previously reviewed by the 2011 JMPR.

Methods of Analysis

The Meeting received description and validation data for analytical methods for residue analysis of glyphosate and its metabolites in various plant commodities using LC-MS/MS. The LOQs are 0.05 mg/kg.

Stability of pesticide residues in stored analytical samples

No new information was received on the stability of glyphosate and its residues in samples stored frozen. The periods of demonstrated stability reported by the 2011 JMPR for other high oil and high protein crops cover the frozen storage intervals used in the residue studies.

Definition of the residue

The 2011 JMPR reviewed glyphosate metabolism studies in tolerant maize and soya bean containing the *gat* trait. Glyphosate, AMPA, N-acetyl-glyphosate and N-acetyl-AMPA were the major components of the residue in both maize and soya bean. In seeds from *gat* rape, N-acetyl-glyphosate

was the major component of the residue (51% TRR) followed by glyphosate (21% TRR) and N-acetyl AMPA (15% TRR). In *gat* rape forage, N-acetyl glyphosate was the major metabolite (90–93% TRR).

To accommodate the use of glyphosate on rape plants containing the *gat* trait the Meeting concluded that the previously established residue definition for enforcement in plants of “glyphosate” should be replaced by “*the sum of glyphosate and N-acetyl-glyphosate expressed as glyphosate*” for soya bean, maize and rape crops and remain “*glyphosate*” for all other crops.

Based on the above the Meeting agreed to amend the previous definition for glyphosate for compliance with MRL for plant commodities as follows:

Definition of the residue for compliance with MRL (for plant commodities): for soya bean, maize and rape - *sum of glyphosate and N-acetyl-glyphosate, expressed as glyphosate*, and for other crops - *glyphosate*.

The Meeting confirmed the residue definition for estimation of dietary intake as (for plant and animal commodities: *glyphosate, N-acetyl-glyphosate, AMPA and N-acetyl AMPA, expressed as glyphosate*).

Results of supervised residue trials on crops

The Meeting received supervised residue trial data for glyphosate on glyphosate-tolerant rape (*gat* trait).

For estimation of maximum residue levels for rape crops glyphosate and N-acetyl glyphosate levels are summed and expressed as glyphosate equivalents.

For estimation of the residue levels for dietary risk assessment of glyphosate in *gat* crops, in general all four analytes may be present in significant amounts. In the *gat* modified rape, N-acetyl glyphosate is the major residue found in rape seed, followed by glyphosate and N-acetyl AMPA. AMPA is a minor component of the residue and is included in the sum of residues when AMPA is reported as < LOQ.

The current Meeting received field trials performed in the USA and Canada involving glyphosate tolerant rape containing the *gat* trait. GAP for Canada is for application pre-emergence at 0.68 kg ae/ha, post-emergence at the 0–6 leaf stage at 0.3–0.68 kg ae/ha followed by a pre-harvest application at 0.9 kg ae/ha (PHI 7 days).

Residues of glyphosate and N-acetyl-glyphosate in rape seed trials matching Canada GAP were: 0.775, 1.8, 1.9, 2.4, 2.85, 3.05, 3.05, 7.8, 9.2 and 15 mg/kg (n=10). The Meeting estimated a maximum residue level of 30 mg/kg for glyphosate in rape seed to replace its previous recommendation of 20 mg/kg.

Corresponding total residues, for dietary intake estimation, were: 0.795, 1.8, 1.95, 2.4, 2.9, 3.1, 3.1, 7.8, 9.2 and 15 mg/kg. The Meeting estimated an STMR for glyphosate in rape seed of 3.0 mg/kg.

It was assumed that rape forage is plant material available from 25 days after planting. Residues in rape forage matching Canada GAP were: 0.4, 0.48, 1.0, 1.1, 1.5, 1.6, 2.1, 2.4, 2.5, 2.5, 3.3, 3.6, 4.7, 5.1, 8.0 and 16 mg/kg (dry matter basis). The Meeting estimated median and highest residues for glyphosate in rape forage of 2.25 and 16 mg/kg respectively, both on a dry-matter basis.

Fate of residues during processing

The Meeting received information on the nature of residues under simulated processing condition on the fate of incurred residues of glyphosate during the processing of rape seeds. Calculated processing factors for total glyphosate acid equivalents (combined results of the four metabolites) are summarized below.

Summary of calculated processing factors and estimated STMR-P values

Commodity	PF _{total}	Best estimate PF _{total}	STMR _{RAC} (mg/kg)	STMR _{RAC} ×PF

				(mg/kg)
Refined oil-cold press	< 0.0009 < 0.003 < 0.003	< 0.003	3.0	< 0.009
Refined oil-solvent extracted	< 0.0009 < 0.003 < 0.003	< 0.003		< 0.009
Meal-cold pressed	0.311 1.47 1.57	1.47		4.41
Meal-solvent extracted	0.107 1.13 1.43	1.13		3.39

The estimated STMR-P values in oil are lower than the previous values reported by the 2011 JMPR (previous 0.093 mg/kg) while the STMR-P estimated for rape seed meal is higher (previous 2.3 mg/kg).

Residues in animal commodities

Animal commodity maximum residue levels

The current evaluation has not led to recommendations that would alter the dietary burdens calculated using the livestock intake figures employed by the 2011 JMPR. The glyphosate dietary burdens for cattle (dairy and beef) were based on grass, cotton seed and barley grain while those for poultry were based on barley, soya bean grain and soya bean hulls and as such do not require a re-evaluation of animal commodity maximum residues levels.

RECOMMENDATIONS

On the basis of the data obtained from supervised residue trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI assessment.

Definition of the residue for compliance with MRL (for plant commodities) for soya bean, maize and rape: *sum of glyphosate and N-acetyl-glyphosate, expressed as glyphosate*, and for other crops - *glyphosate*.

The Meeting confirmed the residue definition for estimation of dietary intake as (for plant and animal commodities): *glyphosate, N-acetyl-glyphosate, AMPA and N-acetyl AMPA, expressed as glyphosate*.

Definition of the residue for compliance with MRL (for animal commodities): *sum of glyphosate and N-acetyl-glyphosate, expressed as glyphosate*.

Definition of the residue for estimation of dietary intake (for plant and animal commodities): *glyphosate, N-acetyl-glyphosate, AMPA and N-acetyl AMPA, expressed as glyphosate*.

The residue is not fat soluble.

Table of recommendations

Commodity		Recommended MRL (mg/kg)		STMR or STMR-P (mg/kg)
CCN	Name	New	Previous	
SO 0495	Rape seed	30	20	3.0
	Rape forage			2.25 (highest residue 16)
OR 0495	Rape seed oil, edible			0.009
	Rape seed meal			4.41

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Daily Intakes (IEDI) of glyphosate for the 13 GEMS/Food regional diets, based on estimated STMRs were in the range 0–1% of the maximum ADI of 1 mg/kg bw for the sum of glyphosate, *N*-acetyl glyphosate, AMPA and *N*-acetyl AMPA, expressed as glyphosate. The Meeting concluded that the long-term intake of residues of glyphosate, *N*-acetyl glyphosate, AMPA and *N*-acetyl AMPA from uses that have been considered by the JMPR is unlikely to present a public health concern. The results are shown in Annex 4 of the JMPR 2013 Report.

Short-term intake

The International Estimated Short Term Intake (IESTI) of glyphosate was not calculated. The 2004 and 2005 JMPR concluded that it was unnecessary to establish an ARfD for glyphosate. The Meeting therefore concluded that short-term dietary of glyphosate residues is unlikely to present a risk to consumers.

IMAZAPIC (266)

*First draft prepared by Dr Yukiko Yamada, Ministry of Agriculture, Forestry and Fisheries,
Tokyo, Japan*

EXPLANATION

Imazapic is an imidazolinone herbicide developed for the control of grasses and broadleaf weeds in a variety of crops. Like all other imidazolinone herbicides, its mode of action is the inhibition of acetohydroxy acid synthase (AHAS or ALS) which catalyses the production of three branched chain amino acids, valine, leucine, and isoleucine, required for protein synthesis and cell growth.

Imazapic has been registered in a number of countries and was included in the Codex Priority List in 2009 as a new compound for evaluation by the current JMPR.

The Meeting received information on physical and chemical properties, animal and plant metabolism, environmental fate, analytical methods, storage stability, use patterns, supervised trials, processing and farm animal feeding.

IDENTITY

ISO common name: Imazapic

Chemical name

IUPAC: 2-[(RS)-4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl]-5-methylnicotinic acid

CAS: 2-[4,5-dihydro-4-methyl-4-(1-methylethyl)-5-oxo-1H-imidazol-2-yl]-5-methyl-3-pyridinecarboxylic acid

CAS Registry No.: 104098-48-8

CIPAC No.: None yet

Structural formula:

Molecular formula: C₁₄H₁₇N₃O₃

Molecular weight: 275.3

Formulations

- Soluble concentrate (SL) formulations containing 25, 90 or 240 g ai/L
- Emulsifiable concentrate (EC) formulations containing 22 or 240 g ai/L.
- Water dispersible granule (WG) formulations containing 175, 525 or 700 g ai/kg.

Except 240 SL and 700 WG, each of these formulations contain one or two other active ingredient(s).

METABOLISM AND ENVIRONMENTAL FATE

The following links code number and structure or description of the compound appearing in the various metabolism and environmental fate studies.

Structure of compounds appearing in metabolism and environmental fate studies

Code (MW)	IUPAC chemical name	Structure	Found in
Imazapic (275.3)	2-(4-isopropyl-4-methyl-5-oxo-imidazolin-2-yl)-5-methyl-nicotinic acid		Livestock (goat, hen), rat, Plants (soya bean, sugar cane, peanut, Bermuda grass) Soil

The metabolism and distribution of imazapic in animals and plants and the fate of imazapic in the environment were investigated using the following $^{14}\text{C}/^{13}\text{C}$ -radiolabelled compounds.

In the descriptions below, the application rates are all in acid equivalents.

Animal metabolism

The Meeting received information on the results of studies on lactating goats and laying hens which were fed isotope-labelled imazapic or CL263284.

Metabolism studies on laboratory animals including rats were reviewed in the framework of toxicological evaluation by the current JMPR and the relevant information is summarized below.

Rat

A metabolism study using rats was evaluated and described in detail by the WHO Panel. Radiolabelled imazapic administered by oral gavage was rapidly and extensively absorbed, minimally metabolized, and excreted primarily in the urine after single dose of 10 or 1000 mg/kg bw, or repeated low dose of 10 mg/kg bw per day over 14 days to rats. Biliary excretion was minimal. The majority of radioactivity was excreted as the unchanged parent compound within the first 6 hours post-dosing. Less than 2% of the administered dose (AD) was detected in the carcass with trace amounts detected in blood, kidneys and liver of the high dose group; however, radiolabelled test substance was not detected in any other organs. There was no evidence of accumulation. Imazapic and its metabolites were not excreted in expired air. Parent compound accounted for 94% of the AD in the urine and 2.3% of the AD in the faeces. The metabolites produced from oxidation, reduction and hydrolysis, including CL 263284, CL 280442 and several other unidentified metabolites, accounted for a total of approx. 6% AD in the urine and faeces.

Lactating goats

Imazapic

A lactating goat was orally given single encapsulated doses of [pyridine-6-¹⁴C]- and [pyridine-6-¹³C]-imazapic daily for 5 consecutive days at a dose of 254 mg/day, equivalent to 175 ppm of test material in the diet, based on the actual food consumption during the treatment period (Sharp and Thalacker, 1999a). A control goat was given placebo capsules for 5 days. Urine and faeces samples were collected daily. Milk samples were collected twice daily. The animals were sacrificed approximately 23 hours after the last dose, and liver, kidneys, fat, bile, muscle, blood, and gastrointestinal (GI) tract and its contents were collected. All samples, except the bile and GI tract and its contents, were analysed for radioactivity content.

Samples were analysed by LSC after combustion. Selected tissue (liver, kidney, muscle and fat) and milk extracts and ¹⁴C-sample eluents were analysed using HPLC and TLC to determine the metabolic profile. The limits of detection were 0.001–0.004 mg/kg with sample sizes of 0.2–5 g. Kidney, liver, muscle and selected milk samples were extracted and analysed for ¹⁴C-imazapic, CL 263284 (imazapic alcohol metabolite) and CL 312622 (5-acid imidazolinone metabolite). Fat (omental and renal) was not extracted and analysed because the concentration of radioactive residues was < 0.010 mg/kg.

Among 90.7% of the total administered radioactivity (TAR) recovered, urine contained 81.7% and faeces 6.7% of TAR with cage wash and wipe accounted 1.2% and 1.2% respectively of

TAR. This indicate that urinary excretion is the major route of elimination from body. Approximately 75% of each daily dose was excreted in the urine in the 24-hours following each dose administration.

From milk 0.03% TAR was recovered and from the edible tissues and blood collected contained 0.01% TAR.

The radioactive residues in the milk from pm milking, the first collection of milk after each capsule administration ranged from 0.045 mg eq/kg (Day 1) to 0.078 mg eq/kg (Day 5), expressed in mg/kg-equivalents of imazapic. The radioactive residues in the milk from am milking, the second milk collection after each capsule administration, ranged from 0.012 to 0.014 mg eq/kg, lower than those in the milk from pm milking. The calculated daily radioactivity residue levels in milk ranged from 0.026 mg eq/kg (Day 1) to 0.037 mg eq/kg (Day 5). The total amount of radioactivity in milk ranged from 53.4 to 83.9 µg eq per day.

Among the tissues collected and analysed, the kidney contained 0.275 mg/kg, liver 0.033 mg/kg, muscle 0.010 mg/kg, blood 0.086 mg/kg and fat 0.003 mg/kg, expressed in mg/kg-equivalents of imazapic.

The results of the TRR in lactating goats are presented in the following table.

Table 1 Total radioactive residues (TRR) in goat treated with ^{14}C -imazapic.

Sample	TRR (mg/kg)*	Imazapic	
		mg/kg	% TRR
Milk (48 h p.m.)	0.058	0.039	66.8
Milk (120 h p.m.)	0.078	0.051	65.0
Kidney	0.275	0.234	85.0
Liver	0.033	0.016	49.1
Muscle	0.010	0.003	33.8

* expressed in mg/kg-equivalents of imazapic.

Parent ^{14}C -imazapic was the only major residue detected in tissues and milk.

In another study (Kao, 1993a), lactating goats were orally treated with a mixture of [pyridine-6- ^{13}C]- and [pyridine-6- ^{14}C]-imazapic. Feeding level for each of two goats was equivalent to 2.0 or 11.8 ppm in the diet daily for 7 consecutive days. One goat was used as a control. Samples of blood, milk and excreta were collected daily and either refrigerated or stored frozen. After seven days of dosing, the goats were sacrificed and the tissues (kidney, liver, muscle, and fat) were collected approximately 20 hours after the last dose. Tissue samples were stored frozen.

Samples were analysed by LSC either after combustion or by direct analysis. The validated detection limit of the radioassay method was approximately 0.01 mg/kg for milk, blood, and all tissues except fat with a validated sensitivity of 0.02 mg/kg. Extracts of the kidney and faeces and aliquots of urine were analysed by reverse phase radio-HPLC with two different phases used for analysis of the kidney.

Elimination of radioactive residues in the urine accounted for 67.2% and 94.0% of the TAR for the low and high doses, respectively. The radioactivity excreted in the faeces represented 7.0% and 9.6% of the TAR for the low and high doses, respectively.

The TRR in the daily collected blood and milk samples were < 0.01 mg eq/kg at both dose levels. The TRR in liver and muscle were < 0.01 mg eq/kg and < 0.02 mg eq/kg in fat regardless of the dose level. The TRR in the kidney was < 0.01 mg eq/kg from the goat dosed at 2.0 ppm and 0.05 mg eq/kg from the goat dosed at 11.8 ppm.

93% of TRR in kidney of the high-dose goat were extracted with acetonitrile and methanol. Analysis of the extract by reverse phase HPLC showed imazapic at 30% TRR (0.02 mg/kg), CL 263284 (hydroxymethyl imazapic) at 8% TRR (< 0.01 mg/g) and unknown A at 7% TRR (< 0.01 mg/kg). An unresolved peak near the solvent front comprised 33% TRR (0.02 mg/kg).

Analysis of the kidney extract by reverse phase HPLC using two different HPLC phases with comparison to reference standards confirmed the identification of the components.

HPLC analysis of the urine showed that radioactive residue was essentially unmetabolized imazapic. HPLC analysis of extracts of faeces showed the presence of imazapic (58% TRR) and the lesser amount of hydroxymethylated metabolite CL 263284 (9% of TRR).

CL 263284

A study (Kao, 1994a) was conducted using the [pyridine-6-¹⁴C]-radiolabelled hydroxymethyl imazapic (CL 263284) fed in capsule to lactating goats daily for seven days. Feeding levels for each of two goats were equivalent to 2.33 or 14.5 ppm of feed. One goat was used as a control. Samples of blood, milk and excreta were collected daily. After seven days of dosing, the goats were sacrificed, and the tissues kidney, liver, muscle and fat were collected 20 hours after the last dose. CL 283284 was eliminated via urine (15–18% of the applied dose) and faeces (82% and 68% of the applied dose at low dose and high dose respectively). The TRR in the daily blood and milk samples and those in liver, muscle, and omental fat were all less than 0.01 mg eq/kg, for both feeding levels. The TRR in kidney was < 0.01 mg eq/kg for low dose and 0.03 mg eq/kg for high dose. Analysis of the extract of kidney from the high dose goat showed that 9% (< 0.01 mg/kg) of the extracted TRR was CL 263284, and the remaining residue was predominantly a labile component M1 (78% TRR, 0.02 mg/kg), possibly a salt of CL 263284, which converted to CL 263284 on exposure to aqueous buffer.

Laying hens

Laying hens were orally dosed with a mixture of [pyridine-6-¹³C]- and [pyridine-6-¹⁴C]-imazapic in capsules (Gatterdam, 1993a). Feeding levels for three groups, each containing 8 hens, were 0, 2.1, or 11.4 ppm in feed daily for 7 consecutive days.

Eggs were collected twice daily and, after compositing, were refrigerated. After 7 days of dosing, the hens were sacrificed and blood and tissues (liver, kidney, muscle and skin with adhering fat) were collected approximately 22 hours after the last dose. Tissue samples were composited for each group and stored frozen at -20 °C.

Samples were analysed by LSC either after combustion or by direct analysis. The validated limit of detection of the radioassay method was approximately 0.01 mg/kg for eggs, blood, and all tissues.

TRR in the all egg samples and all tissue and blood samples were less than 0.01 mg eq/kg. Total recovery of radioactivity in excreta was 90.6% and 95.2% for the low and high dose, respectively.

Study 2 (Afzal, 1994a)

A study was conducted on laying hens with the [pyridine-6-¹⁴C]-radiolabelled hydroxymethyl imazapic (CL 263284). Hens were dosed orally, with feeding levels for each group at 2.14 or 10.9 ppm in diet daily for seven days. After seven days, the hens were sacrificed and the tissues (liver, kidney, muscle and skin with adhering fat) were collected for analysis approximately 22 hours after the final dose. Total recovery of radioactivity in excreta was 85.3% and 88.6% for the low and high doses, respectively. Residues in all tissues, liver, kidney, muscle, skin with adhering fat, blood and eggs, were less than 0.01 mg eq/kg. In summary, orally administered CL 263284, the hydroxymethyl metabolite of imazapic was mainly eliminated from the hen through excreta. No detectable (< 0.01 mg eq/kg) radioactive CL 263284-derived residues were found in eggs or edible tissues.

Proposed metabolic pathway of imazapic in animals

A proposed metabolic pathway for imazapic in rat and the lactating goats is presented in Figure 1. The majority of orally dosed imazapic was eliminated unchanged, mostly via urine (goats) and excreta (hens). The radioactive residues in edible tissues, milk or eggs were very low. In lactating goats, residues remaining in kidney were mostly unchanged parent with a minor amount of CL263284. In laying hens the studies with oral administration of either imazapic or its hydroxymethyl metabolite

did not result in detectable residues in any tissues or eggs. In the case of rats, imazapic was also primarily eliminated rapidly, unchanged, via urine. A small amount of the total dose excreted via faeces, consisted mostly of unchanged parent with minor amounts of metabolites CL 303459, CL 263284 and CL 290610 together with even lower amounts of several unknown radioactive components. Some amount of imazapic remaining in the body of animals did not go through extensive metabolism with minor oxidation to produce hydroxylated metabolite and in the case of rats, another metabolism to produce two minor metabolites through possibly hydrolysis.

Figure 1 Proposed metabolic pathway of imazapic in animals

Plant metabolism

The Meeting received information on the fate of imazapic in sugar cane, peanuts, Bermuda grass and transgenic soya beans.

Sugar cane

Study 1 (Mangels, 1988a)

A metabolism study was conducted to investigate [pyridine-6-¹⁴C]-imazapic in sugar cane variety CP 65-357. [¹⁴C]-labelled imazapic was mixed with unlabelled imazapic and applied to the soil surface as a pre-emergence treatment at a rate approximating 150 g/ha by spraying 200 mL of the

aqueous solution of the compound onto the soil. The test was carried out under natural climatic conditions using one test plot of 0.6×3.1 m size and one control plot.

At harvest, approximately 13 months after pre-emergence treatment, mature sugar canes were cut above the soil and the outer leaves were removed by hand. The stalks were cut into thirds and each third was cut into pieces of 15–20 cm length.

All plant samples were frozen after collection and shipped to the analytical laboratory over dry ice. Twelve pieces from each section were combined and ground to a fine consistency in the presence of solid CO_2 . The radioactive residues present in the sugar canes were determined by combustion and liquid scintillation counting (LCS).

Radioassays of the stalk samples indicated that there were no detectable ^{14}C residues present in the harvest samples (< 0.005 mg/kg).

Study 2 (Grosshans, 2009a)

In another study, the metabolism of [pyridine-6- ^{14}C]-imazapic was investigated in sugar cane grown in plastic boxes ($0.365 \text{ m} \times 0.56 \text{ m}$) filled with a sandy loam soil. The cultivation of the crop and the plant uptake part of the study was conducted in a greenhouse. A calculated amount of ^{14}C -imazapic was dissolved in blank formulation solution (DG formulation with adjuvant BAS 160 00 S in water). This resulted in a nominal target rate of 245 g ai/ha (corresponding to spray volumes of approximately 220 L/ha). The formulation was applied as a pre-emergence treatment using an automatic spray track system.

Sugar cane plants were sampled at 63, 96, 151 and 236 DAT and adult plants were split into leaves and stalks.

Frozen samples (sugar cane forage, leaves or stalks) were mixed with dry ice and homogenized using a Stephan mill. Weighed homogenized subsamples were extracted three times with methanol and twice with water. The methanol extracts of the three steps were combined and adjusted to a defined volume. Aliquots of the combined extracts were measured by Liquid Scintillation Counting (LSC). The residue was further extracted in the same way with appropriate volumes of water (twice). The aqueous extracts were also combined, adjusted to a defined volume, and aliquots of the combined aqueous extracts were radioassayed by LSC as well. Based on the sum of radioactive counts found in the methanol and aqueous extracts, the ERR is calculated. The residue remaining after methanol and water extraction of each sample was air dried, and the weight of the remaining sample was determined. The samples were homogenized using an analytical mill prior to combustion analysis of aliquots for the determination of the PES. The PES after methanol and water extraction of sugar cane samples accounted only for low concentrations, therefore no further processing was attempted.

Additional extraction procedures were carried out to get further information about the extractability of radioactive residues. Solvents or solvent mixtures were used which are applied in residue analytical methods: A three step extraction method with methanol / 25 mM HCl (6/4, v/v; Method SOP-PA.0288); and a three step extraction method with methanol / acetone / water (1/1/1, v/v/v; Method M 2253.01).

The calculated total radioactive residues of the growing sugar cane forage sampled 63 DAT of pre-emergence treatment with ^{14}C -imazapic accounted for 0.0358 mg/kg (Table 2). The TRR of forage sampled 96 DAT was lower with 0.0161 mg/kg. On 151 DAT, small plants were sampled as forage material (TRR 0.0222 mg/kg). The leaves (TRR) and stalks (TRR) of full grown plants sampled 15 DAT contained TRR of 0.0242 and 0.0086 mg/kg respectively. At the last sampling date of 236 DAT, leaves and stalks of the adult plants contained residues at 0.0151 mg/kg and 0.0039 mg/kg, respectively.

Table 2 TRRs in sugar cane samples after pre-emergence treatment with [pyridine-6-¹⁴C]-imazapic

Matrix	Days after Treatment	TRRs in Treated Sugar Cane Matrices

^a young small plants

^b adult plants

The extraction profiles of radioactive residues from sugar cane leaves and stalks are summarized in Table 3.

High percentage (82.0–84.4% TRR) of the radioactive residues in forage (63, 96 and 151 DAT) was extracted, most of which (77.1 to 80.0%) extracted with methanol. The additional water extraction released only 3.2 to 4.4% TRR. Most of the extracted radioactive residues were water-soluble (48.1 to 79.0% TRR). The residual radioactive residues accounted for 15.6 to 19.7% TRR (0.0032 to 0.0064 mg eq/kg).

Equally high percentage (78.1–83.6% TRR) of radioactive residues in leaves (151 and 236 DAT) were extracted, most of which extracted with methanol (72.3 to 78.6%). The additional water extraction released only 5.1 to 5.8% TRR. Most of the extracted radioactive residues were water-soluble (71.5 to 75.8% TRR). The residual radioactive residues accounted for 16.4 and 21.9% TRR (0.0033 and 0.0040 mg eq/kg).

Slightly lower but still quite high percentage (63.4–81.9% TRR) of radioactive residues in stalks (151 and 236 DAT) was extracted, most of which extracted with methanol (59.2 to 78.4%). The additional water extraction released 3.4 to 4.2% TRR. Most of the extracted radioactive residues were water-soluble (63.3 to 65.2% TRR). The residual radioactive residues accounted for 18.1 and 36.6% TRR (0.0014 and 0.0016 mg eq/kg).

The identification of metabolites was based on HPLC analyses of the concentrated extracts and/or clean-up fractions either via solvent partition or fractionation. The parent compound and the metabolites were assigned by comparison of the retention times with synthesized and certified reference compounds. All the quantification of the parent compound and its metabolites was based on the HPLC analyses of the concentrated extracts or clean-up fractions obtained from the individual matrices using two different HPLC methods with radio-detection. The results of identification and characterization are shown in Table 4.

Imazapic was found in all samples investigated (5.7 to 41.3% TRR, 0.0005 to 0.0058 mg/kg). In addition, the hydroxymethyl metabolite CL263284 was detected in all samples investigated (10.1 to 44.5% TRR, 0.0005 to 0.0139 mg eq/kg). Its glucoside CL189215 was found only in forage and leaves (2.7 to 8.0% TRR, 0.0005 to 0.0019 mg/kg) and could not be identified in stalks. Some HPLC peaks in the chromatograms could be characterized by their chromatographic behavior.

In samples taken up to 151 DAT, the degree of identification was 55.1 to 69.0% of the TRR. Additional 14.7 to 30.5% TRR could be characterized for its chromatographic, SPE fractionation, partition or extraction behavior.

Since the extractability of the 236 DAT stalk and leaves samples was lower, only 21.3 and 34.7% TRR, respectively, only known metabolites could be identified. Additional 29.9 and 29.7% TRR could be characterized in stalks and leaves, respectively.

^a in extracted radioactive residues (ERR)

The TRR in adult sugar cane parts were low (leaves 0.024 mg eq/kg and 0.015 mg eq/kg and stalks 0.009 and 0.004 mg eq/kg for the 151 DAT and 236 DAT, respectively). Most of the radioactive residues were extracted with methanol, and only minor portions subsequently with water. The major radioactive components in the extracts were identified as unchanged parent, the 5-hydroxymethyl metabolite CL263284 and its glucose conjugate CL189215 (in forage and leaves only). The glucose conjugate CL189215 was not present in sugar cane stalks.

Peanut

A metabolism study was conducted with [pyridine-6-¹⁴C]-imazapic in peanuts of variety NC7 (Wu, 1993a). The plants were kept in outdoor test plots. Both untreated and treated plots had total area of 1.2 × 2.4 m of sandy loam soil. Radiolabelled imazapic in a 2ASU formulation was applied to peanut plants at a rate of approximately 72 g ai/ha 30 days post-emergence. Pre-harvest (green plant) samples were collected at 0, 31, and 61 DAT. At harvest (131 DAT) hay and peanuts were collected. Soil samples were taken prior to and just after application and at harvest.

Samples were frozen after collection and shipped to the analytical laboratory over dry ice. Each mature harvest sample was separated into hay, hulls, and nutmeat. Green plants sampled at 0, 31, and 61 DAT and hay were first cut into small pieces and then homogenized in dry ice and/or liquid nitrogen. Nutmeat and hull were also ground in dry ice and/or liquid nitrogen. Levels of radioactivity in soil and plant matrices were determined by combusting subsamples in a sample oxidizer. All combustions were performed in triplicate.

Crop samples were sequentially extracted with methanol:water:acetone (1:1:1) and methanol:water (80:20) containing 2% hydrochloric acid except for nutmeat, which was extracted only with the former. HPLC of the peanut green plant, hay, hull, and nutmeat extracts was performed on a Supelco C₁₈ reversed-phase column using an acetonitrile and phosphate buffer gradient system.

The TRR in all plant parts were determined by combustion. Additionally, the TRR was calculated by summing of the ERR extracted with methanol:acetone:water (1:1:1, v/v/v) and the PES. A summary of the TRR values in peanut plant matrices collected at various time intervals is shown in Table 5.

The TRR in the peanut plant declined significantly from 4.23 mg eq/kg at 0 DAT in green plants to 0.216 mg eq/kg (hay). The TRR in nutmeat at 131 DAT was low at 0.022 mg eq/kg (nutmeat)

PES =post extraction solid (after solvent extraction)

* Expressed in mg-imazapic equivalents/kg.

The extraction profiles of radioactive residues from peanut plant samples are summarized in Table 6.

The radioactive residue in peanut plant samples (green plant, hay, hull, and nutmeat) was initially extracted with methanol:water:acetone (1:1:1, v/v/v). Table 9 shows that 76–96% of the TRR in peanut samples was extracted with aqueous methanol:acetone. In order to get sufficient solid residue after solvent extraction for further process of the unextracted radioactivity, fresh peanut samples, with the exception of nutmeat, were extracted with methanol:water:acetone (1:1:1). The resultant residue after solvent extraction containing 6–20% of the TRR was then further processed by extraction with methanol:water (80:20) containing 2% hydrochloric acid. An additional 3–8% of the TRR was extracted into the acid methanol:water mixture. In the case of the green plant (0 DAT), the residue after solvent extraction with 2% HCl-methanol:water was subjected to a third extraction by using methanol:water (80:20) containing 0.5 M sodium hydroxide. An additional 30% of the unextracted fraction (1% of TRR) was soluble in the base methanol:water mixture. Following extraction of the hay with acid:methanol:water, the resulting residue was treated with *Aspergillus* cellulase at 37 °C for 72 hours which solubilized about 36% of ¹⁴C-residues in the marc (4% of TRR). The results suggest the presence of glycosidic linkage of the residues with endocons in the peanut hay.

PES =post extraction solid (after solvent extraction)

* Expressed in mg-imazapic equivalents/kg.

The nature of the radioactive components in the extracts of peanut samples was characterized first by matching the HPLC profile with the reference compounds. The identification of metabolites was then accomplished by isolating them from peanut plant (61 DAT) and harvest peanut hay. Structural characterization of the isolated metabolites was confirmed by mass spectral analysis. The results of identification and quantification are shown in Table 7.

The [¹⁴C]-Imazapic accounted for 76% TRR in the green plant at 0 DAT, 2% in the plant at 31 DAT, 3% in the plant at 61 DAT, 3% in the hay, 2% in the hull, and 1% in the nutmeat. Residues of imazapic in all samples, except at 0 DAT, were < 0.01 mg/kg. This indicates imazapic was significantly metabolized.

The metabolite CL263284 accounted for 1% of the TRR (0.048 mg/kg) in the plant at 0 DAT, 12% (< 0.01 mg/kg) in the plant at 31 DAT, 12% (0.010 mg/kg) in the plant at 61 DAT, 28% (0.055 mg/kg) in the hay, 28% (0.025 mg/kg) in the hull, and 8% (0.001 mg/kg) in the nutmeat, showing increase over time.

The metabolite CL189215, which is glycoside of CL263284, accounted for 2% of the TRR (0.095 mg/kg) in the plant at 0 DAT, 32% (0.023 mg/kg) in the plant at 31 DAT, 46% (0.039 mg/kg) in the plant at 61 DAT, 16% (0.032 mg/kg) in the hay, 36% (0.032 mg/kg) in the hull, and 35% (0.006 mg/kg) in the nutmeat.

No other component of the extracted ¹⁴C-residue from the immature plant and harvest samples exceeded 10% TRR as determined by HPLC. The concentration was all less than 0.01 mg eq/kg, with the exception of one component (0.014 mg eq/kg) detected in the hay.

DAT=days after treatment

Bermuda grass

A metabolism study was conducted to investigate metabolism of [pyridine-6-¹⁴C]-imazapic in Bermuda grass (Fung, 1999a). The Bermuda grass was treated when approximately 51 cm tall (62 days after sprigging) with a blank formulation for the control plot or a single post-emergence application of [¹⁴C]-imazapic at an actual rate of approximately 203 g ai/ha and a spray volume of 300 L/ha for the treated plot. The field portion of the study was conducted in outdoor test plots. Both treated and untreated plots had total area of 0.9 × 4.6 m of loam soil. Bermuda grass forage samples were collected within three hours after application (0 DAT) and at 15, 32, and 49 DAT. Bermuda grass foliage for hay samples was cut at 68 days after treatment.

Samples were frozen after collection and shipped to the analytical laboratory over dry ice. Bermuda grass samples were cut with a pair of shears into small pieces (approximately 5 cm long) and ground to fine powder in two steps with dry ice. The TRR in all plant parts were determined by combustion. Additionally, the Bermuda grass samples were each extracted sequentially with an aqueous methanol/acetone mixture followed by sequential extraction with acidified aqueous methanol, aqueous acid, and aqueous base. The post-extraction solids were treated sequentially with enzymes, 10 N NaOH reflux, and 6 N HCl reflux to attempt releasing of the bound residues. The aqueous methanol/acetone extract, the combined sequential extracts and the post-extraction solids wash were each analysed by HPLC on a reversed phase C₁₈ column.

A summary of the TRR in Bermuda grass samples collected at various time intervals is shown in Table 8. The increased residue concentration in the hay compared to 49 DAT forage is attributed to the dehydration of the grass.

Table 8 TRR in Bermuda grass samples after post-emergence treatment with [pyridine-6-¹⁴C]-imazapic

Matrix	Days after Treatment	TRRs in Treated Sugar Cane Matrices	
		Determined by Direct Combustion (mg eq/kg)*	Sum of Extracted Radioactive Residue and PES (mg eq/kg)*
Forage	0	8.25	8.29
Forage	15	4.58	3.92

Forage	49	0.77	0.78
Hay	68	0.92	0.83

PES =post extraction solid (after solvent extraction)

* Expressed in mg-imazapic equivalents/kg.

The extraction profiles of the radioactive residues from Bermuda grass are summarized in Table 9.

The incurred residues extracted by the neutral aqueous methanol/acetone solvent decreased from 98% for the 0 DAT sample, to the range of 69% to 51% for the 15 to 49 DAT samples, and about 35% for the hay sample at 68 DAT. A significant amount of the radioactivity ranging from

12.6% TRR in the 15 DAT sample to 27% TRR in the 68 DAT hay was extracted with dilute acid and base. Thus, the total extracted radioactive residues were 84% to 101% of the TRR in forage, and 74% of the TRR in hay.

The remaining radioactivity in the residues after solvent extraction (PES) accounted for about 2–3% of the TRR in the 15 and 32 DAT samples, 10% of the TRR in the 49 DAT sample, and 31% of the TRR in the 68 DAT sample. Treatment of the PES with enzymes cellulase and pepsin released only a very small amount of the bound residues (< 5% TRR) suggesting that the unextracted residues in the PES did not contain glycoside or peptide bonds. Following enzymatic treatment, the resulting solids were subjected to base (NaOH) and acid (HCl) hydrolyses under reflux. The acid and base hydrolyses steps also released a very small amount of radioactive residues: < 1% TRR in the 15 and 32 DAT samples, 4.3% TRR in the 49 DAT sample, and 8.0% TRR in the 68 DAT sample. The results suggest that portions of the radiolabelled carbon have been incorporated into undefined plant constituents.

^a combined sequential extracts of (1) methanol: HCl: H₂O, (2) 1 N HCl and (3) 1 N NaOH

* Expressed in mg-imazapic equivalents/kg.

The chemical structure of the parent compound and its putative Bermuda grass metabolites were confirmed by the characteristic ions detected in the Liquid Chromatography - Electrospray Positive Ion Mass Spectrometry (LC-ESP/PIMS) of the purified metabolites and, where available, by authentic reference standard compounds.

When the aqueous methanol/acetone extract, the combined sequential extracts and the post-extraction solids wash were each analysed by HPLC on a reversed phase C₁₈ column, there were 11 discernible regions or peaks, designated as M1 (the most polar) through M10 (the least polar), detected on the radiochromatograms. The chromatographic patterns were compared with those obtained from the known reference compounds including parent compound imazapic, hydroxymethyl analog CL 263284, glucose conjugate CL 189215, 3,5-dicarboxylic acid analog CL 312622, CL 290610 and CL 397695. Chromatography of the isolates of some of the regions or peaks by HPLC on Hypercarb graphitic column and other solid support showed that these peaks were comprised of multiple components as illustrated below:

The enzymes, acid, and base hydrolyzates of the samples from Bermuda grass hay and forage contained radioactivity which was too low to conduct HPLC analysis.

The metabolites detected in Bermuda grass forage and hay are summarized in Table 10.

Imazapic was extensively metabolized in Bermuda grass and accounted for only about 6% of the TRR at 15 DAT. Quantitatively, CL 263284 and CL 189215 were the major Bermuda grass metabolites of imazapic. Although M1 accounted for up to 26.8% of TRR in the grass samples at various time intervals, it was comprised of at least twelve groups of multi-radioactive components.

The 0 DAT (about three hours after application) sample extracts showed a main chromatographic peak that coincided with the standard of the parent compound (89.3% of TRR). In addition, several radioactive residue components including hydroxymethyl metabolite CL 263284 (0.7% TRR) and its glucose conjugate CL 189215 (1.0% TRR) and minor residue fractions M2, M3, M3A, M6, and M8 through M10 of varying quantities were detected. The proportions of these radioactive residue fractions/or metabolites changed with time.

At 15 DAT, the hydroxymethyl metabolite CL 263284 became the single most prominent residue component (30.2% TRR) and the quantity was maintained at > 20% TRR at 32 and 49 DAT, then declined to 8.4% TRR at 68 DAT. The increase of CL 263284 and its glucoside conjugate CL 189215 contents in the grass sample coincided with the decline of the parent compound from about 89% of the TRR at three hours after application to 6% TRR at 15 DAT, 3% TRR at 49 and 2% TRR at 68 DAT.

In addition to the CL 263284 metabolite, a significant amount of highly polar metabolites in the M1 fraction were formed at 15 DAT (20.6% TRR) and at 49 and 68 DAT (~27% TRR). Among at least 12 groups of multi-radioactive components of M1 fraction, groups M1-B and M1-C were present at about 0.1 mg/kg at 15 DAT. Their chemical structures are shown to be multi-substituted pyridine derivatives. M1-B was characterized as 5-hydroxymethyl-nicotinamide derivative and additionally M2-A 5-hydroxymethylquinolic acid anhydride. Some other minor fractions were also identified.

Table 10 Characterization and identification of radioactive residues in Bermuda grass samples after post-emergence treatment with [pyridine-6-¹⁴C]-imazapic

* The values of mg/kg for individual metabolites (M1 to M10) were the sum of mg/kg values obtained from the aqueous methanol-acetone extract, the combined sequential extracts and the post-extraction solids wash except that in case of < 0.01 mg/kg in one of the extract, the sum of mg/kg values was calculated from the sum of % TRR times TRR in mg/kg in the grass or hay.

** The values of % TRR for individual metabolites (M1 to M10) were the sum of % TRR values obtained from the aqueous methanol/acetone extract, the combined sequential extracts and the post-extraction solids wash.

Transgenic soya beans

A metabolism study was conducted in 2011 to investigate metabolism of [pyridine-3-¹⁴C]-imazapic in transgenic soya bean variety BPS-CV127-9 in which the *csr1-2* gene encoding an altered AtAHASL protein was inserted to make the host tolerant to imidazolinone herbicides (Dohn and Estigoy, 2012a). [¹⁴C]-imazapic in DG formulation was sprayed once at BBCH growth stage 65 with an application rate of 80.1 g/ha to the above-ground portion of soya beans plants. This application rate is equivalent to 4.6 times the maximum anticipated label rate. Soya bean forage was harvested approximately one hour after application and hay was harvested 35 days after treatment. Soya bean straw, pods, and seeds were harvested when mature, 97 days after treatment.

Samples were frozen after collection and shipped to the analytical laboratory over dry ice. They were ground to a fine consistency in the presence of solid CO₂ using a food processors. The moisture content of hay and seed was measured by drying subsamples at 105 °C. Portions (25 g of forage, hay, straw, and pods, 50.7 g of soya bean seed) of the processed samples were subjected to sequential solvent extraction. Samples were extracted sequentially by 100% methanol (two times), followed by 100% water and methanol:water:1N HCl (60:39:1,v:v:v). The radioactive residue remaining in the PES samples was measured by combustion analysis and LSC counting. The TRR were calculated as the sum of extracted radioactivity (ERR) and radioactivity recovered in the PES.

The TRR of soya bean forage was 0.689 mg eq/kg, soya bean hay 0.241 mgeq/kg, soya bean seed 0.014 mg eq/kg, soya bean straw 0.092 mg eq/kg and soya bean pod 0.042 mg eq/kg as shown in Table 11. The extraction procedure released 77.8% to 98.4% of the TRR.

Table 11 TRR in transgenic soya bean samples following foliar application of [pyridine-3-¹⁴C]-imazapic

Matrix	Days after Treatment	TRRs in Treated Soya Bean Matrices	
		Determined by Direct Combustion (mg eq/kg)*	Sum of Extracted Radioactive residue and PES (mg eq/kg)*
Forage	0	0.689	0.673
Hay	35	0.241	0.240
Seeds	97	0.014	0.015
Straw	97	0.092	0.088
Pods	97	0.042	0.045

PES = post extraction solid (after solvent extraction)

* Expressed in mg-imazapic equivalents/kg.

The extraction profiles of radioactive residues from soya bean forage, hay, straw, hull and seed are summarized in Table 12. As a consequence of low residual radioactive residues (PES), no further processing was conducted on PES.

The residue extracted from forage 0 DAT was 0.662 mg eq/kg (98.4% of the TRR calculated to be 0.673 mg eq/kg). The methanol extract contained 92.1% of the radioactive residues (0.620 mg eq/kg), the aqueous fraction 5.2% (0.035 mg eq/kg), and the acidic methanol 1.1% of the radioactivity (0.007 mg eq/kg). The PES contained residue of 0.011 mg eq/kg (1.6% of the TRR).

The residue extracted from hay 35 DAT was 0.221 mg eq/kg (92.1% of the TRR calculated to be 0.270 mg eq/kg). The methanol extracts contained 76.7% of the radioactive residues (0.184 mg eq/kg) and the aqueous fraction 12.9% (0.031 mg eq/kg). The acidic methanol extracted 2.5% of the radioactivity (0.006 mg eq/kg) and was not further analysed. The PES contained residue of 0.019 mg eq/kg (7.9% of TRR).

The residue extracted from seeds 97 DAT was 0.013 mg eq/kg (86.7% of the TRR calculated to be 0.015 mg eq/kg). The methanol extracts contained 46.7% of the radioactive residues (0.007 mg eq/kg) and the aqueous fraction 26.7% (0.004 mg eq/kg). The acidic methanol extracted 13.3% of the radioactivity (0.002 mg eq/kg). The PES had 0.002 mg eq/kg of radioactive residue (13.3% of TRR).

The residue extracted from straw 97 DAT was 0.072 mg eq/kg (81.8% of the TRR calculated to be 0.088 mg eq/kg). The methanol extracts contained 59.1% of the radioactive residues (0.052 mg eq/kg) and the aqueous fraction 17.0% (0.015 mg eq/kg). The acidic methanol extracted 5.7% of the radioactivity (0.005 mg eq/kg). The PES had 0.016 mg eq/kg of radioactive residue (18.2% of TRR).

The residue extracted from pods 97 DAT was 0.035 mg eq/kg (77.8% of the TRR calculated to be 0.045 mg eq/kg). The methanol extracts contained 33.3% of the radioactive residues (0.015 mg eq/kg) and the aqueous fraction 24.4% (0.011 mg eq/kg). The acidic methanol extracted 20.0% of the radioactivity (0.009 mg eq/kg). The PES had 0.010 mg eq/kg of radioactive residue (22.2% of TRR).

PES = post extraction solid (after solvent extraction)

(mg/kg): Expressed in mg-imazapic equivalents/kg.

The methanol and water extracts of the forage and hay samples were combined and, after concentration, characterized by reverse phase HPLC. The radioactive residue detected in the acidic extract of soya bean forage and hay was insignificant and no further analyses were performed on these extracts. Representative portions (20% of each extract) of methanol, aqueous and acidic methanol extracts of the soya bean straw, soya bean pods and soya bean seeds were combined and liquid/liquid extracted with hexane. The hexane and the aqueous/methanol phases were assayed by LSC. No radioactive residue was detected in the hexane portions and no further analysis was done on these fractions. The aqueous/methanol portions were concentrated and characterized by reverse phase HPLC. Imazapic and the metabolites CL263284 and CL189215 were identified by co-chromatography of the extracts with reference standards. The results of identification and quantification are shown in Table 13.

A mixture of the methanol and water extracts of forage (0 DAT) containing 0.655 mg eq/kg of residue was analysed. The primary component of the residue was imazapic (0.605 mg/kg, 89.9% of the TRR) with other minor components that did not individually exceed 3.4% TRR. The total identified and characterized residues were 97.3% of the TRR.

The most abundant component of the residue in a mixture of the methanol and water extracts of hay (35 DAT) was imazapic (0.087 mg/kg, 36.3% of the TRR). Imazapic was metabolized to a large number of components including a low amount of a component with the retention time matching that of the analytical standard CL189215, the glucoside of hydroxymethyl imazapic (CL263284) (0.006 mg/kg, 2.5% of the TRR). The total identified and characterized residues were 90.4% of the TRR.

The analysis of a mixture of methanol, water and acidic extracts of seeds (97 DAT) indicated that imazapic was metabolized to a large number of components. Imazapic comprised 0.0030 mg/kg (20.0% of the TRR), and imazapic metabolites CL189215, the glucoside, and CL263284, hydroxymethyl imazapic, comprised 4.7% TRR (0.0007 mg/kg) and 0.7%TRR (0.0001 mg/kg), respectively. A significant radioactive peak (0.0034 mg eq/kg, 22.7% TRR) was very polar and consisted of multiple components by analysis using a Hypercarb method. Multiple minor components were detected at very small concentrations (≤ 0.0014 mg eq/kg). The total identified and characterized residues were 88.7% of the TRR.

Imazapic was the most abundant component of the residue at 0.013 mg/kg (14.8% of the TRR) in a mixture of methanol, water and acidic extracts of straw (97 DAT). The imazapic metabolites CL189215 and CL263284 comprised 6.8% TRR (0.006 mg/kg) and 2.3% TRR (0.002 mg/kg), respectively. The amount of polar radioactive residue (0.004 mg/kg, 4.5% TRR) was less than that seen in the seed and pod. Multiple minor components indicated that metabolism of imazapic was complex and extensive. The total identified and characterized residues were 84.1% of the TRR.

Imazapic comprised 0.004 mg/kg (8.9% of the TRR), and imazapic metabolites CL189215, the glucoside, and CL263284, hydroxymethyl, comprised 4.4% TRR (0.002 mg/kg) and 2.2% TRR (0.001 mg/kg), respectively in a mixture of methanol, water and acidic extracts of pods (97 DAT). As in the seed, significant radioactive residue (0.007 mg/kg, 15.6% TRR) was polar. Multiple minor degradates were present as seen in the straw and bean samples. The total identified and characterized residues were 80.0% of the TRR.

No phytotoxicity was observed in this study.

Despite extensive metabolism, imazapic was the main component in all soya bean matrices. The concentration of imazapic declined from 0.605 mg/kg in forage collected approximately 1 hour

after application to 0.087 mg/kg in the hay sample collected 35 days after application, and then to 0.013 mg/kg in the straw sample collected 97 days after application. Imazapic measured as a percentage of the TRR declined from 89.9% of the TRR in forage to 36.3% of the TRR in hay, and then to 14.8% of the TRR in straw. The imazapic concentration was 0.0030 mg/kg (20.0% of the TRR) in seed, and 0.004 mg/kg (8.9% of the TRR) in pods.

Proposed metabolic pathway of imazapic in plants

[¹⁴C]-Imazapic used for pre-emergence treatment of sugar cane plant or post-emergence treatment of peanut, Bermuda grass plants or transgenic soya bean, was rapidly metabolized over time with significant decline of imazapic concentration and increase of the concentrations of the 5-hydroxymethyl metabolite CL263284 and its glucoside CL189215. There were very low radioactive residues remaining in the soya bean seeds, peanut seeds and sugar cane stalks at the time of harvest. Except for Bermuda grass, the predominant residue was either imazapic, CL263284 or CL189215 with varying ratios. A number of more polar components were found from the extracts of soya bean and Bermuda grass matrices. Such polar components found from the Bermuda grass extracts include nicotinic acid derivatives, 5-hydroxymethylniconinamide derivative and 5-hydroxymethylquinolia acid anhydride, potentially oxidized from the hydroxymethyl metabolite.

Imazapic was very rapidly metabolized in plants by oxidative hydroxylation of the 5-methyl substituent to form a 5-hydroxymethyl metabolite CL263284. Subsequently, the hydroxymethyl metabolite was either rapidly conjugated with glucose to produce a prominent metabolite component CL 189215 or further metabolized to form more polar components.

Figure 2 Proposed metabolic pathway of imazapic in plants

Environmental fate in soil

The Meeting received information on aerobic soil metabolism, photodegradation on soil, anaerobic aquatic metabolism, hydrolysis, photodegradation in water and residues in succeeding crops. Since imazapic is a herbicide with ground or aerial spray, aerobic degradation in soil, soil photolysis (some

included in the Physical and Chemical Properties Section), hydrolysis rate and products (included in the Physical and Chemical Properties Section) and rotational crop were relevant to the current evaluation.

Aerobic soil metabolism

The characteristics of soils used in the aerobic soil metabolism studies are summarized in Table 14.

Study 1 (Madsen, 1993a)

The aerobic soil metabolism of ¹⁴C-Imazapic was studied in Princeton sandy loam soil. [Pyridine-6-¹⁴C]-imazapic was dissolved in acetonitrile and applied to the soil at the rate equivalent to 0.14 kg/ha and kept under aerobic conditions in the dark. Water was added to the soil to bring the moisture of the soil to 75–80% of field capacity. At intervals of 0, 7, 14, 31, 62, 91, 122, 183, 274, and 365 days after soil treatment, the potassium hydroxide traps were analysed for ¹⁴CO₂ by LSC. At the same intervals, the ethylene glycol and sulphuric acid traps were assayed for the ¹⁴C-volatile materials.

The soil was extracted three times with 0.5N aqueous sodium hydroxide and the humic acid was removed by acid precipitation. The aqueous fulvic acid fraction was partitioned with methylene chloride. The humic acid fraction was rinsed with ethyl acetate and the rinse was combined with the methylene chloride partition. The methylene chloride partition was then poured through sodium sulfate. The sodium sulfate was then rinsed with methylene chloride. The extract was then evaporated to dryness. The residue was dissolved in methanol:water (1:1 v:v) and aliquots were analysed by LSC. The extracted soil was finally combusted to determine the bound residues. The solvent extractions were concentrated and analysed by HPLC.

After 12 months of incubation approximately 0.9% of the applied dose was mineralized to ¹⁴CO₂. No other radiolabelled volatile compounds were detected, which indicates that volatilization of the parent compound and other metabolites did not occur. Approximately 70.8% of the applied imazapic remained intact after 12 months. Carbon dioxide was the only major metabolite detected which derived from ¹⁴C-imazapic. No significant degradation of imazapic occurred during 12 months of incubation. The unextracted radioactivity varied from 1.8 to 8.0% of the total applied dose during the 365 days of incubation (Table 15).

Imazapic was found to be very persistent in soil under an aerobic condition, with about 70% remaining after 1 year.

Study 2 (Ta, 1997a)

The aerobic soil metabolism of [pyridine-6-¹⁴C]-imazapic and its metabolites, CL263284, CL312622 and CL299263 was studied in Princeton Sassafras sandy loam soil. Each of the radiolabelled compounds listed above was dissolved in water and each solution was applied separately to the soil at the rate equivalent to 0.14 kg/ha and kept under aerobic conditions at 25 °C in the dark. Water was added to the soil to bring the moisture of the soil to 75% of 0.33 bar. At intervals of 0, 3, 7, 14, 21, 28, 60, 90 and 120 days after treatment with radiolabelled imazapic, CL 263284, CL 312622 and CL 299263, the sodium hydroxide traps were analysed for ¹⁴CO₂ by LSC. At the same intervals, the extracted foam plugs and ethylene glycol traps were assayed for the ¹⁴C-volatile materials. For each compound the soil was extracted three times with 0.5 N aqueous sodium hydroxide. The extracted radioactive residues was filtered through C-18 OH then eluted with methanol:water (1:1 v/v). The solvent was concentrated and analysed by HPLC and HPLC/MS. The extracted soil was combusted to determine the bound residues. No samples were taken at 3 and 7 days for CL 299263 and at 60 days for CL 312622. One sterile soil sample from each incubation group at 28 and 60 days after incubation were analysed as described above.

At 120 days after incubation under non-sterile conditions, approximately 11, 30, 43, and 41% of the applied dose was recovered as ¹⁴CO₂ from ¹⁴C-imazapic, CL 299263, CL 263284, and CL 312622, respectively (Table 16). No volatile compounds were detected in the glycol traps or in the foam plugs from any of the compounds tested. Under sterile conditions, no CO₂ or volatiles were detected in any traps. At 120 days after incubation under non-sterile condition approximately 81% of the parent was still present. Several metabolites less than 5%TAR such as CL 312622 (1.7%) and CL 354825 (4.1%) were also generated. Degradate CL 263284 was formed in a small amount but as data showed its instability, it was not included in the Table.

Approximately 80, 10, 0 and 4% of the applied dose of imazapic, CL 299263, CL 263284, and CL 312622, respectively, remained after 120 days. Under sterile conditions, the total recoveries of radioactivity ranged from approximately 92–95, 99–104, 99–104, and 86–90% of the applied dose of imazapic, CL 299263, CL 263284 and CL 312622, respectively.

DAT=days after treatment

The data were evaluated by plotting the remaining percentage of imazapic, CL299263, CL263284, and CL312622 versus time and the half-lives were estimated assuming a first order kinetic. The half-life of imazapic, CL 299263, CL 263284, and CL 312622 were 133, 12, < 0.5 and 36 days, respectively. For all four compounds studied the unextracted radioactivity varied from 0.7 to 10.2% of the total applied dose during the 120 days of incubation.

Under sterile conditions, all of the compounds tested remained intact after 2 months of incubation and there was no detectable level of evolved CO₂ trapped in NaOH. The results indicate that microbial activity is required for the degradation of imidazolinone herbicides in soil.

Photodegradation on soil surface

The soil photolysis of [pyridine-6-¹⁴C]-Imazapic was studied in Princeton Sassafras sandy loam soil (Ta, 1994b). The ¹⁴C-Imazapic was dissolved in water and applied to the soil at the equivalent rate of about 0.08 kg/ha and exposed continuously for up to 30 days by light from a xenon-arc lamp which had been filtered to remove wavelengths shorter than 290 nm. Control samples were maintained in the

dark. The temperature was maintained at 25°C during the course of the study. The output of the lamp was set to 0.35 w/m² at 340 nm, which is comparable to mid-autumn sunlight in Princeton, NJ, USA. At intervals of 0, 1, 3, 7, 14, 21 and 30 days after treatment of soil with ¹⁴C-imazapic the soil samples were extracted two times with 0.5 M aqueous sodium hydroxide. The NaOH extracts were combined and the pH was adjusted to 1.7 with HCl, and then filtrated through celite. The clear filtrates were then subjected to solid phase extraction using C18-OH three times with methanol followed by three washings with acidified (pH 1.7) Millipore water. The radioactivity was eluted from the cartridges with methanol/water (1/1 v/v). The extract was concentrated and analysed by TLC and HPLC. The soil were dried and then assayed by combustion to determine the bound residues.

A mass balance and the ratio of degradates at each sampling point is shown in Tables 17 and 18. One major product was formed, the diacid CL312622 which accounted for up to 11% of the applied dose. Several minor photoproducts formed, each of which accounted for less than 6.2% of applied dose. The control samples were stable, with less than 4% degradation, throughout the course of the study.

Table 17 Mass balance of photodegradation of imazapic

Days	% of Total Applied Dose					
	Irradiated Extracted	Unextracted	Total	Control Extracted	Unextracted	Total
0	100.8	0.5	101.2	100.8	0.5	101.2
1	97.0	2.3	99.2	98.6	0.9	99.4

21	78.4	9.6	92.1	3.5
30	74.8	11.0	89.0	4.2

The decline of imazapic can be described by first-order kinetics. The half-life was calculated as 106 days.

Hydrolysis

[Pyridine-6-¹⁴C]-Imazapic was dissolved in acetonitrile and applied to the water + soil at a nominal rate of 0.125 µg/g soil (equivalent to about 0.14 kg/ha) and kept under anaerobic conditions with nitrogen gas in the dark at 25 °C (Madsen, 1993b). At intervals of 0, 7, 14, 31, 60, 91, 121, 182, 274 and 366 days after treatment, the potassium hydroxide traps were analysed for ¹⁴CO₂ by LSC. At the same intervals, the ethylene glycol and sulphuric acid traps were assayed for the ¹⁴C-volatile materials.

The analysis of the water was accomplished by centrifuging the samples and decanting the water. The entire water sample's pH was adjusted to approximately 1.7 with 6 N HCl then filtered through the C₁₈ cartridge. The C₁₈ cartridge was eluted with methanol:water (1:1 v:v). The concentrated samples were then analysed by LSC and HPLC-MS. The soil was extracted three times with 0.5 N aqueous sodium hydroxide and the humic acid was removed by acid precipitation. The aqueous fulvic acid fraction was partitioned with methylene chloride. The humic acid fraction was

rinsed with ethyl acetate and combining the rinse with the methylene chloride partition. The methylene chloride partition was then poured through sodium sulfate. The sodium sulfate was then rinsed with methylene chloride. The extract was then evaporated to dryness. The residue was dissolved in methanol:water (1:1, v:v) and aliquots were analysed by LSC. The extracted soil was finally combusted to determine the bound residues. The solvent extractions were concentrated and analysed by HPLC-MS.

After 366 days of anaerobic aquatic incubation, 0.5% of the applied dose was mineralized to $^{14}\text{CO}_2$. No other radiolabelled volatile compounds were collected. Volatilization of the parent compound and other metabolites did not occur. The measured concentration of imazapic decreased from 92.1% (35.7% in the soil extract and 56.4% in the water) at day 0 to 83.0% (54.3% in the soil extract and 28.7% in the water) of the applied dose after 366 days of incubation (Table 2.3/9). This indicates that imazapic is stable against hydrolysis.

Proposed degradation pathway of imazapic in soil under aerobic condition

Imazapic degrades in soil under aerobic conditions, leading to eventual mineralization. Three metabolites were identified as CL263284, CL312622 and CL354825. The rapid degradation of CL 299263 in soil under aerobic conditions proceeds via formation of the diacid metabolite, CL312622, the hydroxy acid, CL354825 and by mineralization to CO_2 . Degradation of imazapic, although much slower than that of CL 299263, gave the same metabolites, and ultimately CO_2 . It is concluded that the routes of degradation for the two imidazolinones proceed through common intermediates. Since the hydroxy methyl derivative, CL263284, was rapidly transformed in the same fashion, this is proposed as an intermediate in the metabolism of imazapic.

Figure 3 Proposed degradation pathway of imazapic in soil under aerobic condition

*Metabolism and Distribution in Succeeding Crops**Confined Rotational Crop Study*

The metabolism and distribution of imazapic in succeeding crops were investigated using [pyridine-6-¹⁴C]- or [pyridine-6-¹³C]-imazapic (Afzal, 1993a).

The field phase of the study was conducted in Madera California from July 1991 through December 1992. Three field plots (labelled A – C, 0.9 × 3.7 m, 0.9 × 5.5 m and 0.9 × 7.3 m, respectively) were treated with ¹⁴C-labelled imazapic at the rate equivalent to approximately 772 g ai/ha. Ninety days (90 Plant back interval (PBI)) and 120 days (120 PBI) after treatment, Plot A was planted with barley in subplots 1 and 2, respectively. At 270 days after treatment (270 PBI), Plot B was planted with barley, cotton and maize in subplots 1, 2 and 3, respectively. Similarly, 300 days after treatment (300 PBI), Plot C was planted with cotton, maize, lettuce and carrots in subplots 1 to 4, respectively. Three test plots D–F were used to grow the corresponding control crops. Soil core samples were taken prior to treatment, immediately following treatment, at planting and at crop sampling (mid-maturity and harvest). All cores were 46 cm deep except immediately after treatment where they were 30 cm.

Samples were frozen after collection and shipped to the analytical laboratory over dry ice. All unprocessed samples from the field were stored frozen (ca. -20 °C) until the time of analysis. All crops sampled at mid-maturity were composited for analysis on a whole plant basis except for carrots where only the root was composited. Samples taken at crop maturity were separated and the following crop parts were analysed: (a) barley straw and grain (removed from seed head); (b) cotton seed and linters (separated from seed); (c) maize fodder (dried stalk + cob + leaves + husks) and grain (removed from cob), (d) carrot root and (e) whole lettuce plants.

Fifty to 100 g of crop sample were homogenized with a mixture of high purity grade water:methanol:acetone (1:1:1). The sample to solvent ratio used for extraction was 1/10 (w/v). The supernatant was filtered through qualitative filter paper. The homogenization process was repeated once more and the supernatant was collected. The supernatants from the first and second extraction were pooled and triplicate aliquots were used for radioactivity measurement by LSC. Residual radioactive residues (PES) after drying were weighed and combusted in triplicate aliquots. The PES in barley straw (120 PBI and 270 PBI planting) and grain contained residues > 0.01 mg/kg. Therefore, they were digested with 2% HCl in MeOH:H₂O (80:20) overnight and homogenized twice with a polytron homogenizer using a tissue to solvent ratio of approximately 1/10 (w/v). The supernatants were pooled and triplicate aliquots were used for radioactivity measurement by LSC. The final residues were air-dried and combusted in triplicate aliquots to determine the amount of unextracted radioactivity.

Selected soil samples at application, planting and different crop sampling intervals containing radioactive residue of > 0.01 mg/kg were extracted twice for approximately 1 hour with water:methanol:acetone (1:1:1) using a mechanical shaker. Celite (30%) was added to aid filtration and the extracts were filtered and pooled. Triplicate aliquots were used for radioactivity measurement by LSC. The PES were air-dried and triplicate aliquots combusted. Soil samples containing residues > 0.01 mg/kg were subjected to mild acid hydrolysis with 2% HCl (80:20 MeOH:H₂O 1/10 w/v) using a mechanical shaker for 1 h. This procedure was repeated once, and the resulting supernatants were pooled and analysed in triplicates by LSC. The final residues were air-dried and combusted in triplicate aliquots.

HPLC of the soil and crop extracts was performed on a Supelco C₁₈ reversed phase column using an acetonitrile and phosphate buffer gradient system.

The TRR in all crop and soil samples were determined by combustion. A summary of the TRR values in rotational crop matrices collected at different plant back intervals is shown in Table 19 and those in soil samples in Table 20.

The TRR in barley and maize samples show the tendency to be higher in samples obtained from longer plant back interval. The TRR in crop samples were quite low with the highest in 270

DAT barley straw at 0.070 mg eq/kg. The TRR in edible portions of rotational crops were lower with the highest in 270 PBI barley grain at 0.045 mg eq/kg. The TRR in 270 PBI lettuce and carrots were < 0.01 mg eq/kg.

* Expressed in mg-imazapic equivalents/kg.

Radioactive residues remained largely confined to the top 0–8 cm soil horizon throughout the course of the study. At 0 DAT, the TRR in soil of 0–8 cm depth ranged from 0.026 to 0.095 mg/kg while the TRR in deeper soil layers were mostly < 0.004 mg/kg. The TRR in soil of 0–8 cm depth declined to the range of < 0.04 to 0.078 mg/kg at the different plant back intervals.

* Expressed in mg-imazapic equivalents/kg.

The extraction profile of radioactive residues from rotational crop matrices is summarized in Table 21 and that from soil samples in Table 22.

The efficiency of extraction of radioactive residues in crop samples was 56.5–90.8% with a mixture of methanol:water:acetone (1:1:1). The unextracted portion of the TRR in selected crops was subjected to mild hydrolysis with 2% HCl in MeOH/H₂O (80:20) which released an additional 9–18% of the radioactivity. The remaining unextracted residues (PES) accounted for ≤ 0.01 mg/kg in all crops.

Table 21 Extracted radioactive residues from rotational crops after soil application of [pyridine-6-¹⁴C]-imazapic

Matrix	Plant back interval	TRR ^a (mg eq/kg)*	Solvent extract ^b (mg eq/kg)* (%TRR)		2% HCl ^c (mg eq/kg)* (%TRR)		PES (mg eq/kg)* (%TRR)

PES = post extraction solid (after solvent extraction)

^a Sum of extracts and PES, if extraction was performed, otherwise TRR combusted. Expressed in mg-imazapic equivalents/kg

^b extracted with methanol:acetone:H₂O (1:1:1)

^c extracted with 2% HCl (methanol:H₂O, 80:20)

* Expressed in mg-imazapic equivalents/kg.

Extracted residues from soil using a mixture of methanol:water:acetone (1:1:1) declined with time from 83% of TRR (0.054 mg eq/kg) at 0 DAT to 38% of TRR (0.007 mg eq/kg) by the last harvest (493 DAT). Exhaustive extraction of soil PES in selected soil samples (90 DAT, 300 DAT and 308 DAT) showed that a majority (34–52% of TRR; 0.013–0.015 mg eq/kg) of the radioactivity was extracted following mild acid hydrolysis with 2% HCl in MeOH/H₂O (80:20). The low residues in soil PES (≤ 0.01 mg/kg) precluded further characterization.

Structural characterization of imazapic in 0 DAT soil extract was performed by thermospray LC-MS. HPLC chromatograms obtained from crop sample extracts suggested the presence of CL 263284 and CL 189215 based on the retention time of reference compounds. The identity of CL 189215 was confirmed both by retention time comparison with a synthetic reference compound and -glucosidase hydrolysis. Because of the low concentrations of CL 189215 and CL 263284 (0.005-0.031 mg/kg combined) no spectroscopic identification was possible. All other components of the crop residues were < 0.01 mg/kg.

Imazapic was the principal component of the residue in all extracted soil fractions at all planting (49–74%; 0.012–0.048 mg eq/kg) and crop sampling intervals (16–49%; 0.003–0.005 mg eq/kg). The identity of the parent in soil was confirmed by mass spectrometry. Furthermore, the radioactivity released from the PES following hydrolysis with 2% HCl in MeOH/H₂O (80:20) indicated that a majority of the radiocarbon accounted for the unaltered parent. One polar unknown component was detected at all intervals, however, its concentration was in all cases < 0.01 mg/kg. All other radioactive components were < 5% of the TRR and were insignificant.

The extracted ¹⁴C-residues from crops were used to determine the metabolic profile of imazapic following HPLC analysis. The two major metabolites detected in crop extracts were the hydroxymethyl derivative of parent, CL 263284, and the corresponding glucoside, CL 189215. Since the two components were not completely resolved in either of the gradient HPLC methods, their concentrations in crop extracts are reported as a sum of the two components. Characterization of the residue components were performed on HPLC by comparing the retention time of each component with known reference compounds.

Barley straw: The unaltered parent imazapic was a minor component of TRR (< 10%) for 120 DAT and 270 DAT planting intervals. The two major radioactive components corresponded to CL 263284 and CL 189215, collectively accounting for 37 and 44% of TRR (0.021 and 0.031 mg /kg) for 120 PBI and 270 PBI, respectively. One minor component designated as a polar unknown metabolite was detected accounting for 2.7% and 4.2% of TRR (0.002 and 0.003 mg eq/kg) at the two planting intervals.

Barley grain: Imazapic was the major component of the TRR (23%; 0.007 mg/kg) for 120 PBI and depleted to 9.6% of the TRR (0.004 mg eq/kg) for 270 PBI. CL 263284 and CL 187215 collectively constituted 18% and 33% of the TRR (0.006 and 0.015 mg/kg) for 120 and 270 PBI, respectively. The minor polar unknown metabolite accounted for 1.5–4.2% of TRR (< 0.001–0.002 mg eq/kg) at the two intervals. The radiocarbon released from barley straw PES and grain PES after hydrolysis with 2% HCl in MeOH:H₂O (80:20) was not amenable to HPLC or TLC characterization.

Maize forage and fodder: The major components of the radioactive residue were CL 263284 and CL 189215. Collectively they accounted for 31% of the TRR (0.006 mg/kg) in fodder for 270 day

PBI; 28% of the TRR (0.005 mg/kg) in forage for 300 day PBI and 28% of the TRR (0.008 mg/kg) in fodder for 300 day PBI. The parent was a minor component accounting for 0.001 mg/kg or less in these samples. The polar metabolite in all cases was < 0.01 mg/kg.

Cotton: The major components of the organosoluble residue corresponded to CL 263284 and CL 189215. Imazapic constituted 23% (0.004 mg/kg) and 17% (0.003 mg/kg) of the TRR in cotton seed and linters for 270 PBI interval, respectively. The minor polar component was insignificant accounting for <10% (0.001 mg/kg) of the TRR in cotton seed and linters for the 270 PBI.

Lettuce and carrots planted 300 DAT showed no significant residues (0.006 and < 0.004 mg eq/kg), respectively.

The metabolites found in rotational crop matrices (barley and maize) are summarized in Table 23.

Table 23 Metabolites found in barley and maize matrices after soil application of [pyridine-6-¹⁴C]-imazapic

Barley												
Component	Straw (90 PBI)		Grain (90 PBI)		Straw (120 PBI)		Grain (120 PBI)		Straw (270 PBI)		Grain (270 PBI)	
	(mg/kg)	(%TRR)	(mg/kg)	(%TRR)	(mg/kg)	(%TRR)	(mg/kg)	(%TRR)	(mg/kg)	(%TRR)	(mg/kg)	(%TRR)
Imazapic	Not analysed		Not analysed.		0.003	5.5	0.007	23	0.004	5.4	0.004	9.6
CL 189215 + CL 263284					0.021	37	0.006	18	0.031	44	0.015	33

Imazapic	Not analysed		< 0.001	2.5	Not analysed		0.001	7.3	< 0.001	3.5	Not analysed	
CL 189215 + CL 263284			0.006	31			0.005	28	0.008	28		
Polar unknown			0.002	8.0			0.007	41	< 0.001	5.7		

While the major component in soil was imazapic, the principal components of the residue in barley, maize and cotton were CL 263284 and CL 189215, the hydroxymethyl derivative of imazapic and the corresponding glucose conjugate, respectively. The metabolic pathway in rotational crops is proposed to be the hydroxylation of the methyl group on the pyridine ring to the hydroxymethyl group followed by conjugation with glucose, similar to the metabolic pathway of most of plants.

Figure 4 Proposed metabolic pathway in rotational crops (barley, maize)

RESIDUE ANALYSIS

Analytical methods

The Meeting received descriptions and validation data (including concurrent recovery data) for analytical methods for residues of imazapic and its metabolites CL263284 and CL189215.

Analytical methods for plant matrices

The descriptions of the analytical methods used in supervised residue trials are shown below.

All of these methods showed good linearity with a correlation coefficient ≥ 0.99 . There were no interferences at the analyte concentration higher than 30% of LOQ. Additional information on method performance is described later.

Method SOP-PA.0288

Analyte: Imazapic, CL263284 and CL189215
 Matrix: Sugar cane (cane, sugar, molasses) and soya bean (seed, oil, hull, flake, meal toasted meal)
 LOQ: 0.01 mg/kg for each analyte.
 Description: Residues are extracted from sugar cane or sugar using methanol:water:1M HCl (60:39:1, v/v/v) with shaking and centrifugation as necessary. and an aliquot is taken and diluted with 0.1% formic acid in water: 0.1% formic acid in methanol (50:50, v/v). Residues in molasses are extracted in the same manner and an aliquot is taken and diluted with 0.1% formic acid in water:0.1% formic acid in methanol (50:50, v/v).
 The final extracts are filtered and the determination is performed by LC-MS/MS (for quantification: imazapic, 276.2 $\rightarrow$ 231.2; CL263284, 292.2 $\rightarrow$ 247.3; CL189215, 454.2 $\rightarrow$ 292.4 and for confirmation: imazapic, 276.2 $\rightarrow$ 163.2; CL263284, 292.2 $\rightarrow$ 179.1;

CL189215, 454.2 → 179.1). Mobile phase solution A, 0.1% formic acid in water; and mobile phase solution B, 1% formic acid in methanol (same for other HPLC separation).
 Reference: Leite, 2008a; Leite and Souza, 2009a; Resende and Takahashi, 2010a;

Method SOP-PA.0249

Analyte: Imazapic
 Matrix: Rice grain and soya bean (seed)
 LOQ: 0.05 mg/kg
 Description: Residues are extracted from samples using methanol:water:1M HCl (60:39:1, v/v/v) in a homogenizer. An aliquot is taken, the volume reduced and diluted with water. The pH is adjusted to 2.1 with 1 M HCl solution. An aliquot is partitioned with dichloromethane. An aliquot of the organic phase is evaporated to dryness and the residue dissolved with 0.1% formic acid in water:0.1% formic acid in methanol (50:50, v/v). The determination is performed by LC-MS/MS (for quantification: imazapic, 276.2 → 231.2; CL263284, 292.2 → 247.3; CL189215, 454.2 → 292.4 and for confirmation: imazapic, 276.2 → 163.2; CL263284, 292.2 → 179.1; CL189215, 454.2 → 179.1).

Method LAADL R0001.01

Analyte: Imazapic
 Matrix: Maize (grain)
 LOQ: 0.1 mg/kg
 Description: Imazapic is extracted from maize with acidic aqueous methanol using an ultrasonic extractor. The analyte is partitioned with methylene chloride from aqueous acid solution. The methylene chloride is evaporated and reconstituted in 50% methanol in pH 2.5 water for cation exchange clean-up. Imazapic is eluted with a saturated KCl in methanol solution, partitioned with methylene chloride, evaporated to dryness and diluted in Milli-Q water for HPLC analysis. The final determination is performed by HPLC-UV with UV detection at 254 nm.
 Reference: Steling, 1998a

Method SOP-PA.0231

Analyte: Imazapic and CL263284
 Matrix: Rice (grain)
 LOQ: 0.05 mg/kg for each analyte.
 Description: Based on method R0001.01. Residues of imazapic are extracted with methanol:water:1M HCl (60:39:1, v/v/v) and the solution is filtered over Celite. The extract is concentrated, and after addition of lead acetate and water, the pH is adjusted to 6.2 with NaOH. Following centrifugation and addition of water, the pH is adjusted to 2.1 with HCl. The solution is solvent-extracted with dichloromethane, and the dichloromethane phase is evaporated to dryness. The residue is dissolved in a solution of methanol:water (1:1, v/v) and cleaned up with an SCX cartridge rinsed with methanol. The residue is eluted from the cartridge with KCl-saturated methanol, evaporated to dryness and dissolved in water at pH 2.5. The solution is again solvent-extracted with dichloromethane, the dichloromethane phase evaporated to dryness and the residue dissolved in water. The final analysis is performed with HPLC with UV detection at 254 nm.

Method M2253.01

Analyte: Imazapic and CL263284
 Matrix: Wheat (grain, forage, stubble), chickpea (seed, forage), barley (grain, forage), peanut (nutmeat, hull)
 LOQ: 0.1 mg/kg for each analyte.
 Description: Residues of imazapic and CL263,284 are extracted from the sample in acetone:methanol:water (1:1:1). Organic layers are removed and samples are centrifuged after addition of 10% lead acetate. The aqueous sample is then cleaned up, using resin AG 1-X8 anion exchange, partitioning with methylene chloride and subsequent benzene sulfonic acid (SCX) cation exchange solid phase extraction (SPE). Determination is performed by HPLC with UV detection and external standards.

Method M3114

Analyte: Imazapic, CL263284 and CL189215
Matrix: Bermuda grass (forage, hay), big bluestem grass (forage, hay), grass mixture (forage, hay)
LOQ: 0.5 mg/kg for each analyte.
Description: Residues are extracted from grass samples with methanol:water:1 M HCl (60:39:1, v/v/v). The extract is cleaned up, using precipitation, centrifugation and solid phase extraction techniques. Determination is performed by capillary electrophoresis equipped with a high sensitivity cell and UV detection at 240 nm and external standards
Reference: Duan and Nejad, 1999a; Nejad, 1999a

Method M2599

Analyte: Imazapic, CL263284 and CL189215
Matrix: Peanut (hay)
LOQ: 0.1 mg/kg for each analyte.
Description: Residues are extracted from the sample with methanol:water:1 M HCl (60:39:1, v/v/v). The extract is then cleaned up, using precipitation, centrifugation and solid phase extraction techniques. Determination is performed by capillary electrophoresis equipped with a high sensitivity cell and UV detection at 240 nm and external standards.
Reference: Nejad H., 1998a

Method L741/1

Analyte: Imazapic
Matrix: Rape (seed, foliage, straw)
LOQ: 0.05 mg/kg for each analyte.
Description: The extract is partitioned with dichloromethane after adjusting the pH to 2 with HCl. Subsequently, the extract is evaporated to dryness and the residue dissolved in methanol/water (1:1, v/v). Following SCX cartridge clean-up, separation and quantification of imazapic is accomplished by reverse phase HPLC with UV detection at 254 nm.
Reference: Anonymous, 1998a

Method M2379

Analyte: Imazapic, CL263284 and CL189215
Matrix: Peanut (nutmeat, hull)
LOQ: 0.1 mg/kg for each analyte.
Description: Residues are extracted from samples using methanol:water: 1M HCl (60:39:1, v/v/v). The extract is then cleaned up, using precipitation, centrifugation and solid phase extraction techniques. Determination is performed by capillary electrophoresis equipped with a high sensitivity cell and UV detection at 240 nm and external standards.
Reference: Nejad H., 1995a; Nejad H., 1994a; Nejad H., 1994b; Safarpour M., 1994a

Method 2463

Analyte: Imazapic, CL263284 and CL189215
Matrix: Wheat (grain, forage, straw, hay)
LOQ: 0.1 mg/kg for each analyte.
Description: Residues are extracted from samples using methanol:water: 1M HCl (60:39:1, v/v/v) in a homogenizer. An aliquot is taken and diluted with 0.1% formic acid in water: 0.1% formic acid in methanol (50:50, v/v). The final extracts are filtered and the determination is performed by LC-MS/MS (for quantification: imazapic, 276.2 → 231.2; CL263284, 292.2 → 247.3; CL189215, 454.2 → 292.4 and for confirmation: imazapic, 276.2 → 163.2; CL263284, 292.2 → 179.1; CL189215, 454.2 → 179.1).

Method SOP-PA.0288

The recoveries from sugar cane matrices or soya bean matrices (fortification range, 0.01-1.0 mg/kg) were within the acceptable range for all fortification levels and matrices tested (Table 25). Good linearity was observed in the range of 0.100 to 2.00 ng/mL for sugar cane matrices and 0.020 to 2.00 ng/mL for soya bean matrices. The repeatability relative standard deviations for all commodities and all fortification levels were below 15%.

* imazapic: 276 → 231; CL263284: 292 → 247; CL189215: 454 → 292

** imazapic: 276 → 163; CL263284: 292 → 179; CL189215: 454 → 179

An independent laboratory validation of Method SOP-PA.0288 was conducted for the determination of imazapic, CL 263284 and CL 189215 in sugar cane matrices (Grosshans, 2009b) and soya bean matrices (Robaugh, 2012a). Fortification levels used are 0.01 and 0.1 mg/kg for sugar cane matrices (Table 26) and 0.01 and 0.5 mg/kg for soya bean matrices (Table 27).

The recoveries were within the acceptable range for all fortification levels and matrices tested. Good linearity was observed in the range of 0.100 to 2.00 ng/mL for sugar cane matrices and 5.00 to 200 ng/g for soya bean matrices. The repeatability relative standard deviations for all sugar cane matrices at all fortification levels were below 20% using matrix-matched standards, except for metabolite CL189215 in molasses at a fortification level of 0.01 mg/kg, where the RSD was 25%; and those for all soya bean matrices were below 30% a fortification level of 0.01 mg/kg and below 10% at the other fortification levels, using matrix-matched standards.

Method SOP-PA.0249

The recoveries from rice grain (Borges, 2004a, c) and in soya bean seed (Borges, 2004a, c) at fortification levels of 0.05 and 5.0 mg/kg were within the acceptable range (Tables 28 and 29). Good linearity was observed in the range of 0.500 to 10.0 ng/mL for rice grain and soya bean seed. The repeatability relative standard deviations for all commodities and all fortification levels were below 10%.

Method LAADL R0001.01

Although the method was not subjected to formal validation, the method showed recoveries of 92 and 96% (n=1) at the fortification levels of 0.1 and 0.2 mg/kg.

Method SOP-PA.0231

The recoveries of imazapic from rice grain at fortification levels of 0.05 and 0.5 mg/kg were within the acceptable range (Table 30). Good linearity was observed in the range of 5.0 to 100 ng/mL (2003/3001442) or 5.0 to 50 ng/mL (2001/3001704, -05 and -06). The repeatability relative standard deviations for all fortification levels were below 15%.

Method 2253.01

The recoveries of imazapic and CL263284 from chick-pea matrices (Minoura, 1995b and 1995e), barley matrices (Minoura, 1995c and 1995f), wheat matrices (Minoura, 1995a, 1995d and 1995g), and

peanut matrices (Nejad, 1993a)(Table 31) at fortification levels from 0.10 to 0.50 mg/kg (wheat stubble up to 5.0 mg/kg) were all within the acceptable range (Table 31).

An independent laboratory validation of Method M 2253.01 was conducted for the determination of imazapic and CL 263284 in peanut hull and peanut meat at fortification levels of 0.10 and 0.50 mg/kg (Nejad and Cenni, 1997b)(Table 32). The recoveries were within the acceptable range for all fortification levels. The repeatability relative standard deviations for both commodities over all fortification levels were below 20%.

The extraction efficiency was investigated using peanut hay obtained 131 days after the treatment of plants with ^{14}C -labelled imazapic (Nejad, 1994b). Two separate samples of peanut hulls containing ^{14}C -residues were extracted with methanol:water:1N hydrochloric acid (60:39:1, v/v/v). Triplicate 30 mL aliquots from the control and each of the ^{14}C -treated sample extracts were evaporated and peanut residue was dissolved in a total of 5 mL methanol, sonicated and centrifuged. Triplicate 0.5 mL of each subsample were combusted using an oxidizer and subjected to liquid scintillation counting (LSC). Aliquots of approximately 250 mg of unextracted peanut hulls from control and treated plants were also combusted and subjected to LSC.

The average percentage of extracted radioactive residues were 73% (range 71–76%) compared with the radioassay result.

An independent laboratory validation of Method M 2379 was conducted for the determination of imazapic, CL 263284 and CL 189215 in peanut matrices at fortification levels of 0.10–0.50 mg/kg (Safarpour, 1994a)(Table 36). The recoveries were within the acceptable range. The repeatability standard deviations were below 20%.

The extraction efficiency was investigated using barley straw from the confined rotational crop study (Nejad and Cenni, 1996a). Two separate samples of barley straw containing ^{14}C -residues were extracted with methanol:water:1N hydrochloric acid (60:39:1, v/v/v). Duplicate 3 mL aliquots from the control and each of the ^{14}C -containing sample extracts were assayed by LSC. The post-extraction solids were collected and combusted and also subjected to LSC.

The average percentage of extracted radioactive residues was 67% compared with the radioassay results.

Analytical methods for animal matrices

The descriptions of the analytical methods related to the current review are shown below.

All of these methods showed good linearity with a correlation coefficient ≥ 0.99 . There were no interferences at the analyte concentration higher than 30% of LOQ. Additional information on method performance is described later.

Method M 3188

Analyte: Imazapic and CL263284
 Matrix: Milks
 LOQ: 0.01 mg/kg for each analyte.
 Description: Residues are extracted from the sample with acidic water. Precipitation, centrifugation and solid phase extraction (SPE) techniques are used for sample clean-up. Measurement of imazapic and CL263284 is accomplished by capillary electrophoresis (CE) equipped with a high sensitivity flow cell and a UV detector set at 240 nm. Results are calculated as imazapic and CL 263284 by the direct comparison of the peak heights in the sample to those of external standards. Confirmation of residues > 0.01 mg/kg for each compound is provided by LC/MS of the final extract.
 Reference: Sweeney and Nejad, 1998a

Method M 3222

Analyte: Imazapic and CL263284
 Matrix: Tissues
 LOQ: 0.05 mg/kg for each analyte.
 Description: Residues are extracted from the sample with acidic methanol water. Precipitation, centrifugation and solid phase extraction (SPE) techniques are used for sample clean-up. Measurement of imazapic and CL 263284 is accomplished by capillary electrophoresis (CE) equipped with a high sensitivity flow cell and a UV detector set at 240 nm. Results are calculated as imazapic and CL 263284 by the direct comparison of the peak heights in the sample to those of external standards.
 Reference: Sweeney and Nejad, 1998b

Method M 3223

Analyte: Imazapic and CL263284
 Matrix: Milk fat and tissue fat
 LOQ: 0.01 mg/kg in milk and 0.05 mg/kg in tissue fat for each analyte.
 Description: Residues are extracted from bovine milk fat and tissue fat with acidic acetonitrile in hexane. Filtration, solvent partitioning and solid phase extraction (SPE) techniques are used for sample clean-up. Measurement of imazapic and CL263284 is accomplished by HPLC/MS (positive ion electrospray ionization tandem mass spectrometry). Results are calculated as imazapic and CL263284 by the direct comparison of the peak area in the sample to those of external standards.
 Reference: Boner and Nejad, 1999a

M 3188

An independent laboratory validation of Method M 3188 was conducted for the determination of imazapic and CL 263284 in cattle milk at fortification levels of 0.01–1.0 mg/kg (Sweeney and Nejad, 1998a)(Table 38). The recoveries were within the acceptable range. The repeatability standard deviations were below 15%.

Table 38 Recovery results obtained during independent laboratory validation of Method M 3188 for milk

The extraction efficiency was investigated using goat milk and kidney from metabolism study (Nejad, 1999b). Two separate samples each of treated milk and kidney tissue containing ^{14}C -residues were analysed for imazapic and CL 263284 by Method M 3188 (milk) and M 3222 (kidney) respectively. With both methods, quantification of residues is made by capillary electrophoresis and UV detection. For milk samples, triplicate 1 mL aliquots of extracted and unextracted milk were assayed by using LSC. For the kidney samples, prior to extraction, the samples were combusted to determine total radioactive residue (TRR). The respective extracts were counted for determination of extraction efficiency.

The extraction procedure used in method M 3188 (milk) yielded a total extractability of 94% for milk (based on total ^{14}C recovery) using 22.1 mL of a 6 N HCl:water:10% lead acetate (0.1:20:2, v/v/v) extraction.

The extraction procedure used in method M 3222 (kidney) yielded a total extractability of 88% in kidney (based on total carbon-14 recovery) using 150 mL of an HCl:water:methanol (1.5:58.5:90, v/v/v) extraction and a 5-minute extraction time.

CE analysis of the treated milk indicated an average of 0.060 mg/kg imazapic compared to 0.051 mg/kg using HPLC radioassay. CE analysis of the treated kidney indicated an average of 0.271 mg/kg imazapic compared to 0.234 mg/kg using HPLC radioassay. No detectable residues for CL 263284 were found in milk or kidney.

M 3223

An independent laboratory validation of Method M 3223 was conducted for the determination of imazapic and CL 263284 in milk fat and tissue fat at fortification levels of 0.01–0.2 or 0.05–1.0 mg/kg respectively (Sweeney and Nejad, 1998a)(Table 40). The recoveries were within the acceptable range. The repeatability standard deviations were below 15%.

Stability of pesticide residues in stored analytical samples

The Meeting received information on freezer storage stability of imazapic and two of its metabolites in various plant and animal commodities.

Frozen samples were homogenized and fortified with test compound. The fortified homogenate was stored in deep freezer. After each specified period, a portion of sample was analysed for test compound. The stability results are expressed as average percentage of the nominal fortification and are not corrected for the procedural recoveries. In order to account for possible variations over the time investigated, the mean procedural recovery results are given in addition.

Table 41 summarized the storage conditions, storage periods and percent remaining after each period

The stability of imazapic and its metabolites CL 263,284 and CL 189,215 was also investigated in standard calibration solutions diluted in 0.1% formic acid in water: 1% formic acid in methanol (1:1, v/v) and stored at 5±3 °C in the dark. The standard solutions contained 0.400 ng/mL per analyte. After 32 days, fresh standard calibration solutions were diluted by the above solution mixture, and the results obtained for the stored standard solutions were compared to the results obtained for the fresh standard solutions.

The storage stability of standard calibration solutions containing imazapic and its metabolites in 0.1% formic acid in water: 1% formic acid in methanol (1:1, v/v) was demonstrated for a period of 32 days when stored at 5±3 °C in the dark.

USE PATTERNS

Imazapic is used to control broad leaf and grassy weeds. It is formulated as a liquid or granular product either as a solo product or in combination with other active substances for use on pulses, cereal grains, grasses for sugar, oilseeds, and straw, forage and fodder of cereal grains. It is registered in a number of countries for crops with pre-emergence and post emergence applications.

The authorized uses relevant to the supervised trials data submitted to the current Meeting is summarized in Table 43.

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received residue data from supervised field trials conducted on soya bean (including GM soya bean) in Brazil, maize in Brazil, rice in Brazil, wheat in Australia, sugar cane in Argentina, Australia, Brazil, Costa Rica and Guatemala, Peanut in Brazil and the USA, rape seed in Australia and grasses (animal feedstuffs) in the USA.

Application rates and residue concentrations were reported as imazapic. Residue concentrations are recorded unadjusted for recoveries or for residue values in control samples. Where multiple samples were taken from a single plot, individual results are reported, and the calculated average concentration is used for estimation of maximum residue level. Where trials were conducted

in the same location, with the same or similar varieties, same or similar formulations, and same equipment, and at the same or similar timing, they are not regarded as independent and only one result from these trials was chosen for the estimation of a maximum residue level.

Residues from the trials conducted according to maximum GAP have been used for the estimation of maximum residue levels and they are underlined.

In many of the following trials, plants resistant to imidazolinone pesticides were used. They are classified into two different categories. The first category is non-GM plants (maize, rape seed, rice, wheat) showing the tolerance due to the mutation(s) of endogenous AHAS gene from conventional breeding technique. and their variety names have "CL" in them. The second category is GM plants (so far soya bean only) to which mutated AHAS gene of Arabidopsis was introduced for imidazolinone tolerance.

Pulses

Soya beans

During the 2006/2007 growing season, eight field trials were carried out in Brazil to determine the residues levels of imazapic in soya bean after treatment with a WG mix formulation of imazapic and imazapyr. In all trial sites, one trial plot was untreated to provide control samples, and one trial plot received one post-emergence application at a rate of 0.0175 kg imazapic/ha (and 0.0525 kg imazapyr/ha), 60 days before harvest (BBCH 24–75). In three trials, the application was performed 40, 60, 80, 100 and 120 days before harvest, each on a separate plot. Samples were taken 60 days after the application (DALA) in all trials; but in three trials, additional samplings were performed 40, 80, 100 and 120 DALA. The soya bean samples were stored frozen until analysis. Soya bean samples were analysed for imazapic using Method SOP-PA.0249. The limit of quantification was 0.05 mg/kg.

During the 2007/2008 growing season, a field trial was carried out in Brazil to determine the residues levels of imazapic in soya bean after treatment with a mix formulation of imazapic and imazapyr. One trial plot was untreated to provide control samples, and one trial plot received one foliar post-emergence spray application at a rate of 0.0175 kg imazapic/ha (and 0.0525 kg imazapyr/ha), either 40, 60, 80, 100 or 120 days before harvest. Samples were taken 40, 60, 80, 100 or 120 days after the application. The soya bean samples were analysed for imazapic and the two metabolites using Method SOP-PA.0288. The limit of quantification was 0.01 mg/kg for each analyte.

During the 2010 growing season, two field trials were carried out in Brazil to determine the residues levels of imazapic in soya bean after treatment with a mix formulation of imazapic and imazapyr. At both trial sites, one trial plot was untreated to provide control samples, and four trial plots received one foliar post-emergence spray application at a rate of 0.0175 kg imazapic/ha (and 0.0525 kg imazapyr/ha), 20, 40, 60 or 80 days before harvest. Samples of soya bean grain were taken 20, 40, 60 and 80 days after the application. Soya bean samples were analysed for residues using Method SOP-PA.0288.

During the 2011 growing season, five field trials were carried out in Brazil to determine the residues levels of imazapic in transgenic soya bean after treatment with a mix formulation of imazapic and imazapyr. At all trial sites, one trial plot was untreated to provide control samples, and one trial plot received one post-emergence application at a rate of 0.0175 kg imazapic/ha (and 0.0525 kg imazapyr/ha), 60 days before harvest (BBCH 66–73). At one trial with five plots, the application was performed 20, 40, 60, 80 and 100 days before harvest. Samples of soya bean grain were taken 60 days after the application (DALA) at all trials; at one trial, additional samplings were performed 20, 40, 80 and 100 DALA, and at one trial aspirated grain fractions were also sampled. Soya bean samples were analysed for residues using Method SOP-PA.0288.

Cereal Grains

Maize

One maize field trial was conducted in Brazil during the 1997 growing season. The trial consisted of an untreated control plot and two treated plots. The treated plots received a single application of a mix formulation of imazapic and imazapyr at growth stage BBCH 17–19 at a rate of either 0.0525 or 0.105 kg imazapic/ha. The maize samples were taken manually at 96 days after treatment. Maize RAC samples were analysed for residues using Method LAADL R0001.01. The limit of quantification was 0.1 mg/kg.

During the 2010/2011 growing season, four field trials were carried out in Brazil to determine the residues of imazapic in imidazolinone tolerant maize after treatment with a mix formulation of imazapic and imazapyr. At all trial sites, one trial plot was untreated to provide control samples, and one trial plot received one post-emergence application at a rate of 0.0525 kg imazapic/ha, 96 days before harvest (BBCH 13-17). At two trials, the application was performed 89, 96 and 103 days before harvest. Samples were taken 96 days after the application at all trials; at two trials, additional samples were obtained 89 and 103 DALA. Maize RAC samples were analysed for residues using Method SOP-PA.0288 with a limit of quantification (LOQ) of 0.01 mg/kg.

Rice

During the 2000/2001 growing season, one field trial was carried out in Brazil to determine the residues of imazapic in rice grain after treatment with a mix formulation of imazapic and imazapyr. One trial plot was untreated to provide control samples, and one trial plot received two post-emergence spray applications at a rate of 0.0375 kg ai/ha each and a retreatment interval of 14–17 days. Samples were taken at physiological maturity 60, 75 and 90 days after the last application. Rice RAC samples were analysed for residues using Method SOP-PA.0231. The limit of quantification was 0.05 mg/kg.

During the 2000/2001 growing season, one field trial was carried out in Brazil to determine the residues of imazapic in rice grain after treatment with a mix formulation of imazapic and imazapyr. One trial plot was untreated to provide control samples, and two trial plots received two post-emergence spray applications, each at a rate of 0.01875 or 0.0375 kg ai/ha, respectively. The retreatment interval was 17 days. Samples were taken at physiological maturity, 60 days after the last application (DALA), at all plots. Rice RAC samples were analysed for residues using Method SOP-PA.0231.

During the 2000/2001 growing season, another field trial was carried out in Brazil to determine the residues of imazapic in rice grain after treatment with a mix formulation of imazapic and imazapyr. One trial plot was untreated to provide control samples, and two trial plots received two post-emergence spray applications, each at a rate of 0.01875 or 0.0375 kg ai/ha, respectively. The retreatment interval was 13 days. Samples were taken at physiological maturity, 60 days after the last application, at all plots. Rice RAC samples were analysed for residues using Method SOP-PA.0231.

During the 2002/2003 growing season, four field trials were carried out in Brazil to determine the residues of imazapic in rice grain after treatment with a mix formulation of imazapic and imazapyr. One trial plot was untreated to provide control samples. In one trial site, the treated plot received two post-emergence spray applications at a rate of 0.025 kg ai/ha each. In three trials, two separate plots received two post-emergence spray applications, each at a rate of 0.025 or 0.05 kg ai/ha, respectively. The retreatment interval was 17–52 days. Samples were taken at physiological maturity, 60 days after the last application at all plots. In the trial treated with the lower rate only, samples were collected at 50, 55, 65 and 70 DALA in addition. Rice RAC samples were analysed for residues using Method SOP-PA.0249. The limit of quantification was 0.05 mg/kg.

During the 2002/2003 growing season, four field trials were carried out in Brazil to determine the residues of imazapic in rice grain after treatment with a mix formulation of imazapic and imazapyr. One trial plot was untreated to provide control samples. At one trial site, the treated plot received two post-emergence spray applications at a rate of 0.015 kg imazapic/ha each. At three trials, two separate plots received two post-emergence spray applications, each at a rate of 0.015 kg imazapic/ha (+0.045 kg imazapyr/ha) or 0.030 kg imazapic/ha (+0.090 kg imazapyr/ha), respectively. The retreatment interval was 17-52 days. Samples were taken at physiological maturity, 60 days after the last application at all plots. At the trial treated with the lower rate only, samples were collected at 50, 55, 65 and 70 DALA in addition. Rice RAC samples were analysed for residues using Method SOP-PA.0231.

Wheat

Five wheat field trials were conducted in Australia during the 1997 and 1998 growing seasons. The trials consisted of an untreated control plot and two (3 trials) or three (2 trials) treated plots. The treated plots received a single application of WG formulation of imazapic. Two trials were treated with either 35, 52.5 or 70 g ai/ha. Three trials were treated at a rate of either 21 or 35 g ai/ha. Wheat forage samples were collected 1–4 times, 0–42 days after treatment. Samples of grain and straw were

taken at normal harvest, 93–113 days after the application. The samples were analysed for residues using HPLC. The limit of quantification was 0.05 mg/kg.

Grasses for sugar or syrup production

Sugar cane

One sugar cane field trial was conducted in Argentina during the 1996/1997 growing season. The trial consisted of an untreated control plot and a treated plot. The treated plot received a single application of a WG formulation of imazapic as pre-treatment at a rate of 350 g ai/ha, 38 days pre-plantation. The sugar cane samples were taken at 392 days after treatment. Sugar cane RAC samples were analysed for residues of BAS 715 H (imazapic) using Method LAADL R0002 with a limit of quantification of 0.05 mg/kg.

Two residue trials on sugar cane were conducted in Guatemala and two in Costa Rica during the growing season 2007-2008. Three test plots were established at each trial site. Treatment 1 was the untreated plot and provided control samples for analysis. For one trial each in Costa Rica and Guatemala, the Treatment 2 plot was designated as a RAC plot (non-processing) and received one pre-plant incorporated application of a WG formulation of imazapic, targeting a rate of 0.245 kg ai/ha. The Treatment 3 plot was designated as a processing plot and received one pre-emergence application of a WG formulation of imazapic targeting the 5× rate of 1.225 kg ai/ha. For the remaining two trials, the Treatment 2 plot was designated as a RAC plot (non-processing) and received one pre-emergence application at a targeted a rate of 0.245 kg ai/ha. The 'Treatment 3' plot was designated as a processing plot and received one pre-emergence application of a WG formulation of imazapic targeting the 5× rate of 1.225 kg ai/ha. At about 150 days after the last application, whole cane samples for RACs were

collected from the 'Treatment 2' and untreated plots at all sites. At about 300 DALA, commercially mature, whole cane samples for RACs and processing samples were collected.

Residues of imazapic in sugarcane RAC were determined using SOP-PA.0288. The limit of quantification (LOQ) of the method was 0.01 mg/kg for imazapic and its two metabolites.

Four residue trials on sugar cane were conducted in Australia during the growing season 1996/97. Three test plots were established on each site, one untreated control plot and two plots treated once with a WG formulation of imazapic, targeting a rate of either 0.144 or 0.288 kg ai/ha. Two trials were treated pre-emergence and two post-emergence at the 'spike' growth stage. The spray volume was 119 l/ha. At 211–217 days after the application, sugar cane foliage and cane samples were collected. Residues of imazapic in sugar cane matrices were determined using Method L 741. The limit of quantification (LOQ) of the method was 0.05 mg/kg.

During 2006 growing season, five field trials were carried out in representative sugar cane growing areas in Brazil to determine the residues levels of imazapic and its two metabolites in sugar cane after treatment with a WG formulation of imazapic. At all trial sites, two trial plots were untreated to provide control samples, and two trial plots each received one pre-plant incorporated application at a rate of 0.245 kg ai/ha. In one untreated and one treated plot at four sites, the whole cane samples were harvested (BBCH 30) at 150 days after the last application. At one trial, the 150 DALA samples were not collected due to the insufficient crop productivity. In one control and one treated plot at all five sites, the mature cane samples were harvested at 360 to 365 days after treatment (BBCH 49). The samples were analysed according to SOP-PA.0288 for the determination of imazapic and its metabolites residues with a limit of quantification (LOQ) of 0.01 mg/kg for each analyte.

Oilseeds

Peanut

One peanut field trial was conducted in Brazil during the 1996/1997 growing season. The trial consisted of an untreated control plot and two treated plots. The treated plots received a single post-emergence application of a WG formulation of imazapic at a rate of either 0.070 or 0.140 kg ai/ha, 22 days after planting. Peanut RAC samples were analysed for residues using Method 2253.01. The limit of quantification was 0.1 mg/kg.

Four peanut field trials were conducted in Brazil during the 2003/2004 growing season. The trials consisted of an untreated control plot and two (3 trials) or five (1 trial) treated plots. The treated plots received a single application of WG formulation of imazapic. In one trial, the plots were treated with 0.098 kg ai/ha, either 60, 65, 70, 75 or 80 days before harvest. In three trials, the plots were treated at a rate of either 0.098 kg ai/ha or 0.196 kg ai/ha, 70 days before harvest. The peanut samples were collected at 70 days after treatment. In one trial, samples were taken at 60, 65, 70, 75 and 80 days after treatment. Peanut RAC samples were analysed for residues using Method SOP-PA.0249. The limit of quantification was 0.05 mg/kg.

A total of six peanut field trial was conducted independently in the USA during the 1992 growing season. Each trial consisted of an untreated control plot and two treated plots. The treated plots received a single post-emergence application of an SL formulation of imazapic at a rate of either 70 or 210 g ai/ha, to the 10–15 cm high (vegetative stage) or 15–25 cm high (pre-bloom) peanut plants. The peanut nut and hull samples were taken 95, 102, 104, 105, 117 or 119 days after treatment. Peanut RAC samples were analysed for residues of imazapic and its metabolite CL 263284 using Method M 2253. The limit of quantification was 0.1 mg/kg.

A total of six peanut field trial was conducted in the USA during the 1993 growing season. Each trial consisted of an untreated control plot and one treated plot. The treated plots received a single post-emergence application of an SL formulation of imazapic at a rate of 70 g ai/ha, to the 5 cm high (seedling stage), 7.5–10 cm high (pre-bloom stage) 10–15 cm high (3 weeks post-emergence), or 15–20 cm high (early bloom stage) peanut plants. The peanut nutmeat and hull samples were taken at 75, 95, 105, 116 and 119 days after treatment. Peanut RAC samples were analysed for residues of imazapic and metabolites CL 263,284 and CL 189,215 using Method M 2379. The limit of quantification was 0.1 mg/kg.

Rapeseed

Six rape seed field trials were conducted in Australia during the 1997 and 1998 growing seasons. The trials consisted of an untreated control plot and two (four trials, 1998) or three (two trials, 1997) treated plots. The treated plots received a single application of a WG formulation of imazapic. In 1997, the plots were treated with either 35, 52.5 or 70 g ai/ha. In 1998, the plots were treated at a rate of either 21 or 35 g ai/ha. The rape seed forage samples were collected 1–5 times, 0–62 days after treatment. Samples of grain were taken once from three trials, 76–95 days after the application. Straw was taken once from two trials, 76–80 days after treatment. Rape seed RAC samples were analysed for residues of imazapic and CL 263222 using Method L741/1. The limit of quantification was 0.05 mg/kg.

Animal Feeds*Legume animal feed**Peanut hay*

A total of six peanut field trials were conducted in the USA during the 1995 growing season. Each trial consisted of an untreated control plot and one treated plot. The treated plots received a single post-emergence application of an SL formulation of imazapic at a rate of 70 g ai/ha except in one trial 84 g ai/ha. Peanut hay samples were taken 90, 95, 98, 100, 102 or 113 days after treatment. Peanut hay samples were analysed for residues of imazapic, CL 263284 and CL 189215 using Method M 2599. The limit of quantification was 0.1 mg/kg.

According to GAP in the USA, grazing and feeding of treated peanut hay to livestock is not allowed.

Hay or fodder (dry) of grasses

The registered use on grass in the USA allows one application at a maximum rate of 0.20 kg ai/ha after grass has reached full (100%) green-up for spring and summer application or grass is dormant before green-up or full green-up for winter application. According to GAP cutting treated area for hay is not allowed within 7 days after treatment. There are grazing restrictions on the US label.

One Bermuda grass (*Cynodon dactylon*) field trial was conducted in the United States during the 1996 growing season. The trial consisted of an untreated control plot and one treated plot. The treated plot received a single post-emergence application of an SL formulation of imazapic at a rate of 0.224 kg ai/ha. Prior to application, the field was observed to contain 85% Bermuda grass. Samples of forage and hay were harvested prior to application (control samples), immediately after application and 7, 14, 28 and 56 days after treatment (DALA). Hay samples were allowed to dry after cutting

before sampling. Bermuda grass forage and hay samples were analysed for residues of imazapic and metabolites CL263284 and CL189215 (CL 189215) using Method M 3114. The limit of quantification was 0.5 mg/kg.

One Bermuda grass field trial was conducted in the United States during the 1996 growing season. The trial consisted of an untreated control plot and one treated plot. The treated plot received a single post-emergence application of an SL formulation of imazapic at a rate of 0.235 kg ai/ha. Samples of forage and hay were cut prior to application (control samples), immediately after application and 7, 14, 28 and 54 days after treatment. Hay samples were allowed to dry for 5–7 days after cutting before sampling.

One Bermuda grass field trial was conducted in the United States during the 1997 growing season. The trial consisted of an untreated control plot and one treated plot. The treated plot received a single post-broadcast application of an SL formulation of imazapic at a rate of 0.224 kg ai/ha. Samples of forage and hay were harvested prior to application (control samples), immediately after application and 7, 14, 28 and 56 days after treatment. Hay samples were allowed to dry for 4–6 days after cutting before sampling.

One Big Bluestem (*Andropogon gerardii*) and Brome grass (*Bromus sp.*) field trial was conducted in the United States during the 1997 growing season. The trial consisted of an untreated control plot and one treated plot. The treated plot received a single post-broadcast application of an SL formulation of imazapic at a rate of 0.224 kg ai/ha. Samples of forage were harvested prior to application (control samples), immediately after application and 7, 14, 28 and 56 days after treatment (DALA). Hay samples were taken after being dried for 4–7 days after cutting.

One common Bermuda grass field trial was conducted in the United States during the 1997 growing season. The trial consisted of an untreated control plot and one treated plot. The treated plot received a single post-broadcast application of an SL formulation of imazapic at a rate of 0.224 kg ai/ha. Samples of forage and hay were harvested prior to application (control samples), immediately after application and 7, 14, 28 and 56 days after treatment. Hay samples were taken after being dried for 5–7 days after cutting.

One Bermuda grass field trial was conducted in the United States during the 1997 growing season. The trial consisted of an untreated control plot and one treated plot. The treated plot received a single post-broadcast application of SL formulation of imazapic at a rate of 0.224 kg ai/ha. Samples of forage and hay were harvested prior to application (control samples), immediately after application and 7, 14, 28 and 56 days after treatment (DALA). Hay samples were taken after being dried on plastic sheets for 1–4 days after cutting.

One Brome grass field trial was conducted in the United States during the 1997 growing season. The trial consisted of an untreated control plot and one treated plot. The treated plot received a single post-broadcast application of an SL formulation of imazapic at a rate of 0.224 kg ai/ha. Samples of forage were harvested prior to application (control samples), immediately after application and 7, 14, 28 and 56 days after treatment (DALA). Hay samples were taken after being dried.

One Little Bluestem and Bluegrass field trial was conducted in the United States during the 1997 growing season. The trial consisted of an untreated control plot and one treated plot. The treated plot received a single post-broadcast application of an SL formulation of imazapic at a rate of 0.224 kg ai/ha. Samples of forage were harvested prior to application (control samples), immediately after application and 7, 14, 28 and 56 days after treatment (DALA). Hay samples were taken after being dried after cutting.

One Little Bluestem (*Schizachyrium scoparium*) and Bluegrass (*Poa sp.*) field trial was conducted in the United States during the 1996/1997 growing season. The trial consisted of an untreated control plot and one treated plot. The treated plot received two post-broadcast applications of SL formulation of imazapic at rates of 0.157 kg ai/ha (1996) and 0.078 kg ai/ha (1997). Samples of forage were harvested prior to each application (control samples), immediately after each application and 7, 14, 28 and 56 days after the first and the last application (DAFA, DALA). Hay samples were taken after being dried after cutting.

One Big Bluestem grass field trial was conducted in the United States during the 1996/1997 growing season. The trial consisted of an untreated control plot and one treated plot. The treated plot received two post-broadcast applications of an SL formulation of imazapic at rates of 0.157 kg ai/ha (September 1996) and 0.078 kg ai/ha (July 1997). Samples of forage were harvested prior to each application (control samples), immediately after each application and 7 and 14 days after the first application (DAFA) and 7, 14, 28 and 56 days after the last application (DALA). Hay samples were taken after being dried after cutting.

In all the trials, hay samples were placed on a drying rack after harvest to dry. Residue concentrations were not adjusted for moisture content and expressed on as received basis.

Table 53 Residues of imazapic in grass forage and fodder from supervised trials conducted in the USA (* average of the two samples)

FATE OF RESIDUES IN STORAGE AND PROCESSING

In processing

The Meeting received information on effects of heating in water and processing on imazapic residues in soya bean. An attempt was made to determine processing factors for processing of sugar cane into sugar and related commodities. However, even at the exaggerated rate (5× GAP rate), no residue was

detected in sugar cane samples above the LOQ of 0.01 mg/kg. For this reason no processing was performed.

High temperature hydrolysis

The hydrolysis of [^{14}C]-imazapic was investigated in sterile buffered aqueous solution under a range of hydrolysis conditions simulating processes such as pasteurization, baking/brewing/boiling and sterilization.

[Pyridine- ^{14}C]-imazapic was dissolved in the aqueous buffer solutions to give a final concentration of about 10 $\mu\text{g/ml}$ and incubated at 90 °C (pH 4) for 20 minutes, 100 °C (pH 5) for 60 minutes or 120 °C (pH 6) for 20 minutes. All test samples were prepared in sterile amber bottles to eliminate possible photolysis and all sterile buffers were bubbled with nitrogen to avoid effects of oxygen on the test systems. The samples were prepared in duplicates for each test system. For each of conditions, the total radioactivity present was determined at the end of the incubation period after cooling and compared to the theoretical radioactivity before incubation. The total radioactivity in each sample was determined by LSC. Radioactivity in the samples was analysed by HPLC immediately upon collection. Characterization of the radioactivity in the buffered samples after incubation was performed by HPLC-MS/MS.

After incubation at different pH, 101–102% of the applied radioactivity remained. At the end of the incubation periods, the detectable radioactive component was unchanged imazapic only. Imazapic was stable under conditions representing pasteurization and baking/brewing/boiling and sterilization.

Soya beans

Soya bean processing studies were conducted to determine the potential for concentration of residues of imazapic in the processed fractions of soya bean (Resende, 2009a and Leite, 2011a). During the 2008 growing season, two field trials were carried out in Brazil. Soya beans were treated with imazapic. Treated plot received one foliar post-emergence spray application at an exaggerated rate (same rates as the above study), 60 days before harvest. Samples of soya bean grain were taken 60 days after the application. The soya bean seed samples were separately processed using simulated commercial processing procedures into flaked soya bean, oil, meal and toasted meal. Soya bean samples were analysed for residues using Method SOP-PA.0288.

The analytical results indicate that imazapic slightly concentrated in meal. For all other analyte/commodity combinations, the processing factors showed residue decline.

Table 55 Residues of imazapic and its metabolites in processed commodities of soya bean seeds

nd = not determined since residues in the RAC were below the LOQ

Another soya bean processing studies were conducted to determine the potential for concentration of residues of imazapic in the processed fractions of soya bean (Jones, 2011a). During the 2009 growing season, two field trials were carried out in Brazil. Soya beans were treated with imazapic. Treated plot received one foliar post-emergence spray application at an exaggerated rate of either 0.035 kg imazapic/ha (2×) or 0.0525 kg imazapic/ha (3×), 60 days before harvest. Samples of soya bean seed were taken 60 days after the application. The soya bean seed samples were separately processed using simulated commercial processing procedures into defatted meal, toasted defatted meal, laminated soya bean, oil, meal and hulls.

Soya bean samples were analysed for residues of imazapic and its metabolites using Method SOP-PA.0288.

The analytical results indicate that imazapic slightly concentrated in defatted and toasted defatted meal and CL189215 slightly concentrated in defatted meal. For all other analyte/commodity combinations, the processing factors showed a residue decline.

RESIDUES IN ANIMAL COMMODITIES

Farm animal feeding studies

The Meeting received information on lactating cow feeding study.

Lactating cows

Four groups of lactating Holstein cows, each group containing three animals, were orally dosed with imazapic in gelatin capsules using a balling gun for 28 days following afternoon milking at levels equivalent to 0, 67, 223, and 676 ppm in feed (Leonard, 1999a). Milk samples were collected twice daily during dosing period and afternoon milk and morning milk were pooled. Within 24 hours after the last dose, cows were sacrificed. After sacrifice, loin muscle, omental fat, liver and kidney were collected. All samples were analysed for imazapic and CL 263284 using Methods M 3188 for milk, M 3222 for tissues, and M 3233 for fat.

In the lowest dose group (67 ppm), residues of imazapic in milk reached a plateau after Day 1 and averaged 0.025 mg/kg. In milk fat and kidney, average residues were 0.013 and 0.384 mg/kg, respectively. In muscle, liver and omental fat, average residues were < 0.050 mg/kg.

In the middle dose group (223 ppm), residues of imazapic in milk averaged 0.077 mg/kg. In milk fat and omental fat, average residues were 0.037 and 0.051 mg/kg, respectively. In loin muscle, kidney and liver, average residues were 0.054, 1.57 and 0.082 mg/kg, respectively.

In the highest dose group (676 ppm), residues of imazapic in milk averaged 0.274 mg/kg. In milk fat and omental fat, average residues were 0.127 and 0.051 mg/kg, respectively. In muscle, kidney and liver, average residues were 0.079, 2.71 and 0.192 mg/kg, respectively.

Levels of CL263284 was below the respective LOQ in all matrices and at all dosing levels.

APPRAISAL

Imazapic is an imidazolinone herbicide developed for the control of grass and broadleaf weeds in a variety of crops and registered in a number of countries. It was considered for the first time by the present Meeting.

Information on the physical and chemical properties, animal and plant metabolism, environmental fate, analytical methods, storage stability, use patterns, supervised trials, processing and farm animal feeding was received by the present Meeting.

The following abbreviated names were used for the metabolites discussed below.

Animal metabolism

The Meeting received information on the fate of orally-dosed imazapic in rat, lactating goats and laying hens.

In metabolism studies, total radioactive residues are expressed in mg/kg imazapic acid equivalents unless otherwise stated.

Metabolism of imazapic in rat

Metabolism studies on laboratory animals including rats were reviewed in the framework of toxicological evaluation by the current JMPR.

Metabolism of imazapic in lactating goats

Imazapic

In two studies on lactating goats, [pyridine-6-¹⁴C]-imazapic was orally administered at three doses via capsule (equivalent to 2.0, 11.8 and 175 ppm in feed) for 5 or 7 consecutive days. The majority was eliminated in urine (67–94% of TAR) in the form of unchanged imazapic and faeces (7–10% of TAR). Milk contained up to 0.03% of TAR and edible tissues 0.01% of TAR at the highest dose.

The TRR of daily collected milk samples were lower than the LOQ of 0.01 mg eq/kg at the two lower doses.

The goats were sacrificed 20 or 23 hours after the last dose at which time tissue samples were obtained. The highest TRR (0.275 mg eq/kg) was observed in kidney from the highest dose regime, reflecting that urinary excretion was the predominant elimination route. At the two lower doses, except that the TRR of the kidney from goat dosed at 11.8 ppm was 0.05 mg eq/kg, the TRR in milk or tissues were below the respective LOQ of 0.01 (milk) or 0.02 mg eq/kg (muscle).

The analysis of acetonitrile+methanol extract of kidney from the highest dose indicates that imazapic was the major residue at 30% TRR (0.02 mg/kg) with CL263284 at 8% of TRR (< 0.01 mg/kg). As the TRRs in milk and tissues, other than kidney, from any dose levels were too low to characterize any of radioactive residues, extraction of radioactive residues was not attempted for these tissues or milk.

CL 263284

In a study on lactating goats with oral administration of [pyridine-6-¹⁴C]- CL 263284 in capsule at doses equivalent to 2.3 or 14.5 ppm in feed for 7 consecutive days, radioactivity was eliminated mostly via faeces (82% TAR for the low dose and 68% TAR for the high dose) and in a lesser amount from urine (15–18% TAR). The TRR of daily milk samples and tissues obtained 20 hours after the last dose were below the LOQ of 0.01 mg/kg except kidney from the high dose goat (0.03 mg eq/kg). About 91% of TRR in the kidney from high dose goat was extracted with methanol and CL 263284 was present at 9% (< 0.01 mg/kg) of the extracted TRR. Component M1 found at significant amounts (78% TRR, 0.02 mg eq/kg) may be an extraction artifact and was converted into CL 263284 on exposure to aqueous buffer.

Metabolism of imazapic in laying hens

In a hen study [Pyridine-6-¹⁴C]-imazapic orally administered in capsule to laying hens, at a dose equivalent to 2.1 or 11.4 ppm in feed for 7 consecutive days, was mostly eliminated into excreta (91–95% of TAR). The TRR in all egg and tissue samples were less than the LOQ of 0.01 mg eq/kg.

The [Pyridine-6-¹⁴C]-CL263284 orally administered to laying hens at 2.1 or 10.9 ppm in feed for 7 consecutive days was mostly eliminated into excreta and the TRR in all tissues, skin with adhering fat and eggs were below the LOQ of 0.01 mg/kg. No detectable radioactive residues were found in eggs or edible tissues obtained 22 hours after the last dose.

Metabolites of imazapic in goat were similar to those in rat. With rapid excretion, the radioactive residues in edible tissues, milk or eggs were mostly below the LOQ. In lactating goats, residues remaining in the kidney were mostly unchanged parent with a minor amount of CL263284.

Plant metabolism

The Meeting received information on the fate of imazapic in sugar cane, peanuts, Bermuda grass and transgenic soya bean.

When [pyridine-6-¹⁴C]-imazapic was applied to the soil surface as a pre-emergent treatment at a rate approximating 0.15 kg ai/ha (within GAP rates) in a small test plot, no radioactive residues were detected above the LOQ of 0.005 mg/kg in the stalk of sugar cane harvested 13 months after the treatment.

When [pyridine-6-¹⁴C]-imazapic was applied to the soil surface as a pre-emergent treatment at a rate approximating 0.25 kg ai/ha (within GAP rates) in a greenhouse, the TRR in the adult sugar cane stalk and leaves collected 236 DAT was 0.0039–0.048 mg eq/kg and 0.015–0.016 mg eq/kg respectively.

High percentages (63–84% TRR) of the radioactive residues in forage, leaves and stalks collected at various timings were extracted by methanol. Most of the extracted radioactive residues were water soluble.

Imazapic was found in all samples but declined with time, e.g., in stalks 0.003 mg/kg (41% TRR) at 151 DAT to 0.0005 mg/kg (11% TRR) at 236 DAT. CL263284 was found in all the samples collected at higher concentrations than the parent, but both the concentration and proportion to TRR also declined with time, e.g., in stalk 0.001 mg/kg (16% TRR) at 151 DAT to 0.0005 mg/kg (10% TRR) at 236 DAT. CL189215 was also found at lower concentrations in leaves (0.0005–0.002 mg/kg, 3–8% TRR), but not in stalks.

[Pyridine-6-¹⁴C]-imazapic was applied to peanut plants at a rate of 0.072 kg ai/ha (within GAP rates) 30 days post-emergence. The TRR declined significantly from 4.2 mg eq/kg at 0 DAT to 0.094 mg eq/kg at 61 DAT in green plants and 0.22 mg eq/kg in hay collected 131 DAT. The TRR in nutmeat at 131 DAT was low at 0.022 mg eq/kg. A mixture of methanol:water:acetone (1:1:1) extracted 76–96% of the TRR in peanut samples.

The concentration of imazapic sharply declined in plants to 0.006 mg/kg at 61 DAT (2% TRR). The concentration in nutmeat, hull and hay samples collected 131 DAT were even lower (< 0.001–0.006 mg/kg, 1–3% TRR). The concentration of CL263284 also decreased over time to 0.010 mg/kg (12% TRR) at 61 DAT in plants. The concentrations of CL189215 declined over time to 0.039 mg/kg at 61 DAT (46% TRR) in plants. The concentrations of these three compounds were all less than 0.01 mg/kg in nutmeat at 131 DAT. No other component in the extracts from immature or mature samples exceeded 10% of TRR or 0.01 mg/kg.

Bermuda grass was treated post-emergence with [pyridine-6-¹⁴C]-imazapic at a rate of 0.2 kg ai/ha (maximum GAP rate for grass in the USA). The TRR in plants decreased over time from 8.3 mg eq/kg at 0 DAT to 0.77 mg eq/kg at 47 DAT and was 0.92 mg eq/kg in hay (68 DAT). From forage and hay samples, 74–100% of radioactive residues were extracted by aqueous solutions with hay sample at the lowest 74%.

The concentration of imazapic declined sharply to 0.02 mg/kg (3% TRR) at 49 DAT. CL263284 concentration showed a sharp increase in the early period to the peak concentration of 1.7 mg/kg (30% TRR) at 15 DAT and then decrease to 0.16 mg/kg (21% TRR) at 49 DAT. It was found in hay at 0.08 mg/kg (8% TRR). CL189215 also increased in concentration in the early stage to the peak concentration of 0.17 mg/kg (4% TRR) at 15 DAT then to 0.08 mg/kg (9% TRR) at 49 DAT. In the hay sample collected 68 DAT, imazapic, CL263284 and CL189215 were present at 0.02, 0.08 and 0.08 mg/kg respectively but all below 10% of TRR.

There were many minor polar components but none exceeded 10% TRR individually.

[Pyridine-3-¹⁴C]-imazapic was applied to the above-ground portion of imidazolinone-tolerant soya bean plants (with mutated AtAHASL protein inserted to make the host tolerant to imidazolinone herbicide) at BBCH 65 at an application rate of 0.08 kg ai/ha. The TRR in soya bean seed and straw were 0.014 mg eq/kg and 0.092 mg eq/kg respectively. From forage, hay, seed, straw and pod samples, 78–98% of radioactive residues were extracted by aqueous solutions.

In seeds, imazapic was the most abundant residue at 20% TRR but only 0.003 mg/kg. Imazapic was the most abundant residue in straw and pods but at 0.00013 and 0.004 mg/kg respectively. CL189215 was the second most abundant compound individually but at < 0.01 mg/kg and less than 10% of TRR. CL263284 was also present but less than imazapic or CL189215. There were many minor polar components detected but none exceeded 0.01 mg/kg or 10% of TRR individually.

In the edible portions of treated food crops harvested at maturity, no or little residues of imazapic are expected to be found. In animal feed crops, such as grasses, imazapic, CL 263284 and CL 189215 are expected to be found above the LOQ.

Environmental fate

The Meeting received information on aerobic soil metabolism, photodegradation on the soil surface, hydrolysis and residues in succeeding crops.

Aerobic soil metabolism

About 70% of the applied imazapic (equivalent to 0.14 kg/ha) remained in sandy loam soils after one year of incubation in one study and about 80% remained in soil after 120 days of incubation in the other. Mineralization occurred but at very low percentage.

CL263284 applied to soil degraded to less than 1% of the applied dose in 3 days forming CL312622, CL354825 and carbon dioxide.

AC299263 and CL 312624 applied to soil degraded more gradually both transforming to CL354825 and carbon dioxide.

Degradation of these compounds was significantly less in soil under sterile conditions, indicating microbial action.

Imazapic was found to be persistent in sandy loam soils under anaerobic conditions. However, its metabolites/degradates were more readily degraded in soil.

Photodegradation

¹⁴C-Labelled imazapic was applied to a sandy loam soil at a rate equivalent to 0.08 kg/ha (within GAP rates). The total radioactivity in the aqueous sodium hydroxide extract (10% AR) and unextracted fraction (3% AR) was about 7% of the applied dose after 30 days of irradiation by a xenon-arc lamp comparable to mid-autumn sunlight in New Jersey, USA.

The imazapic concentration decreased from 94% of the extracted radioactivity on day 0 to 75% after the 30-day irradiation. A diacid degradate, CL 312622, formed up to 11% of the extracted radioactivity. The DT₅₀ was calculated to be 106 days.

Photolysis of imazapic (25 mg/kg) in sterilized water was rapid at pH 5, 7 and 9 under irradiation by a xenon-arc lamp comparable to mid-autumn sunlight in New Jersey, USA, with DT₅₀ in a range of 6.0–7.2 hours. Six degradation products, including carbon dioxide were formed, each of which accounted for around 10%.

Imazapic is photodegraded gradually with a half-life around 100 days on the surface of soil and rapidly with half-life of about 6–7 hours in sterilized water.

Hydrolysis

As imazapic can be used in rice production, ¹⁴C-Labelled imazapic was applied to water+soil at a nominal rate equivalent to about 0.14 kg/ha (within GAP rates) and kept under anaerobic conditions.

Only 0.5% of the applied dose was mineralized. No other radioactive volatile compounds were collected. No volatilization or degradation occurred.

The concentration of imazapic decreased from 92% (36% in the soil extract and 56% in water) on day 0 to 83% (54% in the soil extract and 29% in the water) of the applied dose after 366 days.

Imazapic was stable for 366 days at 25 °C in water+ soil.

Residues in succeeding crops

A confined study was conducted to examine the nature and level of residues of imazapic in succeeding crops. A single application of [pyridine-6-¹⁴C]-imazapic was made on soil in field plots at a nominal rate of 0.72 kg ai/ha, higher than any GAP rates.

At each rotational interval of 90, 120, 270 and 300 days after treatment, barley, maize cotton, lettuce and carrots were sown into the treated soil and harvested at maturity.

Following the application of imazapic to soil, uptake of radioactivity into rotational crops was low (< 0.004–0.070 mg eq/kg). However, the TRR in barley and maize samples show a tendency to be higher in samples obtained from longer plant back intervals. The TRR of lettuce and carrot (both with 20 day plant back intervals (PBI)) were 0.006 and < 0.004 mg eq/kg, respectively.

In barley grain, imazapic was the most abundant residue from the 120 day PBI at 23% TRR (0.007 mg/kg) followed by the sum of CL263284 and CL189215 at 18% TRR (0.006 mg/kg). In the 270 day PBI barley grain, the most abundant residue was the sum of CL263284 and CL189215 at 37% TRR (0.021 mg/kg) followed by imazapic at 10% (0.004 mg/kg). In straw the most abundant residue was the sum of CL263284 and CL189215 at 44% TRR (0.031 mg/kg) for 120 day PBI and

44% TRR (0.031 mg/kg) for 270 day PBI. Imazapic was present in straw at 5.4–5.5% TRR (0.003–0.004 mg/kg).

In the 300 day PBI maize forage and fodder, the sum of CL263284 and CL189215 was the most abundant residue at 28% (0.005 mg/kg) and 28% (0.008 mg/kg) TRR respectively.

Radioactive residues remained mostly in the 0–8 cm depth layer of soil. High percentage (57–91% TRR) of radioactive residues in soil were extracted with aqueous methanol/acetone mixture and 2% HCl. Nine to 43% TRR remained as unextracted residues.

Following the application of imazapic to soil, uptake of radioactivity into rotational crops was low (maximum at 0.070 mg eq/kg). Among registered uses related to the current review, the highest application rate was for sugar cane or grass. In comparison, the application rate used in this confined rotational crop study was about 3 times the GAP rate in Brazil and 7.5 times the GAP rate in Australia for sugar cane or 3.5 times the GAP rate for grass in the USA. This application rate was more than 7.5 times higher than the GAP rate for other crops used in crop rotation. Residues of imazapic in plant portions of rotational crops used as food or feed after approved application are expected to be less than one third of the residues observed in the confined rotational crop study, i.e., around or lower than the lowest LOQ of 0.01 mg/kg.

Methods of analysis

Analytical methods for the determination of residues of imazapic and its metabolites were developed for a wide range of matrices of plant and animal origin.

In general, the methods for data generation employ extraction by homogenization with a mixture of methanol:water:1M HCl (60:39:1) or, in the case of fat, acidic acetonitrile in hexane, clean-up with solid phase extraction or some other techniques, and determination of analytes using LC-MS/MS, HPLC-UV (245 nm) or capillary electrophoresis-UV (240 nm).

A number of specific methods for plant matrices were found suitable for analysis of imazapic, CL263284 and CL189215 with LOQ ranging 0.01–0.1 mg/kg for these analytes except that it was 0.5 mg/kg for grass.

Three methods for animal matrices were found suitable for analysis of imazapic and CL263284 with LOQ of 0.01 (milk and milk fat) and 0.05 (tissues) mg/kg.

No multi-residue methods were submitted.

Stability of residues in stored analytical samples

The stability of imazapic residues during storage of samples frozen at -25 to -5 °C was investigated in a range of plant and animal matrices for which supervised residue trials were submitted.

Compounds tested were imazapic, CL263284 and CL189215. Each compound was spiked to matrices at 0.5 mg/kg.

All of the compounds tested were found to be stable (> 70% remaining) at least during the storage periods tested: 2 years in wheat, sugar cane, peanut and grass matrices; 10 months in soya bean seeds; 3 months in processed soya bean products; 6 months in cattle milk; and 8 months in cattle tissues. These storage periods are longer than the longest storage conditions in trials on respective crops.

Definition of the residue

In animal metabolism, parent imazapic was the predominant residue with CL263284 a minor component at around 10% TRR in goat kidney. In other tissues, milk or eggs, TRR were below the respective LOQs. In a metabolism study in which CL 263284 was administered, TRR in milk and tissues were below the LOQ of 0.01 mg/kg. CL263284 found in goat kidney is also a metabolite in rats and, as such, is covered by the ADI. However, in the livestock feeding study using imazapic, CL 263284 was not detected above the LOQ of 0.01 mg/kg (milk and milk fat) or 0.05 mg/kg (tissues) at

the highest dose of 676 ppm in the feed. Therefore, the Meeting considered that parent imazapic is a suitable residue for enforcement of MRLs and for calculating dietary intake for commodities of animal origin.

With a low $\log P_{ow}$ of 0.054 and given the distribution of residues in animal tissues from the animal metabolism studies and animal feeding study, the Meeting considered imazapic residue not fat-soluble.

The plant metabolism studies indicate that no or little residues of imazapic or its metabolites are expected to be found in the edible portions of food crops harvested at maturity. In supervised trials on soya beans, CL 263284 and CL 189215 were found at lower concentrations than the parent, when measured.

In feed crop such as grass, imazapic, CL 263284 and CL 189215 (a glucoside of CL 263284 found in plants and in a very small amount in rats) are expected to be found above the LOQ of 0.5 mg/kg (in the residue trials) as demonstrated in the metabolism study and in residue trials.

The Meeting considered that the parent imazapic was a suitable residue for enforcement of MRLs and for calculating dietary intake for commodities of plant origin.

Based on the above, the Meeting recommended the following residue definition for plant and animal commodities:

Definition of the residue for plant and animal commodities (both for compliance with the MRL and for dietary intake): *Imazapic*.

Residue is not fat-soluble.

Results of supervised residue trials on crops

The Meeting received supervised trial data for imazapic on conventional and transgenic soya beans, maize, rice, wheat, sugar cane, peanut, grasses and transgenic rape seed.

Soya bean (dry)

A total of 16 supervised trials were conducted on imidazolinone-tolerant soya beans (conventionally bred or transgenic) in different years in Brazil. However, as no GAP for soya bean was available, it was not possible to estimate a maximum residue level.

Maize

A total of five trials were conducted on imidazolinone-tolerant maize in 2010 in Brazil.

The registered use on imidazolinone-tolerant maize in Brazil allows one application at a maximum rate of 0.0525 kg ai/ha with a PHI of 96 days.

Residues of imazapic from trials matching GAP in Brazil were: < 0.01 (4) and < 0.1 mg/kg.

Although the number of trials matching GAP is small, as the metabolism studies indicate that no residues are expected in edible portion of food crops harvested at maturity and the residue trial data on other cereal grains (rice and wheat) indicate that residues were below the respective LOQ at even exaggerated application rates, the Meeting considered that no residues would be expected in maize grain.

The Meeting therefore estimated a maximum residue level and STMR of 0.01* and 0 mg/kg, respectively, for maize.

Rice

A total of 11 trials were conducted on imidazolinone-tolerant rice in Brazil in different years.

The registered use on imidazolinone-tolerant rice in Brazil allows up to two applications at a maximum rate of 0.025 kg ai/ha with a PHI of 60 days.

Residues of imazapic from trials matching GAP in Brazil were: < 0.05 (10) mg/kg. In many trials, $2 \times$ GAP rate was used. In these trials, residues were all < 0.05 mg/kg (9).

The Meeting estimated a maximum residue level and STMR of 0.05 * and 0 mg/kg, respectively, for rice grain.

Wheat

Four trials were conducted for imidazolinone-tolerant wheat in Australia. The registered use of imazapic on wheat in Australia allows one application at a maximum rate of 0.021 kg ai/ha (only for imidazolinone-tolerant wheat) at 4 leaf (Z14) to the commencement of the flag leaf (Z37) stage. No PHI is required. Grazing and cutting for animal feed are not allowed for 4 weeks after application.

Residues of imazapic from trials matching GAP in Australia were: < 0.05 (2) mg/kg.

Although the number of trials matching GAP is small, as residues from trials using higher rate (up to $3.5 \times$ GAP rate) were all < 0.05 mg/kg (total of 4), and the metabolism studies indicate that no residues are expected in edible portions of food crops harvested at maturity, the Meeting considered that no residues would be expected in wheat grain.

The Meeting therefore estimated a maximum residue level and STMR of 0.05* and 0 mg/kg, respectively for wheat.

Sugar cane

A total of 14 trials were conducted on sugar cane in Argentina, Australia, Brazil, Costa Rica and Guatemala.

The registered uses on sugar cane in these countries allow one application at a maximum rate of: 0.35 kg ai/ha with a PHI of 392 days in Argentina, 0.096 kg ai/ha in Australia, 0.245 kg ai/ha with a PHI of 283 days, 0.175 kg ai/ha with a PHI of 85 days in Costa Rica and Guatemala respectively.

The trial data were evaluated against GAP in Brazil. Residues of imazapic in sugar cane from trials matching GAP in Brazil were: < 0.01 (8) and < 0.05 (5) mg/kg. With shorter PHI or at $5 \times$ GAP rate (two trials), residues were < 0.01 mg/kg.

The Meeting estimated a maximum residue level and STMR of 0.01* and 0 mg/kg, respectively, for sugar cane.

Peanut

A total of 17 trials were conducted on peanuts in Brazil (5) and in the USA (12) in different years.

The registered uses on peanut in these countries allow one application at a maximum rate of 0.098 kg ai/ha with a PHI of 70 days in Brazil; and 0.071 kg ai/ha with a PHI of 90 days in the USA.

Residues in peanuts from trials in Brazil matching Brazilian GAP were: < 0.05 (4) and < 0.1 mg/kg. Residues in peanut nutmeat from trials in the USA matching the GAP in the USA were: < 0.1 mg/kg (7). In the 12 trials using exaggerated rates ($2 \times$ or $3 \times$ GAP rate), residues in nut, hull or nutmeat were all below the LOQ (0.05 or 0.1 mg/kg) (10).

The Meeting estimated a maximum residue level and STMR of 0.05* and 0 mg/kg, respectively for peanut.

The Meeting also estimated a median residue of 0 mg/kg for peanut hulls.

Rape seed

Three trials were conducted on imidazolinone-tolerant rape seed in Australia in 1997 and 1998.

The registered use on imidazolinone-tolerant rape seed in Australia allows one application at a maximum application rate of 0.0288 kg ai/ha at the 2–6 leaf stage of the crop. No PHI is required.

Residues of imazapic in rape seed from trials within

25% of GAP in Australia were: < 0.05 mg/kg (3). Residues from trials using exaggerated application rates (up to 2.4× GAP rate) were all < 0.05 mg/kg (2).

The Meeting estimated a maximum residue level and STMR of 0.05* and 0 mg/kg, respectively for rape seed.

Animal feed

Peanut fodder

Six trials involving peanut fodder were conducted in the USA in 1995. However, according to the GAP in the USA, grazing and feeding of treated peanut hay to livestock is not allowed. Therefore, there is no need to evaluate residues in peanut hay.

Wheat straw and fodder, dry, and forage

Five trials were conducted in Australia for wheat forage (four for straw).

According to GAP in Australia, grazing and cutting for stock feed are not allowed for 4 weeks after the application.

Residues of imazapic in wheat forage from trials matching GAP in Australia 4 weeks after application were: < 0.05 (3) mg/kg. Residues in forage from trials with exaggerated rates (up to 3.5× GAP rate; five trials) were < 0.05 mg/kg and residues in forage collected 15–19 days after application at any application rate were also < 0.05 mg/kg.

A median residue and highest residue were estimated for wheat forage at 0.05 and 0.05 mg/kg, respectively.

Residues of imazapic in wheat straw from trials matching GAP in Australia were: < 0.05 mg/kg (2). Residues in wheat straw from trials with exaggerated rates (up to 3.5× GAP rate) were all < 0.05 mg/kg (4).

The Meeting estimated a maximum residue level of 0.05* mg/kg for wheat straw and fodder, dry.

A median residue and highest residue for wheat straw and fodder, dry were 0 mg/kg.

Hay or fodder (dry) of grasses

A total of 10 trials were conducted on grasses in the USA.

The registered use on grasses in the USA allows one application at a maximum rate of 0.20 kg ai/ha after grass is full (100%) green-up for spring and summer application, or grass is dormant before green-up or full green-up for winter application. According to GAP cutting treated area for hay is not allowed within 7 days after treatment. There is no restriction on grazing on the label.

Residues of imazapic in forage from trials matching GAP in the USA were: 7.3, 7.5, 8.8, 10, 12, 13, 15, 15, 22 and 24 mg/kg.

The Meeting estimated a median residue and highest residue at 12.5 and 24 mg/kg respectively for grass forage on an "as received" basis.

Residues of imazapic in hay (> 7 DALA) from trials matching GAP in the USA were: < 0.50 (8), 0.91 and 2.3 mg/kg.

The Meeting estimated a maximum residue level, median residue and highest residue at 3, 0.5 and 2.3 mg/kg for hay or fodder (dry) of grasses, respectively.

Rape seed forage

Five trials were conducted in Australia for rape seed forage.

The approved uses in Australia do not allow grazing or cutting for stock feed for 6 weeks after application. Residues in rape seed forage 42 days after application at application rates within $\pm 25\%$ of the GAP rate were: < 0.05 (4) mg/kg.

The Meeting estimated a median residue and highest residue of 0.05 mg/kg.

Fate of residues during processing

High temperature hydrolysis

The hydrolysis of [^{14}C]-imazapic was investigated in sterile buffered aqueous solution.

After incubation at 90 °C (pH 4) for 20 minutes, 100 °C (pH 5) for 60 minutes or 120 °C (pH 6) for 20 minutes, 101–102% of the applied radioactivity remained. At the end of the incubation periods, the detectable radioactive component was unchanged imazapic only. Imazapic was stable under conditions representing pasteurization and baking/brewing/boiling and sterilization.

Processing

The Meeting received information on processing of soya beans.

A processing factor was calculated for the processing of soya beans to oil to be 0.14.

Processing factors for meal and hulls which can be fed to animals were also calculated but not reported here as no maximum residue level was recommended for soya beans, dry.

Residues in animal commodities

Estimation of dietary burdens

The maximum and mean dietary burdens were calculated using the highest residues or median residues of imazapic estimated at the current Meeting on a basis of the OECD Animal Feeding Table.

Summary of livestock dietary burdens (ppm of dry matter diet)

	US-Canada		EU		Australia		Japan	
	max	mean	max	Mean	max	mean	Max	mean
Beef cattle	0.401	0.094	48.0	25.0	96.0	50.0	5.72	2.71
Dairy cattle	43.2	22.5	57.6	30.0	96.0 ^a	50.0 ^b	11.2	5.34
Broilers	0.009	0.009	0.008	0.008	0	0	0.008	0.008
Layers	0.009	0.009	9.63 ^c	5.03 ^d	0	0	0.009	0.009

^a Suitable for estimating maximum residue levels for milk, meat, fat and edible offal of cattle.

^b Suitable for estimating STMRs for meat, fat and edible offal of cattle.

^c Suitable for estimating maximum residue levels for meat, fat and edible offal of poultry and eggs.

^d Suitable for estimating STMRs for meat, fat and edible offal of poultry and eggs.

Residues in milk and cattle tissues

Four groups of lactating Holstein cows, each group containing three animals, were orally dosed with imazapic in gelatine capsules using a balling gun for 28 days following afternoon milking at levels equivalent to 0, 67, 223, and 676 ppm in the feed. Milk samples were collected twice daily during the dosing period with afternoon and morning milk pooled. Within 24 hours after the last dose, the cows were sacrificed. After sacrifice, loin muscle, omental fat, liver and kidney were collected and analysed.

In the lowest dose group (67 ppm), residues of imazapic in milk reached a plateau after Day 1 and averaged 0.025 mg/kg. In milk fat and kidney, average residues were 0.013 and 0.384 mg/kg, respectively. In muscle, liver and omental fat, average residues were < 0.050 mg/kg.

In the middle dose group (223 ppm), residues of imazapic in milk averaged 0.077 mg/kg. In milk fat and omental fat, average residues were 0.037 and 0.051 mg/kg, respectively. In loin muscle, kidney and liver, average residues were 0.054, 1.57 and 0.082 mg/kg, respectively.

In the highest dose group (676 ppm), residues of imazapic in milk averaged 0.274 mg/kg. In milk fat and omental fat, average residues were 0.127 and 0.051 mg/kg, respectively. In muscle, kidney and liver, average residues were 0.079, 2.71 and 0.192 mg/kg, respectively.

Levels of CL263284 were below the respective LOQ in all matrices and at all dosing levels.

The maximum and mean dietary burdens in cattle were 96 and 50 ppm of dry matter diet respectively for estimating a maximum residue level and STMR for milk and edible tissues. The maximum residue levels, STMRs and HRs for relevant commodities of animal origin were estimated using the residue levels in tissues and milk at 67 and 223 ppm feeding group.

	Feed level (ppm) for milk residues	Imazapic (mg/kg) in	Feed level (ppm) for tissue residues	Imazapic (mg/kg) in			
		milk		Muscle	Liver	Kidney	Fat
Maximum residue level beef or dairy cattle							
Feeding study ^a	67	0.025	67	< 0.05	< 0.05	0.465	< 0.05
	223	0.274	223	0.063	0.126	2.20	0.054
Dietary burden and highest residue	96	0.071	96	0.052	0.064	0.788	0.051
STMR beef or dairy cattle							
Feeding study ^b	67	0.025	67	< 0.05	< 0.05	0.384	< 0.05
Dietary burden and mean residue	50	0.019	50	< 0.05	< 0.05	0.287	< 0.05

^a highest residues for tissues and mean residue for milk

^b mean residues for tissues and mean residue for milk

The Meeting estimated STMRs of 0.019, 0.05, 0.05, 0.287 and 0.05 mg/kg for milk, meat, liver, kidney and fat, respectively.

Based on the above, the Meeting estimated maximum residue levels of 0.1, 0.1, 1 and 0.1 mg/kg respectively for milks, meat (from mammals other than marine mammals), edible offal (mammalian) and Mammalian fats (other than milk fat).

Residues in eggs and poultry tissues

No feeding study on laying hens was conducted as expected dietary burdens for hen were low and the metabolism studies showed extremely low residues remaining in hen tissues.

In the metabolism study, the TRR in all edible tissues and eggs from hens fed orally radiolabelled imazapic at doses equivalent to 2.1 and 10.9 ppm in feed for 7 days were below the LOQ of 0.01 mg/kg.

At the maximum calculated dietary burden of 9.63 ppm in feed, the residues in eggs and edible tissues were estimated to be < 0.01 mg/kg. The Meeting therefore estimated a maximum residue level, STMR and HR at 0.01*, 0 and 0 mg/kg respectively applicable to poultry meat, poultry offal, poultry fat and eggs.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of the residue for plant and animal commodities (for compliance with the MRL and for estimation of dietary intake): *Imazapic*.

Residue is not fat-soluble.

Commodity		Recommended MRL, mg/kg		STMR/STMR-P mg/kg
CCN	Name	New	Previous	
MO 0105	Edible offal (mammalian)	1	-	Liver, 0.05 Kidney, 0.287
PE 0112	Eggs	0.01*	-	0
AS 0162	Hay or fodder (dry) of grasses	3		(see table below)
GC 0645	Maize	0.01*	-	0
MF 0100	Mammalian fats (except milk fats)	0.1		0.05
MM 0095	Meat (from mammals other than marine mammals)	0.1		0.05
ML 0106	Milks	0.1		0.019
SO 0697	Peanut	0.05*	-	0
PF 0111	Poultry fats	0.01*	-	0
PM 0110	Poultry meat	0.01*	-	0
PO 0111	Poultry, edible offal of	0.01*	-	0
SO 0495	Rape seed	0.05*	-	0
GC 0649	Rice	0.05*	-	0
GS 0659	Sugar cane	0.01*	-	0
GC 0654	Wheat	0.05*	-	0
AS 0654	Wheat straw and fodder, dry	0.05*		(see table below)

For calculating animal dietary burdens.

Commodity		Median residue mg/kg	Highest mg/kg
CCN	Name		
	Grass forage	12.5	24
	Hay or fodder (dry) f grasses	0.5	2.3
	Peanut hull	0	-
	Rape seed forage	0.05	0.05
	Wheat forage	0.05	0.05
	Wheat straw and fodder, dry	0	0

Expressed on an “as received” basis.

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Dietary Intakes (IEDIs) of imazapic were calculated for the 13 GEMS/Food cluster diets using STMRs estimated by the current Meeting (Annex 3 of the 2013 JMPR Report). The ADI is 0–0.7 mg/kg bw and the calculated IEDIs were 0% of the maximum ADI. The Meeting concluded that the long-term intake of residues of imazapic resulting from the uses considered by the current JMPR is unlikely to present a public health concern.

Short-term intake

The 2013 JMPR decided that an ARfD is unnecessary. The Meeting therefore concluded that the short-term intake of residues of imazapic is unlikely to present a public health concern.

IMAZAPYR (267)

First draft prepared by Mr Makoto Irie, Ministry of Agriculture, Forestry and Fisheries, Tokyo, Japan

EXPLANATION

Residue and analytical aspects of imazapyr were considered for the first time by the present Meeting. The residue evaluation was scheduled for the 2013 JMPR by the Forty-fourth Session of the CCPR.

Imazapyr is a broad-spectrum herbicide in the imidazolinone family. Its primary use is as a post-emergence herbicide which is particularly effective on hard-to-control perennial grasses. It is non-selective, absorbed by foliage and rapidly translocated. The mode of action of imidazolinone herbicides is the inhibition of the enzyme acetohydroxy acid synthase (AHAS) which is a critical enzyme for the biosynthesis of branched chain amino acids necessary for cell growth and protein synthesis. The Meeting received information on identity, animal and plant metabolism, environmental fates in soil, rotational crops, analytical methods, storage stability, use patterns, supervised trials, farm animal feeding studies and fates of residues in processing.

IDENTITY

Common name	Imazapyr
Chemical name	
IUPAC:	2-[(<i>RS</i>)-4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl] nicotinic acid
CAS:	2-[4,5-dihydro-4-methyl-4-(1-methylethyl)-5-oxo-1H-imidazol-2-yl]-3-pyridinecarboxylic acid
CAS Registry No:	81334-34-1
CIPAC No:	530
Synonyms:	BAS 693 H, CL 243,997
Structural formula:	

Molecular formula:	C ₁₃ H ₁₅ N ₃ O ₃
Molecular weight:	261.3

PHYSICAL AND CHEMICAL PROPERTIES*Pure active ingredient*

Property	Results	Reference
Appearance (colour, physical state, odour)	Dirty white/ egg-shell white powder with a faint non-specific odour (99.6% purity)	Werle <i>et al.</i> , 2001 2001/1024893
Vapour pressure	< 2.7 × 10 ⁻⁵ Pa at 45 °C	Anonymous 1985

Property	Results	Reference
		IZ-301-016
Melting point	170.2–172.0 °C (99.6% purity)	Werle <i>et al.</i> , 2001
Boiling point	Imazapyr decomposes prior to boiling (99.6% purity)	2001/1024893

- Water dispersible granule (WG)
- Water soluble granule (SG)
- Emulsifiable concentrate (EC)
- Dustable powder (DP)

METABOLISM AND ENVIRONMENTAL FATE

The metabolism, distribution of imazapyr has been investigated in animals and plants. The fate and behaviour of imazapyr in animals, plants and the environment was investigated using the [^{14}C] labelled test materials shown in Figure 1.

Figure 1 [^{14}C]-Labelled test materials used in animals, plants metabolism studies, and the environmental fate studies

The chemical structures of the major degradation compounds from the metabolism of imazapyr are provided below.

Compound name	Structure	Found in metabolism studies
CL 252,974 2-[(1-carbamoyl-1,2- dimethylpropyl) carbamoyl] nicotinic acid		Rat, Plants, Soil, Water
CL 60,032 2-carbamoyl-nicotinic acid		Rat, Soil
CL 247,087 5 <i>H</i> -imidazo [1',2':1,2] pyrrolo [3,4- <i>b</i>] pyridine -2(3 <i>H</i>),5-dione, 1.9 <i>b</i> α(β)-dihydro-3α- isopropyl-3-ethyl-		Plants, Soil
240,000 2-(4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl)-3 -carboxymethyl pyridine		Plants, Soil
CL 119,060 Furo[3,4- <i>h</i>]pyridine-5(7 <i>H</i>)-one, 7-hydroxy-		Plants
CL 17,226 Pyridine 2,3-dicarboximide		Plants

Compound name	Structure	Found in metabolism studies
PDC Pyridine 2,3-dicarboxylic acid		Plants, Soil
CL 288,247 2-(4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl)-3-hydroxy pyridine		Soil

Animal metabolism

The Meeting received studies on the metabolism of imazapyr in rats, lactating goat and laying hens. The study on rats was evaluated by the WHO Core Assessment Group of the 2013 JMPR. A summary of the rat metabolism is given in this section.

Rats

The metabolism studies performed on rats indicated that imazapyr was quickly and extensively absorbed following administration. There were no substantial sex differences in the absorption, elimination or distribution of radioactivity in rats receiving an oral dose of radiolabelled imazapyr. The majority of the administered doses were excreted in urine (68–95%) and, to a lesser degree, in faeces (5.5–33%). Most elimination occurred within the first 24 hours after dosing (57–91% in urine; 3–24% in faeces). The half-life of imazapyr in the rat was less than 1 day. Imazapyr was excreted mostly unchanged. Trace levels of polar and nonpolar metabolites were formed and excreted in urine and faeces. Only trace amount of tissue residues were detected in the liver and kidneys on the high dose group, indicating no bioaccumulation.

Lactating goat

Study 1

The metabolism of imazapyr by the lactating dairy goats was studied by Zdybak (1992: IZ-440-002). [pyridine-6-¹⁴C]-imazapyr was orally administered in gelatin capsules to lactating goats. Three lactating goats, each weighing from 44 to 67 kg, were used as model ruminants in the study. Each goat received a single daily oral dosage equivalent to a dietary level of 0 ppm (control), 17.7 ppm, or 42.5 ppm, respectively, for seven consecutive days. Based on actual mean feed consumption of 0.859 kg and 1.08 kg per day for low and high dosed goats during the test period, the mean actual daily dietary dosages of imazapyr were 17.7 ppm and 42.5 ppm for low and high dose goats, respectively.

Urine and faeces were collected daily and analysed for radioactivity content. During the treatment period, blood and milk samples were also collected and analysed for total radioactive residues (TRR). Goats were sacrificed ca. 22 hours after the seventh and final doses. Blood and edible tissues (liver, kidneys, leg muscle, loin muscle and omental fat) were collected.

Orally-administered radioactivity was mainly excreted in the urine (65.3% and 60.4% of the doses in the 17.7 ppm and 42.5 ppm dosed goats, respectively). Faecal elimination accounted for 16.1% and 19.0% of the doses in the 17.7 ppm and the 42.5 ppm dosed goats, respectively.

At both treatment levels, radiocarbon content in blood was less than the validated detection limit of 0.05 mg/kg. The TRR levels were < 0.01–0.01 mg/kg and 0.01–0.02 mg/kg in the milk samples of the 17.7 ppm and 42.5 ppm dosed goats, respectively. TRR levels for leg and loin muscles, liver, and fat were all less than the validated limit of detection of 0.05 mg/kg. Detectable residues were found in the kidneys namely 0.08 mg/kg (17.7 ppm dose) and 0.11 mg/kg (42.5 ppm dose).

Milk (day-7) and kidney samples from the 42.5 ppm dosed goat were subjected to solvent extraction followed by chromatographic analysis. Organosoluble milk residues distributed in hexane and ethyl acetate amounted to 17.7% and 6.4% of the TRR (or < 0.01 mg/kg), respectively. Water soluble residues accounted for approximately 49% (0.01 mg/kg) of the TRR, whereas the remainder was unextractable (26.6%, 0.01 mg/kg). Kidney residues were quantitatively extractable, with the majority (95.5%) isolated in a methanol/water fraction.

Table 1 Total radioactive residue (TRR) in goat milk and tissues

Sample	TRR (mg imazapyr equivalent/kg)		
	Control	Low dose (17.7 ppm)	High dose (42.5 ppm)
Milk (Day 1)	< 0.01	< 0.01	0.01
Milk (Day 2)	< 0.01	0.01	0.02
Milk (day 3)	< 0.01	< 0.01	0.01
Milk (Day 4)	< 0.01	< 0.01	0.01
Milk (Day 5)	< 0.01	0.01	0.01
Milk (Day 6)	< 0.01	0.01	0.02
Milk (Day 7)	< 0.01	0.01	0.02
Leg Muscle	< 0.05	< 0.05	< 0.05
Loin Muscle	< 0.05	< 0.05	< 0.05
Fat	< 0.05	< 0.05	< 0.05
Liver	< 0.05	< 0.05	< 0.05
Kidney	< 0.05	0.08	0.11
Blood (Day 0)	< 0.05	< 0.05	< 0.05
Blood (Day 1)	< 0.05	< 0.05	< 0.05
Blood (Day 3)	< 0.05	< 0.05	< 0.05
Blood (Day 7)	< 0.05	< 0.05	< 0.05

The extracted ^{14}C residue in the milk (0.01 mg/kg) was identified as unchanged parent compound by thin layer chromatography (TLC) and high performance liquid chromatography (HPLC) analyses. Similarly, the ^{14}C residue in the kidney was identified as unchanged parent compound. Chromatographic analyses of the urine showed a single radioactive residue component identical to that found in the kidney and milk.

Study 2

The purpose of this study was to determine the concentration of the total ^{14}C residues and the nature of these residues in kidneys and milk of the lactating goats following administration of daily oral doses of [imidazole-5- ^{14}C]-imazapyr (Tsalta, 2000: IZ-440-005). [^{14}C] imazapyr or blank gelatin capsules were administered orally to lactating goats weighing between 49 and 50 kg (at treatment) that were less than 5 years of age. The two goats were dosed orally by capsule for seven consecutive days with the actual dietary equivalent of 0 ppm and 47 ppm [^{14}C] imazapyr as groups A (control) and B (treated), respectively, to determine total [^{14}C] imazapyr derived residues in daily milk, urine and faeces, and in the kidneys at sacrifice. The dose rate of 47 ppm for the treated goat was slightly higher than the rate of 42.5 ppm used for a goat study (IZ-440-002). That study showed that kidney and milk were the edible matrices that contained detectable residues following oral dosing of 42.5 ppm for 7 days. The study was to provide tissues (kidney and milk) with high enough residues so that they could be used to conduct an extraction efficiency/accountability study.

The TRR in the milk and the urine samples were determined by direct scintillation counting (LSC). The TRR in the kidneys and faeces were determined by combustion followed by LSC. Radioactivity in the extracts of the kidney and in liquid chromatographic fractions was determined by LSC. Radioactivity in the post extraction solids (PES) generated after kidney and milk extraction was determined by combustion followed by LSC. The specific radioactivity afforded a theoretical detection limit of 0.006 mg/kg imazapyr equivalents in the kidney, milk, urine and faeces when 0.5 g or 0.5 mL (nominal) sample aliquots were analysed by combustion and LSC or by direct LSC. The validated detection limit was 0.006 mg/kg for the milk and urine and 0.007 mg/kg for kidney and faeces.

During this study, milk, urine and faeces samples were collected daily. At sacrifice (approximately 22 hours after the last dose) only kidney samples were collected. The TRR levels in all control samples and pre-treatment samples were non-detectable (< 0.006 mg/kg). The TRR levels for the dosed goat were 0.014–0.015 mg/kg for milk and 0.074 mg/kg for kidney. The rate of elimination for the goat treated daily for 7 days with an oral dose of [^{14}C] imazapyr was determined by analysing the daily samples of urine and faeces. After seven days, 58.7% and 34.4% of the administered radioactive doses were excreted in the urine and faeces, respectively.

Radioactive residues were extracted from kidneys using acetone: water (3:1, v/v) as solvent. The overall recovery in the extractable portion was 93.5% and the unextractable (PES) was 6.5%. The concentrated extract was analysed by HPLC to determine the nature of the radioactive residue. The parent compound (imazapyr) was the predominant radioactive residue (81.9% of TRR, 0.061 mg/kg) in the kidney. Minor polar unknowns (total 11.6% of TRR) were also present in the kidney extract. Since these fractions contained multiple components (at least three), each less than 0.004 mg/kg, no further characterization was attempted.

The Day-7 treated goat milk was extracted by a procedure involving sequential extractions with acetonitrile: water, ethyl acetate and hexane. The extractable radioactivity was 82% and the unextractable (PES) was 18% of the TRR. The major component in the milk extract (65.6% of TRR, 0.01 mg/kg) was the parent compound (imazapyr). Minor polar unknowns (total 14.7% of TRR) were also present in the milk extract. Since these fractions were equivalent to 0.002 mg/kg and contained multiple components, no further characterization was attempted.

Table 2 Characterization and identification of radioactive residues in kidney and milk

Compound	Kidney		Milk, Day 7			
	% TRR	mg/kg ^a	% TRR		mg/kg ^a	
			Aqueous	Ethyl acetate	Aqueous	Ethyl acetate
Extract	93.5	0.07	46.3	35.8	0.006	0.005
Imazapyr	81.9	0.061	33.4	32.2	0.005	0.005
Polar unknowns	11.6	0.009	11.3	3.35	0.002	< 0.001
Unextracted	6.5	0.005	18.0			
TRR		0.074			0.014	

^a mg imazapyr equivalent/kg

The results of this lactating goat study showed that orally administered [^{14}C] imazapyr was rapidly absorbed and eliminated in urine and faeces. At the end of the 7-day dosing period, 93.1% of the administered cumulative dose was recovered in the urine and faeces of the treated goat. The kidney and the milk of the treated goat contained 0.074 and 0.014–0.016 mg/kg, respectively, of TRR following seven days of oral treatment at approximately 47 ppm. The parent compound (imazapyr) was the predominant radioactive residue in the kidney (81.9% of TRR or 0.061 mg/kg) and in the milk (65.6% of TRR or 0.01 mg/kg). The concentration of the remaining radioactive components in the kidney and the milk were below 0.01 mg/kg.

Laying hens

The elimination, distribution and metabolic fate of imazapyr by egg laying hens were studied by Tsalta (1995: IZ-440-003). Three groups consisting of eight Dekalb XL white leghorn hens, each hen about 20 weeks old and weighing approximately 2.0 kg were used as test animals in this metabolism study. The three groups of hens were dosed orally by capsule for seven consecutive days with the nominal dietary equivalent of 0 ppm, 2 ppm, and 10 ppm [^{14}C]-labelled imazapyr as groups A (control), B (low dose), and C (high dose), respectively. The hens were used to determine total imazapyr-derived residues in the eggs (daily), in the excreta and in the blood and edible tissues at sacrifice. [pyridine-6- ^{14}C]-imazapyr was used in the study. The specific radioactivity afforded a validated detection limit of 0.01 mg/kg imazapyr equivalents in the egg and hen tissues when 0.5 g sample aliquots were analysed.

The TRR in the daily egg samples were determined by LSC. The TRR in the blood, tissues and excreta were determined by combustion followed by LSC. Radioactivity in the extracts of excreta and in liquid chromatographic fractions was determined by combustion and by LSC; radioactivity in the post extraction solids of excreta was determined by combustion followed by LSC. The metabolite profile of imazapyr was defined by analysing acetone extracts of the excreta using high performance liquid chromatography. The identity of the main residue component imazapyr was determined by GC-MS.

Elimination of ^{14}C via the excreta accounted for 90.5 and 91.7% of the total doses for the low and high doses, respectively. During treatment, TRR in the egg samples was less than the validated detection limit of 0.01 mg/kg. The only significant component of the excreted ^{14}C residue was defined as imazapyr by HPLC analysis and by mass spectrometry.

Residues in blood, skin with adhering fat, muscle, liver and kidney tissues taken at 22 hours after the last dose were all less than the validated detection limit of 0.01 mg/kg. The results of this study clearly show that orally administered imazapyr was rapidly eliminated by the hen as unchanged parent compound and that imazapyr-related residues do not accumulate in eggs or the edible tissues of poultry at 108× the potential maximal dietary exposure level. These data demonstrate that there is no reasonable expectation of finite residues of imazapyr occurring in poultry tissue or eggs as a result of the herbicide use on corn.

Table 3 Total radioactive residues (TRR) in egg and tissues of hens

Sample	TRR (mg imazapyr equivalent/kg) ^a		
	Control	Low dose (1.98 ppm)	High dose (9.72 ppm)
Excreta (Day 1)	< 0.01	1.98	9.52
Excreta (Day 2)	< 0.01	1.57	9.85
Excreta (day 3)	< 0.01	1.62	9.90
Excreta (Day 4)	< 0.01	1.70	8.66
Excreta (Day 5)	< 0.01	1.78	9.73
Excreta (Day 6)	< 0.01	1.54	9.91
Excreta (Day 7)	< 0.01	1.77	9.45
Eggs (Day 1)	< 0.01	< 0.01	< 0.01
Eggs (Day 2)	< 0.01	< 0.01	< 0.01
Eggs (day 3)	< 0.01	< 0.01	< 0.01
Eggs (Day 4)	< 0.01	< 0.01	< 0.01
Eggs (Day 5)	< 0.01	< 0.01	< 0.01
Eggs (Day 6)	< 0.01	< 0.01	< 0.01
Eggs (Day 7)	< 0.01	< 0.01	< 0.01
Blood	< 0.01	< 0.01	< 0.01
Muscle	< 0.01	< 0.01	< 0.01
Skin with adhering fat	< 0.01	< 0.01	< 0.01
Liver	< 0.01	< 0.01	< 0.01
Kidney	< 0.01	< 0.01	< 0.01

^a Excreta: mg/kg calculated on a fresh weight basis. Excreta sample from all hens (eight) from each group were combined for each day and analysed.

Blood and tissues: Values are the average of eight laying hens

The results of this laying hen study conducted at the actual dose levels of 1.98 and 9.72 ppm feed equivalents of imazapyr, showed that the parent compound or derived residues are excreted without retention or accumulation in eggs and edible poultry tissues. Thus, poultry exposed to diets of agricultural commodities containing even highly exaggerated levels of imazapyr residues would not contain or accumulate imazapyr-derived residues in the edible tissues and eggs.

Summary of animal metabolism

The metabolism of ^{14}C -labelled imazapyr has been studied in lactating goat and laying hens. In both studies, imazapyr was mainly eliminated and metabolised to several polar compounds. Imazapyr was the most important component in milk and kidney for lactating goat.

Plant metabolism

Plant metabolism studies were performed on soya bean, maize, sugarcane, oil palm, clover and Bermuda grass with imazapyr ^{14}C -labelled at the 3 or 6-position pyridine ring to track metabolites. Metabolites were identified using multiple chromatographic systems and authentic standards.

Soya beans

A metabolism study was conducted with [pyridine-3- ^{14}C]-imazapyr in transgenic soya bean variety BPS-CV127-9 in which the *csr1-2* gene encoding an altered AtAHS1 protein was inserted to make the host tolerant to imidazolinone herbicide (Dohn, 2012: 2012/7000103). [^{14}C] imazapyr was formulated (a soluble liquid (SL)) and applied once to the above ground portion of soya beans plants at BBCH growth stage 65 with a hand operated pump sprayer. The application rate was 107 g/ha which was 149% of the maximum anticipate use rate of 72 g/ha. The test plots were located outdoors, and consisted of two plots, one control and one treated. The forage was harvested approximately one hour after application and the hay was harvested 35 days after application. Soya bean straw, pods and seeds were harvested when mature at 98 days after treatment.

All crop samples were processed, subjected to combustion analysis, extracted and analysed by reverse phase HPLC. The TRR of soya bean forage from combustion was 0.655 mg/kg, soya bean hay was 0.247 mg/kg, soya bean seed was 0.062 mg/kg, soya bean straw was 0.079 mg/kg and soya bean pod was 0.146 mg/kg. The extraction procedure released 72.5% to 98.7% of the TRR. The unextracted residues were small, 0.008 mg/kg (1.3% TRR) in forage, 0.028 mg/kg (11.1% TRR) in hay, 0.011 mg/kg (15.9% TRR) in seeds, 0.016 mg/kg (21.6% TRR) in straw, and 0.039 mg/kg (27.5% TRR) in pods (see Table 4).

The parent compound imazapyr was identified by co-chromatography with a reference standard and by LC-MS analysis of an isolated fraction from hay. Imazapyr was detected in all matrices and was the most abundant component of the residue in soya bean forage (0.599 mg/kg, 93.6% TRR), hay (0.094 mg/kg, 37.3% TRR), and seed (0.0236 mg/kg, 34.2% TRR). Imazapyr was present in straw at 0.006 mg/kg (8.1% TRR) and pods at 0.018 mg/kg (12.7% TRR).

Table 4 Extractability of Soya bean matrices and Total Radioactive Residues

Matrix	DAT	Distribution of radioactive residues						Total extracted		Unextracted		TRR (calculated)	TRR (combustion)
		Methanol extract		Aqueous extract		Acidic methanol							
		mg/kg	%TRR	mg/kg	%TRR	mg/kg	%TRR	mg/kg	%TRR	mg/kg	%TRR	mg/kg	mg/kg
Forage	0	0.591	92.3	0.035	5.5	0.006	0.9	0.632	98.7	0.008	1.3	0.640	0.655
Hay	35	0.182	72.2	0.036	14.3	0.006	2.4	0.224	88.9	0.028	11.1	0.252	0.247
Seeds	98	0.022	31.9	0.014	20.3	0.022	31.9	0.058	84.1	0.011	15.9	0.069	0.062
Straw	98	0.040	54.1	0.014	18.9	0.004	5.4	0.058	78.4	0.016	21.6	0.074	0.079
Pods	98	0.031	21.8	0.036	25.4	0.036	25.4	0.103	72.5	0.039	27.5	0.142	0.146

A polar component M3 (not retained on reverse phase HPLC) was the most abundant component in the pods (0.041 mg/kg, 28.9% TRR). This component was also present in hay

(0.028 mg/kg, 11.1% TRR), straw (0.009 mg/kg, 12.2% TRR) and seeds (0.0161 mg/kg, 23.3% TRR), but was not detected in forage. The polar peak was isolated from the soya bean seeds, and shown to consist of multiple components, present at ≤ 0.004 mg/kg. A polar component was observed in seed, hay, straw and pod and shown to be comprised of multiple components. Imazapyr was degraded in soya bean to multiple products present in relatively small concentrations.

The remainder of the residues consisted of multiple components individually present in small concentrations. No metabolites were present at levels exceeding 10% TRR in any crop matrices except for M19 in the straw. M19 was present in the straw at 0.013 mg/kg (17.6% TRR) and was also found in hay at 0.022 mg/kg (8.7% TRR).

^a Components code with a retention time of LC-MS

Imazapyr underwent significant metabolism, however, the parent molecule was the most abundant component of the residue in all matrices except straw and pods. The concentration of imazapyr declined from 0.599 mg/kg (93.6% TRR) in forage collected approximately 1 hour after application to 0.094 mg/kg in the hay sample (37.3% TRR) collected 35 days after application, and then 0.006 mg/kg (8.1% of the TRR) in the straw sample collected 97 days after application. The imazapyr concentrations were 0.0236 mg/kg (34.2% TRR) in seed, and 0.018 mg/kg (12.7% TRR) in pods (see Table 5).

Imazapyr was degraded to a number of components in soya bean commodities. In seed, multiple metabolites are present with concentrations at ≤ 0.004 mg/kg (5.8% TRR), and parent was the main component. The very polar peak M3 that was not retained on reverse phase HPLC was isolated from the seed extract. Analysis using a Hypercarb column showed the peak to be comprised of multiple components, each present at ≤ 0.004 mg/kg (5.8%TRR). In straw, component M19, a component of intermediate polarity with a retention time of about 19 minutes, was present at amounts > 10% TRR with concentration of 0.013 mg/kg (17.6% TRR). The component was also present in hay but at levels < 10% TRR. Due to the presence over 10% TRR in only straw which is an animal feed item, the component M19 was not further analysed. In addition to minor components such as M31 and M45.5, a large number of components that did not exceed 0.002 mg/kg were present in the matrices of hay, straw and pod. As was demonstrated with the polar peak isolated from the seed extract, the polar peak in the hay, straw and pod was assumed to be comprised of a large number of low-level components.

Maize

A metabolism study was conducted in imidazolinone-resistant maize (Pioneer hybrid 3245 IR) to determine the total ¹⁴C residues following a post-emergence treatment of maize plants at the 3 to 4 leaf growth stage with [pyridine-6-¹⁴C]-imazapyr at treatment rates of 0.028 kg ai/ha (plot A) and 0.080 kg ai/ha (plot B), and to determine the nature of any significant imazapyr-derived residues in

the green plants, forage, fodder (stalks/husks/cobs), and grain (Zulalian, 1995: IZ-640-003). The treatment rates used in this study correspond to 1× and 2.8× the maximum label rate (0.027 kg ai/ha) for the use of imazapyr on imidazolinone-resistant maize. Soil core samples were taken prior to application of the test substance (−1 DAT), within two hours following application of the test substance (0 DAT), and one day after final harvest (115 DAT) of the mature maize plants. Samples of maize plants were harvested at 0 DAT (green plant), 14 DAT (green plant), 30 DAT (early forage), and 62 DAT (late forage). At maturity (114 DAT), the stalks, husks, and cobs with grain were collected.

The TRR in all plant and soil samples were determined by combustion and liquid scintillation counting (LSC). The TRR in soil (0–3 inches) at 0 DAT was 0.012 mg/kg and 0.047 mg/kg from plots A and B, respectively. At 115 DAT (1 day after maize harvest), the TRR in the soil (0–3 inches) was 0.006 mg/kg and 0.016 mg/kg from plots A and B, respectively. Residues were 0.002 to 0.007 mg/kg in soil at 7.6–15 cm, < 0.002 to 0.003 mg/kg at 15–30 cm and < 0.002 at 30–46 cm.

The green plant and forage samples were extracted with methanol. The fodder was extracted with methanol: water: hydrochloric acid and the grain were extracted with hexane followed by methanol: water: hydrochloric acid.

For the 0 DAT maize plant from plot A, 96.3% (2.37 mg/kg) of the TRR was extracted and 3.7% (0.093 mg/kg) remained in the post extracted solids (PES). The 0 DAT maize plant from plot B was not extracted. For the 14 DAT maize plants from plot A and B, 78.6 to 81.9% (0.046 to 0.126 mg/kg) was extracted and 18.1 to 21.4% (0.012 to 0.028 mg/kg) remained in the PES. For the 30 DAT samples (early forage) from plots A and B, 84.2 to 85.8% (0.008 to 0.022 mg/kg) of the TRR was extracted and 14.2 to 15.7% (0.002 to 0.004 mg/kg) remained in the PES. For the 62 DAT samples (late forage) from plot B, 86.8% (0.022 mg/kg) of the TRR was extracted and 13.3% (0.003 mg/kg) remained in the PES. For the 114 DAT fodder from plot B, 69.9% (0.020 mg/kg) of the TRR was extracted and 30.1% (0.008 mg/kg) remained in the PES. The late forage and fodder samples from plot A were not extracted because the TRR was < 0.01 mg/kg. For the 114 DAT maize grain from plots A and B, 0.8 to 1.5% (< 0.002 mg/kg) was extracted with hexane, 80.0 to 88.8% (0.023 to 0.076 mg/kg) was extracted with methanol: water: hydrochloric acid, and 10.3 to 18.5% (0.005 to 0.009 mg/kg) remained in the PES (see Table 6).

^a Stalks/husks/cobs, combined

The imazapyr-derived residues in the grain did not concentrate in the maize oil since no residues (< 0.002 mg/kg) were detected in the hexane extract of the maize grain from the 1× and 2.8× treatments.

HPLC analyses of the radioactivity extracted with methanol and methanol: water: hydrochloric acid was conducted on a C18 reverse phase column. The radioactivity profiles of the extracts of the green plant, forage, fodder, and grain were similar qualitatively. There was one major component and a minimum of sixteen minor radiolabelled components that were separated and detected by C18 reverse-phase HPLC and LSC. Parent imazapyr constituted the major component of the extractable residue in the green plant, forage, fodder, and grain (12.0 to 80.8% TRR, 0.003 to 1.997 mg/kg). The residue levels of the minor components in the 30 DAT to 114 DAT samples were

all < 0.01 mg/kg. A number of minor components of the TRR exhibited the same HPLC retention times as PDC, CL 60,032, CL 263,078, CL 252,974, CL 252,663 and CL 271,045 (see Table 7).

^a mg/kg TRR

^b Relative percent of extracted TRR

Imazapyr was isolated from the extracts of the 62 DAT forage and 114 DAT grain from plot B by affinity chromatography using an anti-imidazolinone antibody and identified by GC-MS analysis.

Imazapyr is the only significant component of the residue in imidazolinone-resistant maize after application of imazapyr at the maximum intended label rate. All components of the residue in the raw agricultural commodities were < 0.01 mg/kg with the exception of the grain in which imazapyr accounted for only 0.012 mg/kg.

Sugarcane

The metabolism of [^{14}C] imazapyr in sugarcane variety CP 65-357 was investigated (Mangels and Lucas, 1987: IZ-640-001). [pyridine-6- ^{14}C]-imazapyr was formulated and applied to the soil surface once as a pre-emergence application at a rate equivalent to 0.28 kg ai/ha using a hand-sprayer. Stalk samples were taken at maturity approximately 14 months after the pre-emergence treatment. The sugarcanes (without outer leaves) were homogenized and subjected to combustion analysis.

There were no detectable residues in the treated samples, which gave counts that were equivalent to both the control samples and the background levels of the cocktails and the equipment. The TRR of the samples was below the sensitivity of the method (< 0.005 mg/kg). No further investigations and storage stability analyses were carried out.

Oil palm

A metabolism study was conducted with [pyridine-6- ^{14}C]-imazapyr in oil palm (Mallipudi, Taylor and Paniagua, 1986: IZ-640-002). [^{14}C] imazapyr was formulated as the isopropylamine salt and applied to the ground beneath an actively fruiting oil palm. The application rate was 1.0 kg ai/ha. Out of three palms selected as test plots, two were treated with [^{14}C] imazapyr and one was used as control. Fruit samples were collected from the oil palm as they ripened at 0 hour, 7, 30 and 62 days after treatment.

Ripe fruits were collected from untreated palms on the same day as from the treated palms. Palm oil was extracted from the fruits using a hexane: water mixture (3:1, v/v).

Residual radioactivity levels expressed as mg/kg equivalents of imazapyr were below the validated sensitivity of the method (< 0.03 mg/kg) at any given time in the palm oil, aqueous phase, fruit marc, kernel shell and kernel nut. There was no detectable radiocarbon in palm oil and other fruit fractions from the control palm.

The radioactive residues derived from [^{14}C] imazapyr were present in the soil samples (0.30–1.70 mg/kg in the 0–7.6 cm depth) at each sampling interval of oil palm fruits. The results indicate that imazapyr derived residues will not accumulate in the palm oil of an actively fruiting oil palm after application to the ground beneath the palm.

Clover

A metabolism study was conducted with [pyridine-6- ^{14}C]-imazapyr (Wu, 1997: IZ-640-007). [^{14}C] imazapyr was applied to clover at a rate of 1.68 kg ai/ha (acid equivalents) as a 240 g/L water soluble formulation. Soil cores were collected to a depth of 45.7 cm before application (–1 day), after application (0 day), and at final sampling (21 day). Clover foliage was collected at 0, 4, 10, 15 and 21 days after treatment (DAT) and analysed for metabolite identification. The field study was conducted outdoors in two separate plots; plot A received the test material spray treatment, and plot B (control) received the blank spray treatment. Phytotoxic effects were apparent four days after application of the test material to the clover in the test plot. The clover in the untreated control plot appeared healthy. The phytotoxicity remained apparent until the final collection 21 days after treatment.

The soil cores and clover foliage from the control and treated plots were analysed for total radioactive residue (TRR) content. The clover foliage from the treated plot at each sampling interval also was extracted with acidified methanol and analysed for metabolites.

The TRR levels (expressed as mg/kg imazapyr equivalent) in soil were low. For example, levels were 0.084 mg/kg at 0–7.62 cm, 0.017 mg/kg at 7.62–15.2 cm at 0 DAT and < 0.01 to 0.144 mg/kg at different depths at 21 DAT. The level of radioactivity in soil increased due to wash-off by water and release of radioactivity by dying plants. Soil cores at all other sampling times and depths had only background levels (< 0.01 mg/kg).

TRR levels in foliage were 43.0 mg/kg (0 DAT), 37.4 mg/kg (4 DAT), 23.4 mg/kg (10 DAT), 41.6 mg/kg (15 DAT) and 49.2 mg/kg (21 DAT). The high radioactive residues in foliage at 0 DAT resulted from direct application of [^{14}C] imazapyr to clover. The TRR in foliage declined from the time of application to 10 DAT. The increased TRR in 15 and 21 DAT samples was probably attributed to the loss of water from plants as the plants died. TRR values in control soil and plant samples were all less than the minimum quantifiable limit of detection (< 0.01 mg/kg). Control clover from 10 DAT, however, was 0.011 mg/kg.

Each clover sample was extracted by blending with methanol/hydrochloric acid (100/0.75, v/v). The acidified methanol extracted 97.6%, 98.9%, 96.9%, 93.7% and 89.4% of TRR from the 0, 4, 10, 15 and 21 DAT samples, respectively. Post extraction solids (PES-1) were hydrolysed with protease in a phosphate buffer (pH approximately 7.5), followed by cellulase in an acetate buffer (pH approximately 5). The enzyme hydrolysates were combined and concentrated for metabolite analysis. The PES-3 fractions (PES after protease and cellulase hydrolyses of PES-1) from 0, 10, 15 and 21 DAT samples were further hydrolysed using 6 N HCl (Aqueous-3).

The acidified methanol extracts were analysed by HPLC and TLC. The majority of the radioactivity was unchanged imazapyr, ranging from approximately 66% to 99% of TRR. The other major metabolites were CL 247,087 plus CL 240,000 (approximately 0–18% of TRR, 80–90% of the total was estimated to be contributed by CL 247,087) and PDC (approximately 0–5% of TRR). There also appeared to be trace amounts of CL 252,974 (0–3% of TRR) and several other unknown metabolites.

Analysis of the enzyme hydrolysate from PES indicated that parent imazapyr was still the major component identified (28.5–44.2%), other metabolites detected were CL 240,000/CL 247,087 (2.74–12.5%) and PDC (0–17.6%), unknown A (R_t approximately 20–21 min, 0–20.7%), unknown B (R_t approximately 32 min, 5.63–58.3%), and CL 252,974 (0–13.9%). The AQ-3 fractions of the 15 and 21 DAT samples (i.e., hydrolysates after 6 N HCl hydrolysis of PES-3) were analysed by HPLC. The 15 and 21 DAT samples showed a major peak at R_t approximately 8 min, this retention time was very close to that of PDC. In addition, two-dimensional TLC analysis indicated that this peak was very likely PDC.

Table 8 Distribution of metabolites in clover after application of [^{14}C] imazapyr

^a Majority of the total (80 to 90%) was estimated to be contributed by CL 247087.

In conclusion, imazapyr remained mostly unchanged when applied to clover at 1.68 kg ai/ha. Overall, approximately 91.6–99.2% of the incurred residue had been defined in the study. The unchanged imazapyr accounted for 67.5–99.2% of the total residue. A number of minor metabolites, including CL 240,000/CL 247,087, CL 252,974 and PDC were present at 0.02–18.4% (the estimated ratio of CL 240,000/CL 247,087 was in the range of 1:5 to 1:10), 0–3.60% and 0–6.56% of TRR, respectively.

Bermuda grass

A metabolism study was conducted with [pyridine-6- ^{14}C]-imazapyr (Wu, 1997: IZ-640-006). [^{14}C] imazapyr was applied to Bermuda grass at a rate of 1.68 kg ai/ha (acid equivalents) as a 240 g/L water soluble formulation. Soil cores were collected to a depth of 45.7 cm before application (-1 day), after application (0 day), and at the final sampling (21 day). Bermuda grass foliage was collected at 0, 4, 10, 15 and 21 days after treatment (DAT) and analysed for metabolite identification. The field study was conducted outdoors in two separate plots; plot A received the test material spray treatment, and plot B (control) received the blank spray treatment. Phytotoxic effects were apparent four days after application of the test material to the Bermuda grass in the test plot. The Bermuda grass in the untreated control plot appeared healthy. The phytotoxicity remained apparent until the final collection 21 days after treatment.

The soil cores and grass foliage from the control and treated plots were analysed for total radioactive residue (TRR) content. The grass foliage from the treated plot at each sampling interval also was extracted with acidified methanol and analysed for metabolites.

The TRR levels (expressed as mg/kg imazapyr equivalent) in soil were low. For example, levels were 0.041 mg/kg (0 day) at 0–7.62 cm and ranged from 0.048 to 0.131 mg/kg (21 day) at different depths (up to 30.5 cm). The level of radioactivity in soil increased due to wash-off by water

and release of radioactivity by dying plant. Soil cores at all other sampling times and depths had only background levels.

TRR levels in foliage were the highest at 0 DAT (64.3 mg/kg); they then decreased to 17.5 mg/kg at 4 DAT; 22.0 mg/kg at 10 DAT, 24.9 mg/kg at 15 DAT and 47.7 mg/kg at 21 DAT. The high radioactive residues in foliage at 0 DAT resulted from direct application of [^{14}C] imazapyr to Bermuda grass. The increased TRR in 21 DAT compared to the 15 DAT samples was probably attributed to the loss of water as the plants died. TRR values in control soil and plant samples were all less than the minimum quantifiable limit of detection (< 0.01 mg/kg).

Each grass sample was extracted by blending with methanol/hydrochloric acid (100/0.75, v/v). The acidified methanol extracted 97.3%, 97.1%, 94.5%, 88.1% and 85.8% of TRR from the 0, 4, 10, 15 and 21 DAT samples, respectively. Post extraction solids (PES) were hydrolysed with protease in a phosphate buffer (pH approximately 7.5), followed by cellulase in an acetate buffer (pH approximately 5). The enzyme hydrolysates were combined and concentrated for metabolite analysis. The PES-3 fractions from 0, 4, 10, 15 and 21 DAT samples were further hydrolysed using 6 N HCl, yielding AQ-3 and PES-4 fractions. The PES-4 fractions from the 10 and 15 DAT samples were further hydrolysed by 1 N NaOH.

The acidified methanol extracts were analysed by HPLC and TLC. The majority of the radioactivity was unchanged imazapyr, ranging from 74.4% to 94.7% of TRR. Three other identified radio components were PDC, CL 247,087 cyclized product and CL 240,000. The amount of PDC in the acidified methanol fraction increased with time from 0% at 0 DAT to 7.23% of TRR at 21 DAT. The amount of CL 247,087 and CL 240,000 in the acidified methanol fraction was highly variable, ranging from 0% to 10.1% of TRR.

It is known that imazapyr forms methyl ester (CL 240,000) in methanol. Additional experiments were conducted to find out whether the CL 240,000 detected was formed metabolically or as a result of chemical reaction. Extraction of a separate subsample of 0 and 21 DAT grass samples with methanol/HCl or acetone followed by chromatographic analysis showed that CL 240,000 was present in both acetone and acidified methanol extract. The acidified methanol fraction showed higher amounts of CL 240,000; however, acetone had much lower extraction efficiency for the radioactivity. The peak height of CL 240,000 increased after one month storage of acidified methanol extract in the refrigerator. The results indicate that small amounts of CL 240,000 are metabolite generated by the grass; the variability may be a result of the storage stability property.

Analysis of the enzyme hydrolysate from PES indicated that parent imazapyr was still the major component identified (1.10–4.55% of TRR), other metabolites detected were CL 240,000 and/or CL 247,087 (0–0.54% of TRR), PDC (0.08–1.79% of TRR) and unknown C (R_t approximately 20–20.5 min, 0–0.45%). The PES-3 fractions from the 0, 4, 10, 15 and 21 DAT samples were further hydrolysed by 6 N HCl. The hydrolysates were analysed by HPLC. All of the samples showed a single peak at R_t approximately 5 min; this retention time was very close to that of PDC. In addition, two-dimensional TLC analysis indicated that this peak was very likely PDC. The PES-4 samples from the 10 and 15 DAT grass were again hydrolysed with 1 N NaOH, however, the hydrolysates (AQ-4) were not further analysed due to the presence of low radioactive residue levels.

In conclusion, imazapyr remained mostly unchanged when applied to Bermuda grass at 1.68 kg ai/ha. Overall, approximately 94–97% of the incurred residue had been defined in the study. The unchanged imazapyr accounted for 78–97% of the total residue. A number of metabolites, including PDC and CL 247,087 plus CL 240,000 were present at 0.32–12.8% and 0–10.5% of TRR, respectively.

Summary of plant metabolism

Metabolism of [¹⁴C] imazapyr labelled in pyridine ring has been studied in soya bean (imidazolinone-resistant), maize (imidazolinone-resistant), sugarcane, oil palm, clover and Bermuda grass, which are suitable to cover the crop groups of pulses, cereals, oilseeds and animal feed. Imazapyr is the major component of the residues found in soya bean, maize, clover, and Bermuda grass. PDC is also the major components of the residues in clover and Bermuda grass. The following metabolic pathways were speculated in the plant metabolism studies available.

Figure 2 Metabolic Pathway of Imazapyr in Plants (clover and Bermuda grass)

Environmental fate in soil

The Meeting received information on aerobic degradation in soil, photolysis on soil surface, rotational crop and hydrolytic degradation study. Because imazapyr is intended for use as foliar and soil treatment, aerobic degradation, soil photolysis, rotational crop and hydrolytic degradation study relevant to the current evaluations were reported below (FAO Manual 2009).

The fate and behaviour of imazapyr in soils were investigated using [^{14}C -carboxyl] and [^{14}C -pyridine] labelled compounds.

Aerobic degradation

Study 1

The aerobic soil metabolism of [carboxyl- ^{14}C]-imazapyr was studied in Princeton sandy loam soil. Imazapyr was applied to the soil at the rate of 1.12 kg ai/ha and kept under aerobic conditions in the dark (Mallipudi, 1983: IZ-620-001). At sampling intervals of 1, 2, 4, 6, 9 and 12 months, [^{14}C] carbon dioxide collected was 2.0, 4.0, 7.2, 9.8, 11.2 and 13.6% of the applied dose, respectively. Aerobic microbes present in the soil slowly decarboxylated the compound imazapyr. No other ^{14}C volatile materials were collected at any given interval during the course of the experiment, indicating volatilization of the parent compound or metabolites had not occurred.

Table 10 Soil characteristics

Parameters	Soil (Princeton)
pH (water)	5.3
Organic matter (%)	1.8
Cation exchange capacity (meq/100 g soil)	8.5
Soil type (USDA)	Sandy loam
Clay (%)	10.4
Silt (%)	30.8
Sand (%)	58.8
Moisture at 1/3 bar (%)	14.4
Bulk density on dry soil (g/cc)	1.3

At sampling intervals of 1, 2, 4, 6, 9 and 12 months, the ^{14}C residues remaining in the soil were 96.4, 95.8, 95.2, 90.8, 89.3 and 86.0% of the applied dose, respectively. The rate constant and the half-life of imazapyr under laboratory conditions were calculated as 0.041/month and 17 months, respectively. The extractable soil ^{14}C residue at 1 to 12 months intervals was characterized as imazapyr by TLC and mass spectrometry. The unextractable soil-bound radioactive residues varied from 6.6 to 14.0% of the total soil radioactive residue during the 12-month period. ^{14}C labelled CO_2 was the only major metabolite detected using [carboxyl- ^{14}C]-imazapyr. No marked changes were found in the total bacterial and mould counts on untreated and treated soil with imazapyr, indicating that soil aerobic microflora was active throughout the experimental period and imazapyr has no lethal effects on soil aerobic microflora.

Study 2

The aerobic soil metabolism of [carboxyl- ^{14}C]-imazapyr was studied in North Dakota clay loam soil. Imazapyr was applied to the soil at the rate of 1.12 kg ai/ha and kept under aerobic conditions at 22 to 24 °C in the dark (Mallipudi, 1985: IZ-620-002). At sampling intervals of 1, 2, 4, 6, 9 and 12 months, the ^{14}C residues remaining in the soil were 95.1, 91.3, 94.5, 79.0, 83.8 and 79.8%, while [^{14}C] carbon dioxide collected was 2.8, 3.2, 7.3, 13.4, 14.5 and 15.4% of the applied dose, respectively. No other ^{14}C volatile materials were collected at any given interval during the course of the experiment, indicating volatilization of the parent compound or metabolites had not occurred.

Table 11 Soil characteristics

Parameters	Soil (North Dakota)
pH (water)	7.5

Soil type (USDA)	Clay loam
Clay (%)	34.0
Silt (%)	42.8
Sand (%)	23.2
Moisture at 1/3 bar (%)	46.6
Bulk density on dry soil (g/cc)	1.01

The carboxyl [^{14}C] imazapyr found in soil at the end of the 12-month interval was 60.5% of the applied radioactive dose. At the same time interval, some minor metabolites were identified as PDC (0.3%), CL 60,032 (0.6%) and CL 252,974 (5.4%). There were about six other unknowns comprising 3.0% of the applied dose. No attempt was made to identify these minor unknowns. The unextractable soil-bound radioactive residues varied from 6.0 to 11.2% of the total applied dose during the 12-month period. The amount of ^{14}C residues remaining in the aqueous phase and humic acid were very small at all time intervals. Based on the recovered imazapyr in the soil extract, the rate constant and the half-life of imazapyr under laboratory conditions were calculated as 0.019/month and 37.2 months, respectively, which is longer than the sandy loam soil half-life of 17 months.

Study 3

The aerobic soil metabolism of [^{14}C] imazapyr was studied in Princeton sandy loam soil. The [^{14}C] imazapyr labelled at the pyridine ring was dissolved in acetonitrile and applied to the soil at the rate of 1.68 kg ai/ha and kept under aerobic conditions at 35 °C in the dark (Mangles, 1988: IZ-620-036). Water was added to the soil to bring the moisture of the soil to 75% of field capacity. At intervals of 0, 30, 60, 122, 181, 272 and 365 days after treatment of soil aerobically with [^{14}C] Imazapyr were extracted. At the same intervals, the ethylene glycol, sulphuric acid and potassium hydroxide traps were assayed for the ^{14}C -volatile materials. The soil was extracted with 0.1–0.5 N aqueous sodium hydroxide and the humic acid was removed by acid precipitation. The [^{14}C] imazapyr from the

aqueous phase was extracted with dichloromethane. The solvent was concentrated and analysed by TLC. The soil was combusted to determine the bound residues.

Table 14 Soil characteristics

After 12 months of aerobic incubation 89.3% of the initial dose applied remained as parent compound. Two unknown degradates, none of which accounted for greater than 0.8% of the applied dose, were observed intermittently during the study. None of these intermittent products co-chromatographed with the five reference standards used (PDC, CL 60,032, CL 247,087, CL 247,271 and CL 252,974). A half-life of 7.5 years was calculated.

Study 4

The aerobic soil metabolism of [^{14}C] imazapyr was studied in Princeton sandy loam soil. The [^{14}C] imazapyr labelled at the pyridine ring was dissolved in acetonitrile and applied to the soil at the rate of 1.68 kg ai/ha and kept under aerobic conditions at 25 °C in the dark (Mangels, 1987: IZ-620-037). Water was added to the soil to bring the moisture of the soil to 75% of field capacity. At intervals of 0, 30, 60, 122, 181, 272 and 365 days after treatment of soil aerobically with [^{14}C] imazapyr were extracted. At the same intervals, the ethylene glycol, sulphuric acid and potassium hydroxide traps were assayed for the [^{14}C] volatile materials. The soil was extracted with 0.1–0.5 N aqueous sodium hydroxide and the humic acid was removed by acid precipitation. The [^{14}C] imazapyr from the aqueous phase was extracted with dichloromethane. The solvent was concentrated and analysed by TLC. The extracted soil was combusted to determine the bound residues.

Study 5

The aerobic soil metabolism of [^{14}C] imazapyr was studied in Princeton Sassafras sandy loam soil. [pyridine-6- ^{14}C]-imazapyr was dissolved in water and applied to the soil at the rate of 0.25 kg ai/ha and kept under aerobic conditions at 25 °C in the dark (Ta, 1999: IZ-620-053). Water was added to the soil to bring the moisture of the soil to 75% of 1/3 bar. At intervals of 0, 7, 14, 21, 28, 62, 94 and 121 days after treatment of soil aerobically with [^{14}C] imazapyr were extracted. At the same intervals, the ethylene glycol and sodium hydroxide traps were assayed for the ^{14}C -volatile materials. The soil was extracted once with water and three times with 0.5 N aqueous sodium hydroxide. After extraction, the soils were washed with 100 mL of water, followed by 100 mL of methanol. The water and NaOH extracts were cleaned up and concentrated by C_{18} and SCX solid phase extraction then analysed by TLC, HPLC and HPLC-MS. The extracted soil was combusted to determine the bound residues.

Table 18 Soil characteristics

Silt (%)	22.0
Sand (%)	68.0
Moisture at 1/3 bar (%)	14.9

Approximately 26% of the imazapyr was degraded after 121 days of aerobic incubation. The first-order degradation half-life was calculated to be 313 days. The rate of degradation of imazapyr decreased after 1 month of incubation and appeared to be a biphasic pattern with transition point at approximately 28 days. Using the first month degradation data only, the half-life of imazapyr in soil was calculated to be 117 days. The half-life in the second phase was 438 days. Degradation of imazapyr proceeded via the opening of the imidazolinone ring to yield the metabolite CL 252,974 which accounted for approximately 2% of the applied dose at 4 months of incubation. Degradation of imazapyr can also proceed via the conversion of the carboxylic acid group at the 3 position in the

pyridine ring to form the hydroxyl metabolite (CL 288,247) which reached approximately 6% of the applied dose at 4 months of incubation. The metabolites were identified by co-chromatography (TLC and HPLC) with authentic standard and by mass spectrometry analysis.

Table 19 Distribution of Imazapyr and metabolites in soil (analysed by HPLC)

Time (days)	% of Total Applied Radioactivity							
	Imazapyr	CL288,247	CL252,974	CL240,000	CO ₂	Others ^a	Bound Residue	Total

121	67.6	6.4	2.1	2.3	5.6	6.6	6.1	96.7

^a Consist of several unknown components

Approximately 5.6% of the total applied radioactivity was evolved as ¹⁴CO₂ over the 4 months of incubation indicating that the pyridine ring was mineralized. No organic volatiles were detected in the glycol traps. Results showed that imazapyr is aerobically degraded in soil and is ultimately mineralized to CO₂.

Soil photolysis

The photolysis of ¹⁴C labelled imazapyr was studied on sandy loam soil. [pyridine-6-¹⁴C]-imazapyr was dissolved in acetonitrile and applied to the soil surface at a rate equivalent to 1.68 kg ai/ha, then exposed continuously for 28 days to light from a borosilicate-filtered Xenon-arc lamp in a custom-made environmental chamber (Mangels, 1986: IZ-620-010). The soils were irradiated approximately 80 cm from the light, which was operated continuously at 6000 watts and 25 °C. The light produced by the lamp is comparable to summer sunlight in Chicago, Illinois.

^a Mean of two replicates

There was 11% degradation of imazapyr over the 28 days of continuous irradiation. There were at least five degradation products formed, none of which accounted for > 10% of the applied dose. The photodegradation half-life of imazapyr under the conditions of this test was calculated to be 149 days.

Residues in rotational crops

Confined rotational crop studies

Study 1

The field phase of the confined rotational crop study was conducted in North Carolina and initiated in the summer of 1993 (Zulalian, 1995: IZ-640-004). The study consisted of one treated and one control plot. For the treated plot, pyridine-6-¹⁴C-labeled imazapyr was mixed with [pyridine-6-¹³C]-imazapyr to afford a final specific activity of 20.8 μ Ci/mg. The radioactive test substance, formulated as an aqueous ammonium salt solution, was applied as a post-emergence application to IMI-Maize plants (Pioneer hybrid 3245 IR) at the 6-leaf stage at a rate of 0.028 kg ai/ha. The IMI-Maize plants in the control plot were treated with the blank formulation. The final specific activity of the radiolabelled imazapyr afforded a detection limit of 0.002 mg/kg in the radio-assay of soil and plant samples. Soil core samples were taken prior to application (–1 DAT), within two hours following application (0 DAT) and at final harvest (86 DAT) of the mature maize plants.

Winter wheat (cereal grain) was planted 120 DAT. Soya beans (legume), lettuce (leafy vegetable), and radishes (root crop) were planted 271 DAT. Lettuce and radishes were also planted 420 DAT. Samples were collected from the respective plots at immature and mature stages of crop development. The total radioactive residues (TRR) were determined by combustion and liquid scintillation counting. The TRR in winter wheat forage, straw and grain; lettuce; radish foliage and root; and soya bean forage, hay, and seed were all < 0.002 mg/kg, the limit of detection of the radioassay.

Table 22 Total radioactive residues (TRRs) found in crops for confined rotational crop study

Sample		Planting Interval (DAT)	Harvest Interval (DAT)	TRR (mg/kg)
Wheat (Pioneer 2548)	Mid Harvest Forage	120	278	< 0.002
	Final Harvest Straw		337	< 0.002
	Final Harvest Grain		337	< 0.002
Lettuce (Black Seeded Simpson)	Mid Harvest	271	316	< 0.002
	Final Harvest		328	< 0.002
Lettuce (Buttercrunch)	Mid Harvest	420	457	< 0.002
	Final Harvest		474	< 0.002
Radish (White Icicle)	Mid Harvest Foliage	271	306	< 0.002
	Mid Harvest Root		306	< 0.002
	Final Harvest Foliage		321	< 0.002
	Final Harvest Root		321	< 0.002
Radish (White Icicle)	Mid Harvest Foliage	420	449	< 0.002
	Mid Harvest Root		449	< 0.002
	Final Harvest Foliage		461	< 0.002
	Final Harvest Root		461	< 0.002
Soya bean	Mid Harvest Forage	271	356	< 0.002

Sample		Planting Interval (DAT)	Harvest Interval (DAT)	TRR (mg/kg)
(Hartz 6686)	Final Harvest Hay		484	< 0.002
	Final Harvest Seed		484	< 0.002

DAT = days after treatment

The TRRs in soil (0–8 cm) at 0 DAT was 0.013 mg/kg. At the time of maize harvest (86 DAT) the residue in the soil (0–8 cm) was 0.004 mg/kg. Residues were < 0.002 mg/kg in deeper soil layers (8–15 cm, 15–30 cm and 15–46 cm).

In summary, the results of this study indicate that residues in rotational crops would be expected to be < 0.01 mg/kg at the recommended planting intervals following a post-emergence application of imazapyr on IMI-Maize at a maximum label rate of approximately 0.028 kg ai/ha.

Study 2

An outdoor confined rotational crop study with ^{14}C -labelled imazapyr was conducted at Lucama, North Carolina during the year 1997–1999 (Mallipudi, 2000: IZ-640-008). The study was designed to determine the nature and amount of imazapyr-related residue uptake in rotational crops. A leafy vegetable, root crop and small grain were planted at various time intervals after a single application of [^{14}C] imazapyr to the soil at a rate of 0.885 kg ai/ha. [pyridine-6- ^{14}C]-imazapyr was used in the study. The position of the ^{14}C label was considered metabolically stable to allow determination of the metabolic profile in the confined rotational crops. The radiolabelled imazapyr-spray mixture was formulated as a liquid end-use product in water. The control plot was treated with a blank formulation and water mixture without test substance.

Five months after treatment with the test substance, the test and control plots were planted with annual weeds and maintained the plots with weeds until the designated rotational crop planting time. The treated test plot and control plot were planted with a series of rotational crops, namely carrot and lettuce were planted at 330 and 540 days after treatment (DAT), winter wheat planted at 359 DAT, spring wheat at 520 DAT. Confined rotational crop samples were collected from the respective plants at immature and mature stages of crop development. Soil core samples were taken to a depth of approximately 30 to 46 cm prior to test substance application, immediately following application, and at each rotational crop replant and harvest. No soil samples were taken for carrot and lettuce planted at 330 DAT.

Before analysis, individual crop samples were homogenized by grinding with dry ice. Soil samples were air dried and homogenized by grinding. Total radioactive residues (TRR) in all plant parts and in soil were determined by combustion of aliquots to yield $^{14}\text{CO}_2$. LSC counting was used to analyse trapped $^{14}\text{CO}_2$. The LSC techniques were used to analyse fractions from HPLC. The identity of the extractable residue component was determined by chromatography with unknown reference compounds using HPLC.

TRR levels were less than 0.01 to 0.02 mg/kg in different crop samples at various plant-back intervals. TRR values in control samples were all less than the validated minimum quantifiable limit of detection of 0.005 mg/kg. A summary of the TRR values in the treated crop samples is shown below.

Table 23 Total radioactive residues (TRRs) found in crops for confined rotational crop study

Sample		Planting Interval (DAT)	Harvest Interval (DAT)	TRR (mg/kg)
Winter wheat	forage	359	514	< 0.005
	hay		582	0.005
	straw		596	0.006
	grain		596	0.007
Spring wheat	forage	520	574	< 0.005
	hay		590	0.018
	straw		623	0.015

Sample		Planting Interval (DAT)	Harvest Interval (DAT)	TRR (mg/kg)
	grain		623	0.016
Carrot	mature top	330	427	< 0.005
	mature root			< 0.005
Carrot	mature top	540	646	0.007
	mature root			< 0.005
Lettuce	mature	330	391	< 0.005
Lettuce	mature	540	623	0.009

Significant levels of soil radioactive residues were present throughout the experiment period. TRR in the top zero to 8 cm soil layer were 0.472 mg/kg at 0 days after treatment (0 DAT). Residues in the top 8 cm of soil ranged from 0.022 to 0.028 mg/kg up to 646 DAT during which time various crops were grown. The soil TRR ranged between 0.016 to 0.023 mg/kg in the 8 to 15 cm soil core during the same period. During the same time interval, the soil TRRs were 0.029 to 0.051 mg/kg in 15 to 30 cm soil layer and 0.018 to 0.036 mg/kg in 15 to 46 cm soil layer. TRR levels in the control (untreated) soil core samples were all less than the validated limit of detection (0.005 mg/kg).

The radioactivity in the various rotational crop matrices was moderately extractable (ranging from about 23.6% for the winter wheat hay to 51.1% for lettuce) by aqueous acetone. An additional amount of radioactivity (about 5.0% for the spring wheat grain to 15.0% for the winter wheat grain) was extracted with 2% acidified aqueous acetone. Exhaustive extraction and digestion procedure using acetone: water: HCl (3%), 6 N aqueous HCl and 6 N aqueous NaOH yielded additional 3.1% to 18.7% of TRR (< 0.001 to 0.002 mg/kg) in various fractions from different crops. The unextractable radiocarbon in various solids after solvent extraction of crop samples ranged from 12.7% to 71.2% of TRR (0.001 to 0.004 mg/kg).

Table 24 Extraction efficiency of residues of imazapyr in rotational crops

Sample		Harvest DAT	TRR (mg/kg)	Extractable (%TRR)			Unextracted (PES)	
				Aqueous Acetone ^a	Acetone: H ₂ O:HCl ^b	Total	mg/kg	%TRR
Winter wheat	hay	582	0.005	23.6	7.0	30.6	0.004	71.2
	grain	596	0.007	31.0	15.0	46.0	0.006	80.1
Spring wheat	hay	590	0.018	37.8	10.9	48.7	0.009	51.1
	straw	623	0.015	28.0	5.5	33.5	0.010	67.2
	grain	623	0.016	47.9	5.0	52.9	0.007	46.2
Carrot	mature top	646	0.007	49.8	7.7	57.5	0.003	45.2
Lettuce	mature	623	0.009	51.1	9.9	61.0	0.004	48.1

DAT = days after treatment

^a: extracted with acetone:H₂O (1:1)

^b: extracted with 2% HCl (acetone:H₂O:HCl 49:49:2)

Table 25 Distribution of radioactivity in fractions extracted from post extraction solid (PES) of rotational crops

Sample	Harvest DAT	TRR (mg/kg)	Residue in crop PES		Residue Fraction	Residue in crop	
			mg/kg	%TRR		mg/kg	%TRR
Winter wheat grain	596	0.007	0.006	80.1	6 N aqueous HCl	0.001	12.7
					6 N aqueous NaOH	0.001	18.7
					PES (unextractable)	0.001	19.3
Spring wheat straw	623	0.015	0.010	67.2	Aqueous:Acetone:HCl (3%)	0.002	15.0
					6 N aqueous HCl	0.002	15.1
					6 N aqueous NaOH	0.002	12.1
					PES (unextractable)	0.003	19.2
Spring wheat grain	623	0.016	0.007	46.2	Aqueous:Acetone:HCl (3%)	0.002	9.8
					6 N aqueous HCl	0.002	13.2
					6 N aqueous NaOH	0.001	8.4

Sample	Harvest DAT	TRR (mg/kg)	Residue in crop PES		Residue Fraction	Residue in crop	
			mg/kg	%TRR		mg/kg	%TRR
Lettuce	623	0.009	0.004	48.1	PES (unextractable)	0.002	12.7
					Aqueous:Acetone:HCl (3%)	0.001	7.6
					6 N aqueous HCl	0.001	13.2
					6 N aqueous NaOH	< 0.001	3.1
					PES (unextractable)	0.002	22.4

DAT = days after treatment

Analysis of the aqueous acetone and aqueous acetone: HCl (2%) fractions from various crop parts by HPLC was possible. The results showed that the major fraction comprised of unchanged imazapyr, which ranged from < 0.001 to 0.003 mg/kg in various crops. Chromatographic region of interests corresponded to CL 247,087, CL 252,974, CL 17,226 and CL 119,060 were each at less than 0.001 mg/kg by calculations.

When [pyridine-6-¹⁴C]-imazapyr was applied to bare sandy loam soil at a use rate of 0.885 kg ai/ha (acid equivalents) radioactivity in soil was present throughout the experiment period. A trace amount of imazapyr-related residue in soil was transported into leafy vegetable, root crop and small grain. Total radioactive residues in follow crops were at < 0.01 to 0.02 mg/kg at the various plant back intervals: Winter wheat at 359 days, spring wheat at 520 days, and carrot and lettuce at 330 and 540 days.

Attempts to elucidate the metabolic profile of imazapyr in rotational crops showed terminal residue in the rotational crops included the unchanged imazapyr which ranged from < 0.001 to 0.003 mg/kg. Metabolites CL 247,087, CL 252,974, CL 17,226, and CL 119,060, each at 0.001 mg/kg or less were present. Thus, it appeared that imazapyr was metabolized in the rotational crops by hydrolysis of imidazolinone ring and cyclization of the carboxyl group and imidazolinyl nitrogen.

Environmental fate in water systems

Hydrolysis

Study 1

The [pyridine-6-¹⁴C]-imazapyr was dissolved in water and applied in to the water layer at an application rate of 1.5 mg/kg (Mangels, 1990: 1990/7001955). Samples were incubated at 25 °C under aerobic conditions in the dark. After various time intervals (0, 1, 2, 3 and 4 weeks), the water samples were directly, analysed by LSC and by TLC two-dimensional TLC upon comparison with authentic standards. Since there was less than 2% of the radioactivity presented in the sediment, no extraction was performed and the radioactivity in the sediment was determined by combustion.

Greater than 98% of the applied radioactivity (AR) was recovered. A total of 1.12% AR mineralized to ¹⁴CO₂ during four weeks of aging and no volatile organic compounds were detected. Greater than 95% of the applied imazapyr remained in the water layer. Less than 2% of the applied radioactivity was detected in the sediment. No measurable degradation occurred during the 1 month experiment indicating imazapyr is stable under aerobic aquatic conditions. In conclusion, imazapyr is stable under aerobic aquatic conditions.

Study 2

The [carboxyl-¹⁴C]-imazapyr was dissolved in water to give stock solutions containing 50 mg/L of [¹⁴C] imazapyr (Mangels, 1990: 1990/7001950). Aliquots were placed into flasks and diluted in aqueous buffer solutions of pH 5 (0.01 M citrate), pH 5.2 (Distilled water), pH 7 (0.01 M phosphate) and pH 9 (0.01 M borate). Thereafter, aliquots duplicate samples containing each approximately 50 µg/mL were placed into test tubes and incubated in the dark at a controlled temperature of at 25 °C for 30 days. After various time intervals (0, 2, 12, 19, 26 and 30 days), the samples were directly, analysed by LSC and by TLC two-dimensional TLC upon comparison with authentic standards.

The recovery of radioactivity in all samples was between 92.3% and 107.0% of the total applied radioactivity. There was no detectable degradation of imazapyr in distilled water, pH 5 or pH 7 buffers. In pH 9 buffer, there was a slow degradation to a single product which reached a maximum level of 6.9% of the applied dose 30 days after treatment. The degradate was identified as CL 252,974.

Half-life =	pH 5	pH 7	pH 9	Distilled water
	NDD	NDD	325 days	NDD

NDD = No Detectable Degradation after 30 days

In conclusion, imazapyr is hydrolytically stable in distilled water (pH 5.2) pH 5, 7 and 9.

RESIDUE ANALYSIS

Analytical methods

Descriptions of analytical methods together with validation data for residues of imazapyr in plant and animal matrices were submitted to the Meeting. The methods rely on an initial extraction, usually with acetonitrile/water. After solvent partition and column cleanup, the imazapyr and metabolites residues are prepared for LC analysis. Imazapyr residues can be measured either by UV detector or mass selective detector (MS), typically to an LOQ of 0.01 mg/kg. Determinations for the metabolites were conducted using HPLC with mass spectrometric detector (MS/MS). The LOQ for the metabolites were typically 0.01 mg/kg. Since the methods use standard extraction solvents and standard detection techniques, they have the potential to be incorporated into existing multi-residue methods.

Brief descriptions of all these analytical methods are presented below.

Plant matrices

Imidazolinone-tolerant sunflower and rape (seeds, meal and refined oil) (2008/7019225, 2008/7019227)

Analyte:	Imazapyr	LC-MS/MS	M 3519 modified
	(m/z 262→217 for quantification, 262→149 for confirmation)		
LOQ:	0.05 mg/kg		
Description	Samples are extracted with acidic aqueous methanol. An aliquot of the extract is diluted with methanol then passed through a SCX cartridge, which retains the analyte. The SCX cartridge is washed with methanol to remove co-extractives then the residues are selectively eluted with a water-methanol solution. The eluate is evaporated to dryness and the residues are dissolved in acidic water for analysis. Residue of imazapyr is determined by LC-MS/MS.		

Soya bean (grain, flaked, meal, toasted meal and oil) (2010/1033332)

Analyte:	Imazapyr	LC-MS/MS	SOP-PA.0288
	(m/z 262→217 for quantification, 262→149 for confirmation)		
LOQ:	0.01 mg/kg		

Description 5 g $\pm$ 0.1 of sample are weighed and 50 mL of extraction solution (methanol/water/HCl 1 mol/L, 60/39/1, v/v/v) is added. A mechanical shaker is used for 10 minutes to extract the analytes. The extract is centrifuged for 5 minutes at 3000 rpm and an aliquot of 1 mL is taken into a 5 mL volumetric flask. The volume is filled to the mark with solution 1. The solution is filtered, when necessary, and injected in the liquid chromatographic system, mass/mass spectrometer (LC-MS/MS).

Solution 1: 0.1% formic acid in water/0.1% formic acid in methanol (1/1, v/v)

Soya bean (grain, flaked, meal, toasted meal and oil) (2010/1090461)

Analyte: Imazapyr LC-MS/MS SOP-PA-0288_E
(m/z 262 $\rightarrow$ 217 for quantification, 262 $\rightarrow$ 149 for confirmation)

LOQ: 0.01 mg/kg

Description The residues of imidazolinones and its metabolites are extracted from samples using extraction solution (methanol/water/1 M HCl 60/39/1, v/v/v) in a homogenizer for 5 minutes. The addition of HCl provides additional extraction capability for the analytes with acidic properties. Centrifugation is done whenever it is necessary for 5 minutes at 2000 rpm. For sunflower (seed or oil) shaking is to be done in a mechanical shaker for 10 minutes. A 1 mL aliquot is taken and complete to the mark with solution 1 in a 5 mL volumetric flask. Filter it in a filter unit, when necessary. The residues of imidazolinones and its metabolites are performed by LC-MS/MS and quantified by directive comparison with external standards.

Solution 1: 0.1% formic acid in water/0.1% formic acid in methanol (1/1, v/v)

Sunflower (seed, meal and refined oil) (2002/5004111)

Analyte: Imazapyr LC-MS

LOQ: 0.05 mg/kg

Description Residues of imazapyr are extracted from sunflower seed and meal samples with an acidified methanol/water solution, filtered, and concentrated. The residues are purified on a C₁₈ solid phase extraction (SPE) column eluted with 25% MeOH in 0.05 M aqueous ammonium acetate and brought to final volume with water. Residues in refined oil samples are diluted in hexane and extracted by shaking with acidified acetonitrile/water solution. Following phase separation, the lower aqueous ACN layer is collected and adjusted to final volume with water. The final chromatography analysis of imazapyr residues is performed using LC-MS.

Sunflower (seed, flower) (2002/3000641)

Analyte: Imazapyr LC-UV (254 nm) SOP-PA.0200, Rev.02-RE.01

LOQ: 0.05 mg/kg

Description: Residues of imazapyr are extracted from sunflower seed and flower samples with acidic aqueous methanol. The extract is filtered, and an aliquot is taken and concentrated. After adding water and acetate, the pH is adjusted to 6.2 with 1 N NaOH solution. Following centrifugation, an aliquot of the upper layer is taken and the pH is then adjusted to 2.1 with 1 N HCl solution. The sample is then partitioned four times with dichloromethane (DCM). The DCM layers are combined and concentrated to dryness. The residue is re-dissolved in methanol-water and passed through an SCX cartridge. The SCX cartridge is washed with methanol to remove co-extractives, and then the residue is selectively eluted with KCl in methanol. The residue is then evaporated to dryness and re-dissolved in acidic water (pH 2.5). The samples are partitioned again four times with DCM and concentrated to dryness. The final extract is dissolved in water for HPLC analysis. A liquid chromatograph (HPLC) equipped with a diode array detector (DAD) set at 254 nm is used for detection.

Soya bean (seed) (2010/1149746), Rice (grain) (2010/1141978)

Analyte: Imazapyr LC-MS/MS SOP-PA.0249
(m/z 262→217 for quantification, 262→149 for confirmation)

LOQ: 0.05 mg/kg

Description: The sample is weighed into an extraction container. 100 mL of 1 N methanol/water/HCl (60:39:1 v/v/v) are added and extracted in the homogenizer for 5 minutes or in the extraction bath for 20 minutes. The extract is centrifuged for 20 minutes at 2000 rpm and an aliquot of 20 mL is transferred to a concentration flask. The volume is reduced to approximately 7 mL. The extract is transferred to a volumetric flask and filled up to the mark with Milli-Q water. The pH is adjusted to 2.1 with HCl 1 N solution. An aliquot of 2 mL is transferred to a centrifuge tube. 10 mL of dichloromethane are added. Partitioning is performed for 1 minute, followed by centrifugation for 5 minutes to separate the phases. An aliquot of 4 mL of the organic phase (lower phase) is evaporated to dryness. The residue is dissolved in 2 mL of mobile phase A / mobile phase B (1/1, v/v) and injected into the chromatographic system, MS/MS detector.
Mobile phase A: 0.1% formic acid in water, Mobile phase B: 0.1% formic acid in methanol

Maize (grain, forage and fodder) (IZ-731-001, IZ-244-006, IZ-244-005)

Analyte: Imazapyr GC-MS M 2468

LOQ: 0.05 mg/kg

Description: The sample is weighed into an extraction flask and 200 mL of acidic acetone/water (1:3 v/v) is added. The extract solution is allowed to soak for 15 minutes, and then blended at medium speed for approximately 5 minutes using an Omni mixer. After mixing, 10 g Celite 545AW are added to the extract and the solution is swirled. The extract is then vacuum-filtered using a glass fibre filter on a Buchner funnel. A 2 mL aliquot of the extract is transferred into a flask and evaporated to near dryness on a rotary evaporator. The extract is then cleaned-up by solid-phase extraction on a Varian Bond Elut C18 cartridge using Milli-Q water, hexane and methylene chloride as wash solvents. After evaporation to dryness, the residue is re-dissolved in 1 mL methanol and sonicated, then transferred to an auto-injector vial for GC-MS analysis. Determination is done at m/z 289 in the negative ion monitoring mode.

Maize (grain) (IZ-731-021, 1997/7004635 and 1999/7004025)

Analyte: Imazapyr LC-UV (254 nm) M-LAADL R0001

LOQ: 0.05 mg/kg

Description: Residues are extracted with acidic aqueous methanol using a Polytron ultrasonic extractor. Residues are partitioned with methylene chloride from concentrated aqueous acid solution. The methylene chloride is evaporated and the remaining material is reconstituted in 50% methanol in pH 2.5 for SPE SCX—Benzenesulfonic acid (Strong Cation Exchange) clean-up. The residue is eluted from the SCX with a saturated KCl in methanol, partitioned with methylene chloride, evaporated to dryness and diluted in 2 mL of Milli-Q water for HPLC analysis.

Sugarcane (juice and bagasse) (IZ-790-015 and IZ-790-017)

Analyte: Imazapyr LC-UV (254 nm) M-LAADL R0002

LOQ: 0.05 mg/kg

Description: Residues are extracted from sugar cane or sugar cane juice with acetone/methanol/water (1/1/1, v/v/v). The extracts are subjected to suitable clean-up involving solid phase extraction (Ag 1-X8 and SCX cartridge). The determination of imazapyr residues in the final extracts is performed by HPLC-UV (juice) or HPLC-DAD (cane) at 254 nm. Residue concentrations are calculated by direct comparison to external standards.

Rape (seed) (1998/1008995)

Analyte: Imazapyr LC-UV (254 nm) L741/1

LOQ: 0.05 mg/kg

Description: Residues are extracted from samples with methanol/HCl/water (60:1:39, v/v/v). The extract is partitioned with dichloromethane after adjusting the pH to 2 with HCl. Subsequently, the extract is evaporated to dryness and the residue dissolved in methanol/water (1:1, v/v). Following SCX cartridge clean-up, separation and quantitation of imazapyr is accomplished by reverse phase high performance liquid chromatography (HPLC).

Maize (grain, forage, fodder) (IZ-244-009)

Analyte: Imazapyr GC-MS

LOQ: 0.05 mg/kg

Description: After soaking for 15 minutes imazapyr is extracted from the sample with 200 mL of acetone/water/HCl (25:74:1 v/v/v) at medium speed in an Omni-Mixer for 5 minutes. The extract is mixed with 10 g of Celite 545 AW and filtered. A 2 mL aliquot of the filtrate is taken, the acetone is evaporated and the remaining extract is transferred to a C18-cartridge. Imazapyr is eluted from the cartridge with CH₂Cl₂. Subsequently, CH₂Cl₂ is evaporated and the residue is dissolved in 1 mL CH₃OH and sonicated for 30 seconds. Of the final extract 0.5 mL are mixed with 50 µL of 0.1 M trimethyl anilinium hydroxide. The determination is performed by GC-MS using ion m/z 289.

Maize (grain, forage, fodder) (IZ-244-008)

Analyte: Imazapyr Capillary Electrophoresis M 2657

LOQ: 0.05 mg/kg

Description: The sample is weighed into an extraction flask and 200 mL of acidic acetone/water (1:4 v/v) are added. The extract solution is allowed to soak for 15 minutes, and then blended using an Omni mixer. After mixing, 10 g Celite 545AW are added to the extract and the solution is swirled. The extract is then vacuum-filtered. An aliquot of the extract is transferred into a separatory funnel. Methylene chloride is added and shaken for 15 seconds. The lower, methylene chloride, layer is drained into a beaker. The aqueous, upper, fraction is partitioned with another 25 mL of methylene chloride, which is added to the previously drained fraction. Solid-phase extraction is done using an Isolute SCX cartridge, the extract allowed to drain through the cartridge by gravity. The cartridge is then washed with acetone, followed by methanol and saturated KCl/methanol. After evaporation to dryness using a rotary evaporator, the residue is re-dissolved in 1% formic acid, then subjected to further clean-up using Spe-ed RP 102 cartridge and washing with methanol and water. After evaporation to dryness, the sample is re-dissolved in 1 mM Tris/1 mM NaH₂PO₄ solution, sonicated for 15 seconds, then transferred to a sample vial for capillary electrophoresis (CE) analysis. The CE system is equipped with a high sensitivity optical flow cell and a UV detector set at 240 nm.

Maize (1999/7004026)

Analyte: Imazapyr LC-UV (254 nm) M 2020

LOQ: 0.05 mg/kg

Description: The sample is weighed into an extraction container. Then, the extraction solution of methanol/water/1 N HCl (60:39:1, v/v/v) is added and blended using an Omni mixer. The extract is filtered, and then Celite 545AW is added. The extraction jar is washed and filtered with extraction solvent. The filtrate is poured into a mixing cylinder, diluted to 250 mL with methanol, mixed and an aliquot is taken. The methanol is evaporated to approx. 50 mL using a flash evaporator. The sample solution is extracted and filtered again, using acetone and Celite, then evaporated to a volume of 10 mL. 1 N HCl is added, the solution filtered and the filter rinsed using methanol and 0.05 N HCl. The solution is partitioned twice, using methylene chloride, before evaporating to dryness. Further partitioning is done using methanol, acetonitrile and hexane. The hexane layer is discarded, the acetonitrile solution evaporated to dryness and the residue dissolved in methanol and 0.05 N HCl. The extract is cleaned-up by solid-phase extraction on a Bond Elut C18 cartridge with deionized water, 0.05 N and 1 N HCl, hexane and methanol as wash solvents. The eluate is discarded, and the system eluted with saturated KCl in methanol. After evaporation to dryness, the residue is re-dissolved in methanol and 0.05 N HCl, and poured into a separatory funnel with methylene chloride. Three more portions of methylene chloride are added for partitioning, then the solution is evaporated to dryness, and partitioning is repeated with methylating reagent and methanol. After re-evaporation to dryness, the residue is dissolved in methanol in preparation for analysis by LC with a UV detector set at 254 nm.

Validation data for methods on plant matrices are summarized in Table 26.

Table 26 Summary of Recovery Data for imazapyr fortified into plant matrices

CR: Concurrent Recovery, MV: Method Validation, ILV: Independent Laboratory Validation

Animal matrices

Milk (IZ-245-003, IZ-245-009 and IZ-245-010)

Analyte: Imazapyr Capillary Electrophoresis M 3075

LOQ: 0.01 mg/kg

Description Residues are extracted from milk with 1 M hydrochloric acid. The imazapyr residues are subjected to suitable clean-up involving solvent partitioning (methylene chloride and acetone) and solid phase extraction (SCX and C18 cartridge). Measurement of imazapyr is accomplished by capillary electrophoresis (CE) with UV detection (240 nm) and results are calculated using external standards.

Muscle, Liver, Kidney and Fat (IZ-245-004)

Analyte: Imazapyr Capillary Electrophoresis M 3184

LOQ: 0.05 mg/kg

Description Residues are extracted from bovine tissues with an acidic water/acetone solution (3:1, v/v). The mixture is centrifuged and then filtered through celite. An aliquot of the filtrate containing the imazapyr residues is subjected to partitioning with methylene chloride. The extract is purified by solid phase extraction. Quantitation of imazapyr is accomplished by capillary electrophoresis (CE) using UV detection (265 nm). The results are calculated by direct comparison to external standards.

Milk fat (IZ-245-007)

Analyte: Imazapyr Capillary Electrophoresis M 3223

LOQ: 0.01 mg/kg

Description: Residues are extracted from milk fat (5 g) with water (19 mL), acetonitrile (50 mL) and hexane (100 mL). The mixture is filtered and the filtrate containing the imazapyr residues is subjected to solvent partitioning (dichloromethane) and solid phase extraction (SCX and C18 cartridge). Quantitation of imazapyr is accomplished by capillary electrophoresis (CE) using UV detection (265 nm), results are calculated by direct comparison to external standards.

Validation data for methods on animal matrices are summarized in Table 27.

Stability of pesticide residues in stored analytical samples

The Meeting received data on the stability of imazapyr residues in maize (grain, forage and fodder) and soya bean (seeds and processed fractions) samples for plant and animal commodities stored frozen.

The freezer stability study of imazapyr was conducted on maize grain, forage and fodder (Fletcher, 1997: IZ-326-004). Samples of control maize grain, forage and fodder were fortified with imazapyr at 1.0 mg/kg and stored frozen at -5 to -26 °C. Samples were analysed after storage using GC/MS Method M 2468. The LOQ was 0.05 mg/kg.

18 months	96	77, 92	85
27 months	106	78, 81	80

The storage stability of imazapyr was investigated under deep frozen conditions over a time period of about 10 months for soya bean (seeds) and over a time period of about 3 months for soya bean processed fractions (oil, laminated soya bean, meal and toasted meal), all at -20°C or lower (Leite, 2011: 2011/1207286). Soya bean samples were spiked with the test items at a concentration level of 0.10 mg/kg. The storage conditions correspond to the usual storage conditions for field samples. The samples were analysed using Method SOP-PA.0288.

Table 29 Recovery of imazapyr from stored fortified samples of soya bean

The stability of imazapyr was investigated in bovine milk during freezer storage (Khunachak, 1999: IZ-326-010). The storage conditions chosen were equivalent to the storage conditions used for residue samples awaiting analysis. Milk samples were spiked with the test items at a concentration level of 0.1 mg/kg. The samples were analysed using Method M 3075.

Table 30 Recovery of imazapyr from stored fortified samples of bovine milk

USE PATTERN

Imazapyr is registered for the control of broad leaf and grassy weeds on pulses, cereals and oilseed etc. The Meeting received labels from Argentina, Australia, Brazil and the USA. The information available to the Meeting on registered uses of imazapyr is summarized in the table below.

Table 32 Registered uses of imazapyr for crops

Crop	Country	Formulation		Application				PHI, days or Application timing
		Type	Conc. of imazapyr	Method	Rate kg ai/ha	Volume L/ha	No. max	
Grasses for sugar or syrup production								
Sugarcane	Argentina	SL	250 g/L	Spray onto weeds	0.5	150–200	2	30–45 days before planting
Sugar cane	Brazil	SL	266.3 g/L	Spray onto weeds	0.125–0.5	100–400	1	not required when used as directed

Table 33 Registered uses of imazapyr for imidazolinone tolerant crops

^a Do not graze or cut for stock food for 4 weeks after application, not required to harvest for grains when used directed.

^b Do not graze or cut for stock food for 5 weeks, not required for grains when used as directed

^c Do not graze or cut for stock food for 6 weeks, not required for grains when used as directed

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received information on imazapyr supervised field trials for the following crops.

Group	Commodity	Table
Pulses	Lentil (dry)	Table 34
	Soya bean (dry)	Table 35
Cereal grains	Maize	Table 36
	Rice	Table 37
	Wheat	Table 38
Grasses for sugar or syrup production	Sugar cane	Table 39
Oilseed	Rape seed	Table 40, 41
	Sunflower seed	Table 42
Straw, fodder and forage of cereals	Maize fodder and forage	Table 43
	Wheat straw and forage	Table 44
Miscellaneous fodder and forage crops	Rape straw and forage	Table 45

Imazapyr formulation was applied for foliar treatment. Each of the field trial sites generally consisted of an untreated control plot and a treated plot. Application rates and spray concentrations have generally been rounded to two significant figures.

Residue values from the trials, which have been used for the estimation of maximum residue levels, STMRs and HRs, are underlined.

Laboratory reports included method validation with procedural recoveries from spiking at residue levels similar to those occurring in samples from the supervised trials. Date of analyses and duration of residue sample storage were also provided. Although trials included control plots, no control data are recorded in the tables except when residues were found in samples from control plots. Residue data are not corrected for percent recovery.

Conditions of the supervised residue trials were generally well reported in detailed field reports. Most field reports provided data on the sprayers used, plot size, field sample size and sampling date.

Pulses

Lentil (dry)

The Meeting received five trials on imidazolinone-tolerant lentil which were conducted in Canada (Norris, 2009: 2008/7019226). In each trial, a single broadcast foliar application of a SL formulation (15 g/L imazapyr) was made to lentil targeting 0.009 kg ai/ha of imazapyr. The application was made 58–60 days prior to the normal harvest of mature (dry) seed.

The lentil seed samples were analysed for residues of imazapyr using Method M3519 (modified). The maximum storage interval for field-treated samples was 166 days (5.5 months).

Soya bean (dry)

Eight residue trials in soya beans were conducted in different representative growing areas in Brazil (Resende, 2008: 2008/1097472). The 480 g/L SL formulation was applied once at a rate equivalent to 0.072 kg ai/ha in a spray volume of 200 L/ha. Method SOP-PA.0249 rev.03 was used to analyse soya bean seed samples for the residues of imazapyr. Imazapyr was quantified by LC-MS/MS with a LOQ of 0.05 mg/kg.

Eight residue trials in soya beans were conducted in different representative growing areas in Brazil (Resende, 2008: 2008/1097470). The WG formulation containing 525 g/kg imazapyr was applied once at a rate equivalent to 0.0525 kg ai/ha in a spray volume of 200 L/ha. Method SOP-

PA.0249 rev.04 was used to analyse soya bean seed samples for the residues of imazapyr. Imazapyr was quantified by LC-MS/MS with a LOQ of 0.05 mg/kg.

One trial (with five plots) in soya bean was conducted in Brazil (Resende, 2010: 2010/1079212, 2010/1010261). The WG formulation containing 525 g/kg imazapyr was applied once at a rate equivalent to 0.0525 kg ai/ha in a spray volume of 200 L/ha. Method SOP-PA.0288 was used for analysis of imazapyr residues in soya bean quantifying the analyte by LC-MS/MS with a LOQ of 0.01 mg/kg.

Two trials in soya beans were conducted in Brazil (Jones, 2011: 2010/1127505). The WG formulation containing 525 g/kg imazapyr was applied once at a rate equivalent to 0.0525 kg ai/ha in a spray volume of 200 L/ha. Each trial consisted of four plots. Method SOP-PA.0288 was used for analysis of imazapyr residues in soya beans quantifying the analyte by LC-MS/MS with a LOQ of 0.01 mg/kg.

Five trials in soya beans were conducted in Brazil (Jones, 2012: 2012/3000423). The WG formulation containing 525 g/kg imazapyr was applied once at a rate equivalent to 0.0525 kg ai/ha in a spray volume of 200 L/ha. Method SOP-PA.0288 was used for analysis of imazapyr residues in soya beans quantifying the analyte by LC-MS/MS with a LOQ of 0.01 mg/kg.

*Cereal grains**Maize*

Residue data have been collected from 19 field trials located in the USA. At each trial, one broadcast application was made to the treated plot. The formulations used in the trials were 240 g/kg ASU and 240 g/kg WP formulation. Method M 2468 was used for analysis of imazapyr residues in maize grains quantifying the analyte by gas chromatography/negative ion chemical ionization mass spectrometry (GC/ECNICI) with a limit of quantitation of 0.05 mg/kg.

Six trials in maize were conducted in Australia to determine the residue level of imazapyr in/on maize grains. The SL formulations containing 250 g/L imazapyr was applied once as broadcast foliar application. The applications were made in half of the trials post sowing—pre-emergence and in the second half of the trials at early post-emergence. Imazapyr was analysed in the maize grains using method L 741/1. Separation and quantitation were accomplished with reverse phase high performance liquid chromatography using a UV-VIS detector with a limit of quantitation of 0.05 mg/kg.

Seven trials in maize were conducted in the Argentina to determine the residue level of imazapyr on maize. Method LAADL R0001 was used for analysis of imazapyr residues in maize grains quantifying the analyte by HPLC/UV with a limit of quantitation of 0.05 mg/kg.

Three trials in maize were conducted in Brazil to determine the residue level of imazapyr in/on maize. The WG formulation was applied to the plots as broadcast foliar application in spray volumes of 200 L/ha. Method SOP-PA.0200 rev.02-re.01, based on methods MR0001.01, M-2020 and M-1928, was used for analysis of imazapyr residues in maize grains. Imazapyr was determined by LC-MS/MS (mass transition 262/217). The limit of quantitation for this method in maize grains was 0.05 mg/kg.

Rice

Four trials with 11 plots in rice were conducted in Brazil (Dantas, 2003: 2003/3001441). The WG formulation containing 525 g/kg imazapyr was applied twice to each trial with rate equivalents of 0.12 kg ai/ha or 0.24 kg ai/ha for each application. Method SOP-PA.0231 was used for analysis of

residues in rice. Imazapyr was measured by liquid chromatography with a UV detector. The limit of quantitation for this method in rice grain samples was 0.05 mg/kg.

Wheat

The trials were conducted at six locations in Australia (Mooney, 1999: 1999/1013037). The SL formulation containing 250 g/L imazapyr or the WG formulation containing 750 g/kg imazapyr were applied once as broadcast foliar or band application. Samples were collected 83–104 days after application and stored frozen at or below –18°C until analysis. Imazapyr was analysed in the wheat grains using method L 741/1. In principle the active substance is extracted from the matrix using several extraction and separation steps involving HCl:water (1:39) and DCM (dichloromethane). The extract is then cleaned-up by elution through a SCX cartridge and further extractions with DCM. Separation and quantitation are accomplished with reverse phase high performance liquid chromatography using a UV-VIS detector and external standard calibration procedures. The limit of quantitation for this method in wheat grain samples was 0.05 mg/kg.

Grasses for sugar or syrup production

Sugar cane

The trials were conducted at two locations in Argentina and Brazil to determine the residue level of imazapyr in/on sugar cane. The SL formulation containing 250 or 500 g/L imazapyr, were applied once at a rate equivalent to 0.18, 0.35 and 0.50 kg ai/ha in a spray volume of 168 and 400 L/ha. Method LAADL R0002 was used for analysis of imazapyr residues in sugar cane. Imazapyr was extracted from the sugar cane with acetone:methanol:water (1:1:1) and then subjugated the extract to suitable cleanup involving solid phase extraction techniques. Measurement of imazapyr was accomplished by high performance liquid chromatography (HPLC). Results were calculated by direct comparison of the sample peak heights to those of external standards. The limit of quantitation of the method is 0.05 mg/kg for sugar cane.

Oilseed

Rape seed

A total of 12 trials were conducted on rape in Canada (Norris, 2009: 2008/7019227). At each test location, a single broadcast foliar application of a SL formulation containing 15 g ai/L was made to rape seed targeting 0.009 kg ai/ha. The applications were made in 98–102 L/ha of water using ground equipment, and an adjuvant (0.5% v/v) was added to the spray mixture for all applications. The rape seed RAC (seed) samples were analysed for residues of imazapyr using Method M 3519, modified. Imazapyr was quantified by liquid chromatography, mass/mass detector (LC-MS/MS) with a limit of quantitation (LOQ) of 0.05 mg/kg.

In the growing seasons 1997/1998, trials were conducted at three locations in Australia to determine the residue level of imazapyr in/on rape seed. The WG formulation containing 175 g/kg imazapyr was applied once as broadcast foliar application. The application was generally made post-emergence. Imazapyr was analysed in the rape matrices using method L 741/1. Quantitation was accomplished with reverse phase high performance liquid chromatography using a UV-VIS detector and external standard calibration procedures. The LOQ of the method is 0.05 mg/kg for rape matrices.

Sunflower seed

During the two growing seasons 2007/2008 and 2008/2009, trials were conducted for imidazolinone-resistant sunflower at three locations in Argentina to determine the residue level of imazapyr. The WG formulation containing 800 g/kg imazapyr were applied once at rates of 0.06 and 0.12 kg ai/ha. Method SOP-PA.0288 was used to analyse sunflower seed samples for the residues of imazapyr by liquid chromatography using a mass/mass detector (LC-MS/MS) with a limit of quantitation (LOQ) of 0.01 mg/kg.

During the growing season 2010/2011, four trials were conducted in sunflower in Argentina to determine the residue level of imazapyr. The SL formulation containing 15 g/L imazapyr was applied once at a rate of 0.030 kg ai/ha while on the other 4 plots 0.060 kg ai/ha were applied. Method SOP-PA.0288 was used to analyse sunflower seed samples for the residues of imazapyr by liquid chromatography and mass/mass detector (LC-MS/MS) with a limit of quantitation (LOQ) of 0.01 mg/kg.

Straw, fodder and forage of cereals

Maize fodder and forage

Residue data have been collected from 19 field trials located in the USA. Method M 2468 was used for analysis of imazapyr residues in maize samples quantifying the analyte by gas chromatography/negative ion chemical ionization mass spectrometry (GC/ECNICI) with a limit of quantitation of 0.05 mg/kg.

Six trials in maize were conducted in Australia to determine the residue level of imazapyr in/on maize. The SL formulation was applied once as broadcast foliar application. The applications were made in half of the trials post sowing—pre-emergence and in the second half of the trials at early post-emergence. Imazapyr was analysed in the maize matrices using method L 741/1. Separation and quantitation were accomplished with reverse phase high performance liquid chromatography using a UV-VIS detector with a limit of quantitation of 0.05 mg/kg.

Seven trials in maize were conducted in the Argentina. Method LAADL R0001 was used for analysis of imazapyr residues in maize quantifying the analyte by HPLC/UV with a limit of quantitation of 0.05 mg/kg.

Three trials in maize were conducted in Brazil. The WG formulation was applied to the plots as broadcast foliar application in spray volumes of 200 L/ha. Method SOP-PA.0200 rev.02-re.01, based on methods MR0001.01, M-2020 and M-1928, was used for analysis of imazapyr residues in maize samples. Imazapyr was determined by LC-MS/MS (mass transition 262/217). The limit of quantitation for this method in maize samples was 0.05 mg/kg.

ASU: Aqueous Solution with urea

Wheat straw and forage

The trials were conducted at six locations in Australia. The SL formulation or the WG formulation were applied once as broadcast foliar or band application. Imazapyr was analysed in the wheat matrices using method L 741/1. Quantitation was accomplished with reverse phase high performance liquid chromatography using a UV-VIS detector and external standard calibration procedures. The limit of quantitation for this method in wheat samples was 0.05 mg/kg.

FATE OF RESIDUES IN STORAGE AND PROCESSING

In Processing

The Meeting received information on high temperature hydrolysis of imazapyr and the fate of imazapyr residues during the processing of soya bean seeds, maize grains, rape seeds and sunflower seeds.

Soya bean, maize, rape and sunflower of the crops that the Meeting received information on supervised field trials may be processed prior to consumption. Processing factors have been calculated for imazapyr residues in soya bean seeds, maize grains, rape seeds and sunflower seeds.

High temperature hydrolysis

The degradation of [¹⁴C] imazapyr was studied under hydrolytic conditions at high temperatures in sterile aqueous buffers at pH 4, 5 and 6 for periods of up to 60 minutes so as to simulate common processing practices (pasteurization, baking/brewing/boiling/, and sterilization) (Osterman, 2012: 2012/7000341). All test samples were prepared in sterile amber bottles to eliminate possible photolysis and all sterile buffers were bubbled with nitrogen to avoid the effects of oxygen on the test systems. The concentration of imazapyr was approximately 10 mg/L. The hydrolysis tests were conducted with [¹⁴C] imazapyr in sterile 0.1 M aqueous solutions buffered at pH 4, 5 and 6. The samples were prepared in duplicates for each test system. Samples were analysed immediately at time zero (these samples were not heated). Two additional samples at pH 4 ± 0.1 were placed in an oven and maintained at 90 °C ± 5 °C for 20 minutes, another two samples at pH 5 ± 0.1 were placed in an

oven and maintained at $100\text{ }^{\circ}\text{C} \pm 5\text{ }^{\circ}\text{C}$ for 60 minutes, and two more samples at $\text{pH } 6 \pm 0.1$ were placed in an autoclave and maintained at sterilizing conditions ($121\text{ }^{\circ}\text{C}$) for 20 minutes.

Radiocarbon recoveries ranged from 99.7 to 101.5% for all samples. The test solutions were analysed by reverse phase HPLC. The experiments showed that imazapyr was stable under hydrolytic conditions at high temperatures. No degradates were detected at any of the investigated pH and temperature ranges.

Table 46 Hydrolysis recovery under the conditions for processing simulation

Temperature	Time	pH	Representative process	Recovery (%) [10 mg/L]	
				% remaining	Mean
$90\text{ }^{\circ}\text{C} \pm 5\text{ }^{\circ}\text{C}$	20 minutes	4 ± 0.1	Pasteurization	100.2, 99.7	100
$100\text{ }^{\circ}\text{C} \pm 5\text{ }^{\circ}\text{C}$	60 minutes	5 ± 0.1	Baking/brewing/boiling	101.5, 101.2	101
$121\text{ }^{\circ}\text{C}$ (actual)	20 minutes	6 ± 0.1	Sterilization	100.1, 100.5	100

Soya bean seeds

Processing studies for soya bean were conducted in Brazil to determine the potential for concentration of residues of imazapyr in the processed fractions of soya bean. The SC formulation containing 480 g/L imazapyr was applied once at exaggerated rates of 0.22 kg ai/ha ($3\times$) or 0.14 kg ai/ha ($2\times$), respectively. The WG formulation containing 525 g/kg imazapyr was applied once at exaggerated rates of 0.16 kg ai/ha or 0.11 kg ai/ha, respectively. Samples of soya bean seeds (RAC) were processed according to simulated commercial procedures into flaked soya bean, oil, meal, toasted meal, defatted meal, toasted defatted meal, laminated soya bean fractions and hulls. For one trial, The WG formulation containing 525 g/kg imazapyr was applied once at a rate equivalent to 0.053 kg ai/ha in a spray volume of 200 L/ha. Soya bean seeds were used for processing and aspirated grain fractions (AGF) were produced. Method SOP-PA.0288 was used for analysis of imazapyr residues in soya bean quantifying the analyte by LC-MS/MS with a LOQ of 0.01 mg/kg.

The soya bean grains were initially dried in a ventilated oven at $60\text{ }^{\circ}\text{C}$, for approximately 5 hours and after drying they were cleaned. The soya bean grains were rolled in an “expeller” press type. The layers of soya bean presented an average thickness of 2 mm (flaked/laminated). Part of rolled material was submitted to the extraction of the oil in “batch” type equipment, using indirect vapor for heating the solvent n-hexane between $45\text{--}50\text{ }^{\circ}\text{C}$. The extractors were heated with indirect vapour during 20 min to evaporate the residual solvent from the meal. The material was heated with direct vapour for 5 min (defatted meal). The material was submitted under pressure of 0.4 kg/cm^2 during 2 min to finish the toasting process (toasted meal). The first part (oil mixture and solvent), produced after the extraction was collected in the tank and the solvent was removed under indirect heating at $60\text{ }^{\circ}\text{C}$ (oil). The humidity of the meals was reduced by a ventilated oven at $60\text{ }^{\circ}\text{C}$ for 12 hours (meal).

Maize grains

A processing study was conducted on maize in the USA during the 1993 growing season to determine the potential for concentration of residues of imazapyr in maize processed fractions. At the test location, a single broadcast foliar application of the ASU formulation containing 240 g/L imazapyr was made to maize targeting 0.27 kg ai/ha (10×) of imazapyr. Grains for processing were harvested at 136 days after application and were later processed according to simulated commercial procedures into maize processed commodities meal and oil. The maize grain RAC and processed commodity samples (meal and oil) were analysed for residues of imazapyr using Method M 2468 with a LOQ of 0.05 mg/kg. Measurement of imazapyr was accomplished by gas chromatography/negative ion chemical ionization mass spectrometry.

Rape seeds

A processing study for rape seed was conducted to determine the potential for concentration of residues of imazapyr in the processed fractions of rape seed. The study was conducted in Canada during the 2008 growing season to determine the potential for concentration of residues of imazapyr in rape seed processed fractions. At the test location, a single broadcast foliar application of a SL formulation containing 15 g/L imazapyr was made to rape targeting 0.045 kg ai/ha. Rape seed bulk samples harvested from the plot treated at an exaggerated rate (5×) were harvested 70 days after treatment and were later processed according to simulated commercial procedures into rape seed meal and refined oil. Method M 3519 was used to analyse rape seed samples for the residues of imazapyr. Imazapyr was quantified by liquid chromatography and mass/mass detector (LC-MS/MS) with a LOQ of 0.05 mg/kg.

Sunflower seed

A processing study for sunflower seed was conducted in the USA in the year 2000 to determine the potential for concentration of residues of imazapyr in the processed fractions of sunflower seeds. The applications were made as broadcast, post-emergence sprays targeting when the plants were 18–30 cm tall. Replicate sunflower seed RAC samples were harvested at normal crop maturity, 88 days after treatment. The whole sunflower seed samples were processed into meal and refined oil according to simulated commercial procedures.

The method used for analysis determines residues of imazapyr using HPLC with MS detection. Residues of imazapyr were extracted from sunflower seed and meal samples with an acidified methanol: water solution, filtered, and concentrated. The residues are then purified on a C18 solid phase extraction (SPE) column and eluted with 25% MeOH in 0.05 M aqueous ammonium acetate. Residues in refined oil samples are diluted in hexane and extracted by shaking with acidified acetonitrile: water solution. Following phase separation, the lower aqueous ACN layer is collected and imazapyr residues are detected by LC-MS with a LOQ of 0.05 mg/kg.

RESIDUES IN ANIMAL COMMODITIES*Farm animal feeding studies*

The Meeting received lactating dairy cow feeding studies.

Lactating dairy cow

The study was designed to determine the residues of imazapyr found in milk and tissues following oral administration to dairy cow (Khunachak, 1999: IZ-705-001). Five groups of cows, each group containing three animals, were orally dosed with imazapyr for 28–29 days at dosages of approximately 1.2, 3.6, 12 and 36 g imazapyr per animal per day. This would be equivalent to total dietary residues of approximately 58, 157, 607 and 1680 ppm feed. Dose levels were based on a nominal feed intake of 20 kg (dry matter equivalent) per day for a cow. Gelatin capsules containing imazapyr were used for administration.

Milk samples (composites of the pm and am milking of the following day) were collected from all cows. Milk fat samples were prepared from composite milk samples of all cows in each group at 8, 15 and 22 days of treatment. Within 24 hours of the last dosing, all cows were sacrificed and the edible tissues (muscle, fat, liver and kidney) from each animal were collected. All samples were analysed for imazapyr using Methods M 3075 (milk), M 3184 (tissues, fat) and M 3223 (milk fat). Quantitation in milk, muscle, fat, liver, and kidney was performed using capillary electrophoresis with UV detection, and quantitation in milk fat was performed using LC-MS with single ion monitoring (SIM). The LOQ of the individual methods for imazapyr detection in milk and milk fat was 0.01 mg/kg and for tissues and fat 0.05 mg/kg.

Imazapyr residues in milk samples from cows in group A (control) were less than LOQ. The pre-treatment milk samples from all cows from the treated groups showed imazapyr residues of < 0.01 mg/L. In the three highest dose groups (157, 607, 1.680 ppm feed), residues of imazapyr in milk reached a plateau after about 2–3 days

na: not analysed

Imazapyr residues in milk fat samples from cows in group A (control) were < 0.01 mg/kg. Averages imazapyr residues in milk fat samples from cows in treated groups B, C, D and E were < 0.01, 0.013, 0.037 and 0.10 mg/kg, respectively.

Table 52 Residues of imazapyr in milk fat

Group	Residue, mg/kg		
	Day 8	Day 15	Day 22
A (control)	< 0.01	< 0.01	< 0.01
B (58 ppm)	< 0.01	< 0.01	< 0.01
C (157 ppm)	0.012	0.011	0.015
D (607 ppm)	0.039	0.041	0.032
E (1680 ppm)	0.10	0.093	0.11

Imazapyr residues in muscle, fat, kidney and liver samples from cows in group A (control) were all < 0.05 mg/kg. In kidney, imazapyr was detected as predominant residue in all treated groups.

Table 53 Residues of imazapyr in tissues

Group	Residues, mg/kg			
	Muscle	Fat	Kidney	Liver
A (control)	< 0.05 (3)	< 0.05 (3)	< 0.05 (3)	< 0.05 (3)
B (58 ppm)	< 0.05 (3)	< 0.05 (3)	0.11, 0.36, 0.28 mean 0.25	< 0.05 (3)
C (157 ppm)	< 0.05 (3)	< 0.05 (3)	0.32, 0.90, 0.34 mean 0.52	< 0.05, 0.070, < 0.05 mean 0.057
D (607 ppm)	0.15, 0.083, 0.064 mean 0.097	0.15, < 0.05, < 0.05 mean 0.083	7.0, 3.9, 2.1 mean 4.4	0.32, 0.39, 0.20 mean 0.30
E (1680 ppm)	0.19, 0.25, 0.27 mean 0.23	0.086, 0.11, 0.080 mean 0.092	7.3, 7.2, 8.0 mean 7.5	0.55, 0.70, 1.2 mean 0.81

APPRAISAL

Residue and analytical aspects of imazapyr were considered for the first time by the present Meeting. The residue evaluation was scheduled for the 2013 JMPR by the Forty-fourth Session of the CCPR.

Imazapyr is a broad-spectrum herbicide in the imidazolinone family. Its primary use is as a post-emergence herbicide which is particularly effective on hard-to-control perennial grasses. It is non-selective, absorbed by foliage and rapidly translocated. The mode of action of imidazolinone herbicides is the inhibition of the enzyme acetohydroxy acid synthase (AHAS) which is a critical enzyme for the biosynthesis of branched chain amino acids necessary for cell growth and protein synthesis. The Meeting received information on identity, animal and plant metabolism, environmental fates in soil, rotational crops, analytical methods, storage stability, use patterns, supervised trials, farm animal feeding studies and fates of residues in processing.

2-[(*RS*)-4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl] nicotinic acid

Imazapyr is a 1:1 mixture of the enantiomers.

In this appraisal, the following abbreviated names were used for metabolites.

CL 247, 087	CL 240,000	CL 60,032	PDC
5 <i>H</i> -imidazo [1',2':1,2] pyrrolo [3,4- <i>b</i>] pyridine - 2(3 <i>H</i>),5-dione, 1.9 <i>b</i> α(β)-dihydro-3α- isopropyl-3-ethyl-	2-(4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl)-3-carboxymethyl pyridine	2-carbamoyl-nicotinic acid	Pyridine 2,3-dicarboxylic acid

Animal metabolism

The Meeting received animal metabolism studies with imazapyr in rats, lactating goats and laying hens. The metabolism and distribution of imazapyr in animals were investigated using the [^{14}C -carboxyl], [^{14}C -6-pyridine] and [^{14}C -5-imidazole]-labelled imazapyr.

Metabolism in rats was summarized and evaluated by the WHO panel of the JMPR in 2013.

Lactating goats were dosed with [pyridine-6- ^{14}C]-imazapyr as a single daily oral dosage equivalent to a dietary level of 17.7 or 42.5 ppm for 7 consecutive days. Radioactivity was mainly excreted in the urine (65.3% and 60.4%) and faeces (16.1% and 19.0%) of the dose in the 17.7 ppm and 42.5 ppm dosed goats, respectively).

The TRR levels were <0.01–0.01 mg equiv/kg and 0.01–0.02 mg equiv/kg in the milk samples of the 17.7 and 42.5 ppm dose goats, respectively. TRR levels for leg and loin muscles, liver, and fat were all less than the LOQ (0.05 mg equiv/kg) and these tissues were not analysed further. Detectable residues were found in the kidneys at 0.08 mg equiv/kg (17.7 ppm dose) and 0.11 mg equiv/kg (42.5 ppm dose).

Kidney residues were quantitatively extractable, with the majority (95.5%) isolated in a methanol/water fraction. The extracted ^{14}C residue in the milk and kidney was identified as unchanged imazapyr.

Lactating goats received [imidazole-5- ^{14}C]-imazapyr at a dose equivalent to 47 ppm in the diet once daily for 7 consecutive days. After seven days, 58.7% and 34.4% of the administered radioactive dose were excreted in the urine and faeces, respectively. The TRR levels for the dosed goat were 0.014–0.015 mg equiv/kg for milk and 0.074 mg equiv/kg for kidney.

The major component in the milk (day-7) extract (65.6% of TRR, 0.01 mg/kg) was the parent compound (imazapyr). Polar unknowns (total 14.7% of TRR) were also present in the milk extract. Since these fractions were 0.002 mg equiv/kg and contained multiple components, no further characterization was attempted. Imazapyr was the predominant radioactive residue (81.9% of TRR,

0.061 mg/kg) in the kidney. Polar unknowns (total 11.6% of TRR) were also present in the kidney extract. The concentration of the remaining radioactive components in the kidney and the milk was below 0.01 mg equiv/kg individually.

Laying hens were orally dosed with [pyridine-6-¹⁴C]-imazapyr at the actual dietary dose equivalent to 2.0 or 9.7 ppm in the feed for 7 consecutive days. The majority of the dose was rapidly eliminated in the excreta. Elimination of ¹⁴C via the excreta accounted for 90.5 and 91.7% of the total dose for the low and high dose, respectively.

During treatment, TRR in the egg samples was less than the LOQ (0.01 mg equiv/kg). Residues in skin with adhering fat, muscle, liver and kidney tissues were all less than the LOQ (0.01 mg equiv/kg). Parent compound or derived residues are excreted without retention or accumulation in eggs and edible poultry tissues.

In animal metabolism studies, imazapyr was the major component in milk and kidney of lactating goat, but no residue was found in eggs and all tissues of laying hens.

Plant metabolism

Imazapyr is used in three different situations:

- Directed sprays for weed control (crop not intentionally treated)
- Use for weed control with a crop (crop treated)
- Selective use in genetically modified imidazolinone-resistant crops (crop treated)

Plant metabolism studies were conducted with imazapyr to investigate these three situations.

The Meeting received plant metabolism studies performed on soya bean, maize, sugarcane, oil palm, clover and Bermuda grass with imazapyr [¹⁴C] labelled in two positions ([¹⁴C-3-pyridine] and [¹⁴C-6-pyridine]).

Directed sprays to weeds

In a sugar cane metabolism study, [pyridine-6-¹⁴C]-imazapyr was applied to the soil surface once as a pre-emergence application at a rate equivalent to 0.28 kg ai/ha. Stalk samples were taken at maturity approximately 14 months after the pre-emergence treatment. There were no detectable residues in the treated samples.

In an oil palm metabolism study, [pyridine-6-¹⁴C]-imazapyr was applied to the ground beneath an actively fruiting oil palm at an application rate of 1.0 kg ai/ha. Fruit samples were collected from the oil palm as they ripened at 0 hour, 7, 30 and 62 days after treatment. Palm oil was extracted from the fruits using a hexane: water mixture (3:1, v/v). Residual radioactivity levels were below the LOQ (0.03 mg equiv/kg) at any given time in the palm oil, aqueous phase, fruit marc, kernel shell and kernel nut. The results indicate that imazapyr derived residues will not accumulate in the palm oil of an actively fruiting oil palm after application to the ground beneath the palm.

Weed control

In a clover metabolism study, [pyridine-6-¹⁴C]-imazapyr was applied to clover at a rate of 1.68 kg ai/ha. Clover foliage was collected at 0, 4, 10, 15 and 21 days after treatment (DAT). Phytotoxic effects were apparent four days after application of the test material to the clover in the test plot. The phytotoxicity remained apparent until the final collection 21 days after treatment. The TRR levels in foliage ranged from 23–49 mg equiv/kg. The majority of the radioactivity was unchanged imazapyr ranging from 68–99% of TRR. The major metabolite was CL 247,087 with CL 240,000 as a minor metabolite (their sum accounting for 0.02–18% of TRR).

In a Bermuda grass metabolism study, [pyridine-6-¹⁴C]-imazapyr was applied to Bermuda grass at a rate of 1.68 kg ai/ha. Bermuda grass foliage was collected 0, 4, 10, 15 and 21 days after treatment (DAT). Phytotoxic effects were apparent four days after application of the test material to

the Bermuda grass in the test plot. The phytotoxicity remained apparent until the final collection 21 days after treatment. TRR levels in foliage were the highest at 0 DAT (64 mg equiv/kg), and then were 18 mg equiv/kg (4 DAT), 22 mg equiv/kg (10 DAT), 25 mg equiv/kg (15 DAT) and 48 mg equiv/kg (21 DAT). The majority of the radioactivity was unchanged imazapyr ranging from 78–97% of TRR. Three other identified radio-components were PDC, CL 247,087 and CL 240,000. The amount of PDC increased with time to 13% of TRR at 21 DAT. The amount of CL 247,087 plus CL 240,000 ranged from 0% to 10.5% of TRR between 4 DAT and 21 DAT.

Imidazolinone-resistant crops

In a soya bean metabolism study, [pyridine-3-¹⁴C]-imazapyr (SL formulation) was applied once to the above ground portion of transgenic soya bean plants at BBCH growth stage 65 at an application rate of 0.11 kg ai/ha. The forage was harvested approximately one hour after application and the hay was harvested 35 days after application. Soya bean straw, pods and seeds were harvested when mature at 98 days after treatment.

The TRR of soya bean forage was 0.66 mg equiv/kg, soya bean hay was 0.25 mg equiv/kg, soya bean seed was 0.062 mg equiv/kg, soya bean straw was 0.079 mg equiv/kg and soya bean pod was 0.15 mg equiv/kg. Imazapyr was detected in all matrices and was the most abundant component of the residue in soya bean forage (0.60 mg/kg, 93.6% TRR), hay (0.094 mg/kg, 37.3% TRR), and seed (0.024 mg/kg, 34.2% TRR). Imazapyr was present in straw at 0.006 mg/kg (8.1% TRR) and pods at 0.018 mg/kg (12.7% TRR). A polar component M3 was the most abundant component in the pods (0.041 mg equiv/kg, 28.9% TRR). This component was also present in hay (0.028 mg equiv/kg, 11.1% TRR), straw (0.009 mg equiv/kg, 12.2% TRR) and seeds (0.0161 mg equiv/kg, 23.3% TRR), but was not detected in forage. This polar peak was isolated from the soya bean seeds, and shown to consist of multiple components, each present at ≤ 0.004 mg equiv/kg. M19 was present in the straw at 0.013 mg equiv/kg (17.6% TRR) and was also found in hay at 0.022 mg equiv/kg (8.7% TRR). This component had an intermediate polarity with a retention time of about 19 minutes and was not identified.

In a maize metabolism study, [pyridine-6-¹⁴C]-imazapyr was applied to imidazolinone-resistant maize at the 3 to 4 leaf growth stage at treatment rates of 0.028 and 0.080 kg ai/ha. Samples of maize plants were harvested at 0 DAT (green plant), 14 DAT (green plant), 30 DAT (early forage), and 62 DAT (late forage). At maturity (114 DAT), the stalks, husks, and cobs with grain were collected.

For the 0 DAT, 96.3% (2.37 mg equiv/kg) of the TRR was extracted. For the 114 DAT fodder, 69.9% (0.020 mg equiv/kg) of the TRR was extracted and 30.1% (0.008 mg equiv/kg) remained in the PES. For the 114 DAT grain, 0.8 to 1.5% (< 0.002 mg equiv/kg) was extracted with hexane, 80.0 to 88.8% (0.023 to 0.076 mg equiv/kg) was extracted with methanol:water:hydrochloric acid (80:18:2, v/v/v), and 10.3 to 18.5% (0.005 to 0.009 mg equiv/kg) remained in the PES. Parent imazapyr constituted the major component of the extractable residue in the green plant, forage, fodder and grain (16.8 to 84.0% of extracted TRR, 0.003 to 2.0 mg/kg). The residue levels of the minor components in the 30 DAT to 114 DAT samples were all < 0.01 mg equiv/kg.

In the plant metabolism studies on soya bean (imidazolinone-resistant), maize (imidazolinone-resistant), sugarcane, oil palm, clover and Bermuda grass, Imazapyr is the major component of the residues found in soya bean, maize, clover, and Bermuda grass. CL 247,087 and PDC were also significant components of the residues in clover and Bermuda grass.

Environmental fate

The Meeting received information on aerobic soil metabolism, soil photolysis, rotational crop and hydrolysis.

In soil under the aerobic conditions, the DT_{50} ranged from 15 months to 7.5 years at 20 °C–35 °C. At 12 months after application, imazapyr remained in soil was 60.5–89.3% of the applied radioactivity. Minor degradates were identified as PDC, CL 60,032 and CL 240,000.

In soil photolysis study, there was 11% degradation of imazapyr over the 28 days of continuous irradiation. There were at least five degradation products formed, none of which accounted for > 10% of the applied dose. The photodegradation half-life of imazapyr was 149 days at 25 °C.

In confined rotational crop study, rotational crops (wheat, radish, lettuce and soya bean) were planted at 120 days after treatment (DAT) for wheat, 271 DAT for radish, lettuce and soya bean, 420 DAT for radish and lettuce. The test substance was applied as a post-emergence application to imidazolinone-resistant maize plants at the 6-leaf stage at a rate of 0.028 kg ai/ha.

The TRR in wheat forage, straw and grain; lettuce; radish foliage and root; and soya bean forage, hay, and seed were all < 0.002 mg/kg, the limit of detection of the radio assay.

A series of rotational crops, namely carrot and lettuce were planted at 330 and 540 DAT, winter wheat planted at 359 DAT, spring wheat at 520 DAT. A single application of [¹⁴C] imazapyr was made to the soil at a rate of 0.885 kg ai/ha which is 10 times the highest GAP rate for crops used in rotation.

The TRR in follow crops were at < 0.01 to 0.02 mg equiv/kg at the various plant back intervals. Residue in the rotational crops included the unchanged imazapyr which ranged from < 0.001 to 0.003 mg/kg. Metabolites were not detected (< 0.001 mg/kg). The Meeting noted that residues are not expected on rotational crops.

Imazapyr is used for paddy rice. In a hydrolysis study, imazapyr was stable in water (pH 5, 7 and 9) at 25 °C.

Methods of analysis

The Meeting received description and validation data for analytical methods for residues of imazapyr in plant and animal commodities.

In most of the methods for determination of imazapyr in plants, homogenized samples were extracted with acidic aqueous methanol or acidic aqueous acetone, and the extract was cleaned up with column chromatography using solid phase extraction and/or strong cation exchange cartridges. Residues were determined by HPLC with UV or MS/MS detection. The methods of analysis for a range of substrates were validated with LOQs of the 0.05 mg/kg for imazapyr.

In the methods for animal commodities, homogenized samples were extracted with acidic solvent, and the extract was cleaned up by solvent partition and solid phase extraction. Residue of imazapyr was determined by capillary electrophoresis with UV detection. The methods of analysis were validated with the LOQ of 0.01 mg/kg for milk and milk fat, and 0.05 mg/kg for tissues of cattle.

No multi-residue method was submitted.

Stability of residues in stored analytical samples

The Meeting received information on the freezer storage stability of imazapyr in plant (maize grain, forage and fodder and soya bean seed), their processed (soya bean meal and oil) commodities and animal products.

Storage stability results indicate that imazapyr residue was stable for at least 3 months in soya bean (seed, laminated soya bean, meal and oil), at least 6 months in milk, at least 8 months in muscle and liver, and at least 27 months in maize (grain, forage and fodder).

The periods of storage stability studies generally cover the sample storage intervals of residue trials.

Definition of the residue

In the lactating goat metabolism studies, TRRs in kidney (0.074–0.11 mg equiv/kg) was higher than those in milk (< 0.01–0.02 mg equiv/kg), liver (< 0.05 mg equiv/kg), muscle (< 0.05 mg equiv/kg) and fat (< 0.05 mg equiv/kg). Imazapyr is the major component of the residue in kidney (82% TRR)

and milk (67% TRR). The concentration of the remaining radioactive components in the kidney and milk were below 0.01 mg/kg.

The Meeting decided that imazapyr is suitable analytes for enforcement purposes and dietary risk assessment in animal commodities.

The octanol/water coefficient ($\log P_{ow}$) of imazapyr is -3.96 at $20\text{ }^{\circ}\text{C}$ (pH 7). The Meeting considered the residue of imazapyr is not fat soluble.

In plant metabolism studies, parent imazapyr was a major component (8.1–99% TRR) in soya bean (forage, hay, seed, straw and pods), maize (forage, grain and fodder), clover and Bermuda grass. Imazapyr was a major compound in conventional and tolerant crops. Though PDC was found as a significant compound in Bermuda grass (13% TRR) which is a feed commodity, it may not be necessary to consider this compound for the definition of residue for food commodities.

The Meeting decided that parent imazapyr is a suitable analyte for enforcement purposes and dietary risk assessment in plant commodities.

The Meeting recommended the following residue definition:

For plants and animals the definition of the residue (for compliance with the MRL and for estimation of dietary intake): *Imazapyr*

The residue is not fat soluble

Results of supervised residue trials on crops

The Meeting received supervised trial data for the foliar application of imazapyr on lentil, soya bean, maize, rice, wheat, sugar cane, rape and sunflower. Residue trial data was made available from Argentina, Australia, Brazil, Canada, Uruguay and the USA.

Labels were available from Australia, Canada, Latin American countries and the USA describing the registered uses of imazapyr.

Pulses

Lentil (dry)

Data were available from supervised trials on imidazolinone-tolerant lentils in Canada.

The GAP on imidazolinone-tolerant lentil of Canada is a foliar application at a maximum rate of 0.0091 kg ai/ha with a PHI of 60 days.

Imazapyr residues in lentil seeds from independent trials in Canada matching GAP were (n=4): 0.06 (2) and 0.08 (2) mg/kg.

Based on the trials for lentils in Canada, the Meeting estimated a maximum residue level and an STMR value for imazapyr in lentil seeds of 0.3 and 0.07 mg/kg respectively.

Soya bean (dry)

Data were available from supervised trials on imidazolinone-tolerant soya beans in Brazil.

No GAP of Brazil was available for imidazolinone-tolerant soya beans.

The Meeting agreed that no recommendation could be made for soya beans.

Cereal grains

Maize

Data were available from supervised trials on imidazolinone-tolerant maize in Argentina, Brazil, Australia and the USA.

The GAP on imidazolinone-tolerant maize of Argentina is a foliar application at a maximum rate of 0.025 kg ai/ha with the application timing before reaching 6th fully developed leaf status.

Imazapyr residues in maize grains from trials in Argentina matching GAP were (n=7): < 0.05 (7) mg/kg.

Trials from Australia on maize were reported for a foliar application of a SL formulation (GAP: a foliar application at a rate of 0.018–0.022 kg ai/ha with a PHI not required when used as directed at the application timing of 2–6 leaf stage for crop). Imazapyr residue in maize grains from data in Australia at exaggerated rate of 0.032 kg ai/ha ($1.5 \times$ GAP rate) were < 0.05 (2) mg/kg and 0.048 kg ai/ha ($2.2 \times$ GAP rate) were < 0.05 (2) mg/kg.

The GAP on imidazolinone-tolerant maize of the USA is a foliar application at a maximum rate of 0.016 kg ai/ha with a PHI of 45 days at the application timing of before 6 leaf stage for crop. However, imazapyr residue trials on maize in the USA did not match the GAP of the USA.

The Meeting decided to use the data of imazapyr residues in maize grain from the trials in Argentina.

Based on the trials for maize in Argentina, the Meeting estimated a maximum residue level, an STMR value for imazapyr in maize of 0.05 (*) and 0.05 mg/kg respectively.

Rice

Data were available from supervised trials on imidazolinone-tolerant paddy rice in Brazil.

The GAP on imidazolinone-tolerant rice of Brazil is two foliar applications at a maximum rate of 0.074 kg ai/ha with a PHI of 60 days.

Trials from Brazil on rice were reported for two foliar applications at a rate of 0.12 kg ai/ha with a PHI of 60 days. Imazapyr residues in rice grains from trials at a rate of 0.12 kg ai/ha in Brazil were (n=4): < 0.05 (3) and 0.05 mg/kg. However, the trials for rice in Brazil were insufficient to estimate a maximum residue level for the commodity.

The Meeting could not estimate a maximum residue level for imazapyr in rice.

Wheat

Data were available from supervised trials on imidazolinone-tolerant wheat in Australia.

The GAP on imidazolinone-tolerant wheat of Australia is a foliar application at a rate of 0.004–0.007 kg ai/ha with a PHI not required for wheat grains when used as directed.

Imazapyr residues in wheat grains from trials in Australia matching GAP were (n=3): < 0.05 (3) mg/kg. Imazapyr residues in wheat grains from data in Australia at exaggerated rate of 0.014 kg ai/ha ($2 \times$ GAP rate) were < 0.05 (5) mg/kg and 0.028 kg ai/ha ($4 \times$ GAP rate) were < 0.05 (5) mg/kg.

Based on the trials for wheat in Australia, the Meeting estimated a maximum residue level and an STMR value for imazapyr in wheat grains of 0.05 (*) and 0 mg/kg respectively.

Grasses for sugar or syrup production

Sugar cane

Data were available from supervised trials on sugar cane in Argentina and Brazil.

The GAP on sugar cane of Argentina is two applications with spray to weeds at a maximum rate of 0.5 kg ai/ha with 30–45 days before planting. The GAP on sugar cane of Brazil is an application with spray to weeds of a rate of 0.13–0.5 kg ai/ha with a PHI not required when used as directed.

Imazapyr residue in sugar cane from trials in Argentina matching GAP was (n=1): < 0.05 mg/kg. However, the trial for sugar cane in Argentina was insufficient to estimate a maximum residue level for the commodity.

The Meeting could not estimate a maximum residue level for imazapyr in sugar cane.

Oilseed

Rape seed

Data were available from supervised trials on imidazolinone-tolerant rape in Australia and Canada.

The GAP on imidazolinone-tolerant rape of Canada is a foliar application at a maximum rate of 0.0091 kg ai/ha with a PHI of 60 days.

Imazapyr residues in rape seeds from independent trials in Canada matching GAP were (n=10): < 0.05 (10) mg/kg.

Trials from Australia on rape were reported for a foliar application of a WG formulation (GAP: a foliar application at a rate of 0.0045–0.011 kg ai/ha with a PHI not required when used as directed).

Imazapyr residues in rape seeds from trials in Australia matching GAP were (n=2): < 0.05 (2) mg/kg. Imazapyr residues in rape seeds from data in Australia at an exaggerated rate of 0.028 kg ai/ha ($2.3 \times$ GAP rate) were < 0.05 (2) mg/kg.

Based on the trials for rape seeds in Canada and Australia, the Meeting estimated a maximum residue level, an STMR value for imazapyr in rape seed of 0.05 (*) and 0 mg/kg respectively.

Sunflower seed

Data were available from supervised trials on imidazolinone-tolerant sunflower in Argentina and Uruguay.

The GAP on imidazolinone-tolerant sunflower of Argentina and Uruguay is a foliar application at a maximum rate of 0.080 kg ai/ha with the application timing of early post emergence.

Imazapyr residues in sunflower seeds from trials in Argentina and Uruguay approximating GAP were (n=15): < 0.01 (10), 0.01, 0.03 (2) and < 0.05 (2) mg/kg.

Based on the trials for sunflower in Argentina and Uruguay, the Meeting estimated a maximum residue level and an STMR value for imazapyr in sunflower seed of 0.08 and 0.01 mg/kg respectively.

Animal feedstuffs

Maize fodder and forage

Data were available from supervised trials on imidazolinone-tolerant maize in Argentina, Australia and the USA.

Trials from Argentina on maize forage were reported for the foliar application of SC or WG formulation (GAP: a foliar application of a maximum rate of 0.025 kg ai/ha, the application timing before reaching 6th fully developed leaf status).

Trials from Australia on maize forage were reported for the foliar application of a SL formulation (GAP: a foliar application of a rate of 0.018–0.022 kg ai/ha at the application timing of 2–6 leaf stage for crop, do not graze or cut for stock food for 4 weeks after application and not required to harvest for grains when used directed).

Trials from the USA on maize fodder and forage were reported for the foliar application of ASU or WP formulation at a rate of 0.027 kg ai/ha (GAP: a foliar application of a maximum rate of 0.016 kg ai/ha, PHI of 45 days at the application timing of before 6 leaf stage for crop).

Maize fodder

In the residue trials for imazapyr on maize fodder in the USA, no samples were collected on 45 days after application. The Meeting could not estimate a maximum residue level for imazapyr in maize fodder.

Maize forage

Imazapyr residues in maize forage from trials in Argentina matching GAP were (n=4): < 0.05 (4) mg/kg as received basis. Imazapyr residues in maize forage from data in Argentina at exaggerated rate of 0.040 kg ai/ha ($1.6 \times$ GAP rate) were < 0.05 (4) mg/kg and 0.050 kg ai/ha ($2 \times$ GAP rate) were < 0.05 (4) mg/kg.

Imazapyr residues in maize forage from data in Australia at exaggerated rate of 0.032 kg ai/ha ($1.5 \times$ GAP rate) were < 0.05 (2) mg/kg and 0.048 kg ai/ha ($2.2 \times$ GAP rate) were < 0.05 (2) mg/kg.

Imazapyr residues in maize forage from trials in the USA at exaggerated rate of 0.027 kg ai/ha ($1.7 \times$ GAP rate) were < 0.05 (18) mg/kg as received basis.

Based on the residues in maize forage from trials in Argentina, Australia and the USA, the Meeting estimated a median residue value and a highest residue value for imazapyr in maize forage both at 0 mg/kg.

Wheat straw and forage

Data were available from supervised trials on imidazolinone-tolerant wheat in Australia.

Trials from Australia on wheat were reported for the foliar application of a SL formulation (GAP: a foliar application of a rate of 0.004–0.007 kg ai/ha, do not graze or cut for stock food for 4 weeks after application and not required to harvest for grains when used directed).

Wheat straw

Imazapyr residues in wheat straw from trials in Australia matching GAP were (n=3): < 0.05 (3) mg/kg as received basis. Imazapyr residues in wheat straw from data in Australia at exaggerated rate of 0.014 kg ai/ha ($2 \times$ GAP rate) were < 0.05 (5) mg/kg and 0.028 kg ai/ha ($4 \times$ GAP rate) were < 0.05 (5) mg/kg.

Based on the residues in wheat straw from trials in Australia, the Meeting estimated a maximum residue level, a median residue value and a highest residue value for imazapyr in wheat straw and fodder of 0.05 (*), 0 and 0 mg/kg respectively.

Wheat forage

Imazapyr residues in wheat forage from trials in Australia matching GAP were (n=3): < 0.05 (3) mg/kg as received basis. Imazapyr residues in wheat forage from data in Australia at exaggerated rates of 0.014 kg ai/ha ($2 \times$ GAP rate) were < 0.05 (5) and 0.087 mg/kg, and 0.028 kg ai/ha ($4 \times$ GAP rate) were < 0.05 (5) and 0.11 mg/kg as received basis.

Based on the residues in wheat forage from trials in Australia, the Meeting estimated a median residue value and a highest residue value for imazapyr in wheat forage both at 0.05 mg/kg.

Rape forage

Data were available from supervised residue trials on imidazolinone-tolerant rape in Australia.

Trials from Australia on rape were reported for the foliar application of a WG formulation (GAP: a foliar application of a rate of 0.005–0.012 kg ai/ha, do not graze or cut for 5 weeks).

Imazapyr residues in rape forage from trials in Australia matching GAP were (n=1): < 0.05 mg/kg. Imazapyr residues in rape forage from data in Australia at an exaggerated rate of 0.028 kg ai/ha ($2.3 \times$ GAP rate) or at DALA 25–29 days were < 0.05 (4) mg/kg.

Based on the residues in rape forage from trials in Australia, the Meeting estimated a median residue value and a highest residue value for imazapyr in rape forage both at 0 mg/kg.

Fate of residues during processing

High temperature hydrolysis

The degradation of [¹⁴C] imazapyr was studied under hydrolytic conditions at high temperatures in sterile aqueous buffers at pH 4, 5 and 6 for periods of up to 60 minutes so as to simulate common processing practice (pasteurization, baking/brewing/boiling, and sterilization). No degradates were detected at any of the investigated pH and temperature ranges. Imazapyr is stable under hydrolytic conditions at high temperatures.

Residues in processed commodities

The fate of imazapyr residues has been examined in maize grains, rape seeds and sunflower seeds processing studies. Based on the results of processing studies conducted in Canada and the USA in combination with the residues from supervised trials, the Meeting concluded that no residues are expected in processed rape and sunflower commodities. Estimated processing factors and the derived STMR-Ps are summarized in the Table below.

Processing factors, STMR-P and HR-P for food and feed

Raw agricultural commodity (RAC)	Processed commodity	Calculated processing factors*	PF (Mean or best estimate)	RAC STMR (mg/kg)	STMR-P (mg/kg)
Maize grain	Meal	1.2	1.2	0.05	0.06
	Crude oil	< 0.50	< 0.50		0.025

* Each value represents a separate study. The factor is the ratio of the residue in processed commodity divided by the residue in the RAC.

Residue in animal commodities

Farm animal dietary burden

The Meeting estimated the dietary burden of imazapyr in farm animals on the basis of the diets listed in Appendix IX of the FAO Manual 2009. Calculation from highest residue, STMR (some bulk commodities) and STMR-P values provides levels in feed suitable for estimating MRLs, while calculation from STMR and STMR-P values for feed is suitable for estimating STMR values for animal commodities. The percentage dry matter is taken as 100% when the highest residue levels and STMRs are already expressed in a dry weight basis.

Estimated maximum and mean dietary burdens of farm animals

Dietary burden calculations for beef cattle, dairy cattle, broilers and laying poultry are provided in Appendix IX of the FAO manual. The calculations were made according to the animal diets from US-Canada, EU, Australia and Japan in the Table (Appendix IX of the FAO manual).

Livestock dietary burden, imazapyr, ppm of dry matter diet								
	US-Canada		EU		Australia		Japan	
	Max	Mean	Max	Mean	Max	Mean	Max	Mean
Beef cattle	0.063	0.063	0.085	0.085	0.20 ^a	0.20 ^b	0.061	0.061
Dairy cattle	0.083	0.083	0.057	0.057	0.15	0.15 ^c	0.045	0.045
Poultry—broiler	0.056d	0.056e	0.040	0.040	0.014	0.014	0.040	0.040
Poultry—layer	0.056	0.056	0.073 ^d	0.073 ^c	0.014	0.014	0.045	0.045

^a Highest maximum beef cattle dietary burden suitable for MRL estimates for mammalian meat, fat, edible offal and milk

^b Highest mean beef cattle dietary burden suitable for STMR estimates for mammalian meat, fat and edible offal

^c Highest mean dairy cattle dietary burden suitable for STMR estimates for milk

^d Highest maximum broiler poultry dietary burden suitable for MRL estimates for poultry meat, fat, edible offal and eggs

^c Highest mean broiler poultry dietary burden suitable for STMR estimates for poultry meat, fat, edible offal and eggs

Farm animal feeding studies

The Meeting received a lactating dairy cow feeding studies using imazapyr, which provided information on likely residues resulting in animal commodities and milk from imazapyr residues in the animal diet.

A poultry feeding study was not submitted as the expected residues of imazapyr in poultry feed were extremely low. A poultry metabolism study at a dose rate of 9.7 ppm imazapyr in feed demonstrated that there was very low transfer to eggs and tissues with all residues of imazapyr less than 0.01 mg/kg.

Lactating dairy cows

Lactating dairy cows were dosed with imazapyr for 28–29 days at the dose equivalent to 58, 157, 607 and 1680 ppm in the diet. Residues of imazapyr were at or less than the LOQ (0.01 mg/kg) in whole milk at 58 ppm of feeding level. In the three higher dose groups (157, 607 and 1680 ppm feed), imazapyr residues in milk reached a plateau after 2–3 days. In kidney, imazapyr was detected as the highest concentrations among all tissues and milk in all treated groups.

Animal commodities maximum residue levels

For MRL estimation, the residue in the animal commodities is imazapyr.

The maximum dietary burden for beef and dairy cattle is 0.20 and is lower than the dose level in the lactating goat metabolism study of 18 ppm and the lactating cow feeding study of 58 ppm. In the metabolism study, in which imazapyr equivalent to 18 ppm in the diet was dosed to lactating goats for 7 consecutive days, residues of imazapyr were detected at 0.01 mg/kg in milk and 0.08 mg/kg in kidney. The maximum dietary burden for beef and dairy cattle is 1% of the dose rate in feed of the metabolism study.

The Meeting estimated a maximum residue level of 0.01 (*) mg/kg and an STMR value of 0 mg/kg in milk.

The Meeting estimated a maximum residue level of 0.05 (*) mg/kg, an STMR value of 0 mg/kg and an HR value of 0 mg/kg in mammalian meat and fat.

The Meeting estimated a maximum residue level of 0.05 (*) mg/kg, an STMR value and an HR value of 0.0008 in mammalian edible offal.

The maximum dietary burden for broiler and layer poultry is 0.073 and is lower than the dose level in the laying hen metabolism study of 9.7 ppm. In the metabolism study, in which imazapyr equivalent to 9.7 ppm in the diet was dosed to laying hens for 7 consecutive days, no residues of imazapyr exceed 0.01 mg/kg were detected in tissues and eggs.

The Meeting estimated a maximum residue level of 0.01 (*) mg/kg, an STMR value of 0 mg/kg and an HR value of 0 mg/kg in poultry meat, fat, edible offal and eggs.

RECOMMENDATIONS

On the basis of the data from supervised trials, the Meeting concluded that the residue levels listed below are suitable for estimating maximum residue limits and for IEDI and IESTI assessment.

Plant and animal commodities:

Definition of the residue for plant commodities (for compliance with the MRL and for estimation of dietary intake): *Imazapyr*

The residue is not fat soluble.

Commodity		Recommended MRL, mg/kg	STMR or STMR-P, mg/kg	HR or HR-P, mg/kg
CCN	Name	New		
MO 0105	Edible offal (Mammalian)	0.05*	0.0008	
PE 0112	Eggs	0.01*	0	
VD 0533	Lentil (dry)	0.3	0.07	
GC 0645	Maize	0.05*	0.05	
MF 0100	Mammalian fats (except milk fats)	0.05*	0	
MM 0095	Meat (from mammals other than marine mammals)	0.05*	0	
ML 0106	Milks	0.01*	0	
PO 0111	Poultry, Edible offal of	0.01*	0	
PF 0111	Poultry fats	0.01*	0	
PM 0110	Poultry meat	0.01*	0	
SO 0495	Rape seed	0.05*	0	
SO 0702	Sunflower seed	0.08	0.01	
GC 0654	Wheat	0.05*	0	
AS 0654	Wheat straw and fodder, dry	0.05*	0	0

* At or about the LOQ.

Commodity Name	STMR or STMR-P, mg/kg	HR or HR-P, mg/kg
Maize forage	0	0
Maize meal	0.06	
Maize oil	0.025	
Rape forage	0	0
Wheat forage	0.05	0.05

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Daily Intakes (IEDIs) of imazapyr were calculated for the 13 GEMS/Food cluster diets using STMRs/STMR-Ps estimated by the current Meeting (Annex 3). The ADI is 0–3 mg/kg bw and the calculated IEDIs were 0% of the maximum ADI (3 mg/kg bw). The Meeting concluded that the long-term intakes of residues of imazapyr, resulting from the uses considered by current JMPR, are unlikely to present a public health concern.

Short-term intake

The 2013 JMPR decided that an ARfD is unnecessary. The Meeting therefore concluded that the short-term intake of residues of imazapyr is unlikely to present a public health concern.

INDOXACARB (216)*First draft prepared by Dr. Yibing He,**Department of Science and Education, Ministry of Agriculture, China***EXPLANATION**

Indoxacarb is an indeno-oxadiazine insecticide that is used for control of lepidopteran and other insect pests. It was first evaluated by the 2005 JMPR when an ADI of 0–0.01 mg/kg bw and an ARfD of 0.1 mg/kg bw were established. It has been re-evaluated for residues in 2007 and 2009. At the Forty-fifth Session of the CCPR, indoxacarb was scheduled for the evaluation by the current Meeting for additional uses on tea (REP13/PR-Appendix XIV). The present Meeting received information on the residue analysis, storage stability, use pattern, supervised field trials and processing study. The supervised trial information included data on tea.

RESIDUE ANALYSIS*Analytical methods*

The Meeting received descriptions and validation data for analytical methods for residues of indoxacarb in tea. Methods rely on HPLC-MS-MS for analysis of indoxacarb in tea and infusion.

Fresh tea leaves and tea. Fresh tea leaf or tea leaf sample was extracted with water, acetonitrile and ammonia, with the addition of NaCl before centrifugation. Supernatant was cleaned up with SPE cartridge, and centrifuged again. The supernatant was filtered and analysed by UPLC-MS/MS.

Tea infusion. Crushed and blended tea leaves were added into boiling water, and filtered. Cool tea infusion was cleaned up with SPE cartridge and analysed with UPLC-MS/MS. Both recoveries from tea leaf and tea infusion were shown in Table 1.

Table 1 Recoveries of indoxacarb in fresh tea leaves, tea and tea infusion.

Samples	Spiked concentration (mg/kg)	Recoveries (%)						mean. (%)	RSD (%)
		1	2	3	4	5	6		
Tea	0.020	111.4	107.0	111.3	112.6	92.6	---	107.0	7.8
	0.200	110.2	102.2	93.2	95.9	104.6	105.7	102.0	6.3
	4.000	110.8	103.8	107.8	106.3	100.6	98.6	104.6	4.4
Fresh tea leaves	0.010	108.0	102.1	106.1	102.0	101.5	95.0	102.5	4.4
	0.100	104.3	97.8	101.3	103.1	100.8	103.8	101.9	2.3
	2.000	103.0	104.9	103.9	102.1	100.4	101.0	102.5	1.7

RSD-relative standard deviation

Stability of residues in stored analytical samples

The Meeting received information on the stability of residues of indoxacarb in tea.

The storage stability of indoxacarb residue in tea was conducted under freeze storage conditions (-18 °C). The samples were analysed after 30 days, 60 days and 180 days with the above method. The results are listed in Table 2.

Table 2 The storage stability of indoxacarb residue in tea during storage under -18 °C

Tea sample	Residue levels (mg/kg)	Residues (mg/kg)			Remaining (%)		
		30 days	60 days	180 days	30 days	60 days	180 days
1	28.969	28.485	28.198	27.369	1.7	2.7	5.5

USE PATTERN

Indoxacarb is an indeno-oxadiazine insecticide that is registered for use against a large number of insect pests on a wide range of crops in many countries. It is used to control lepidopteran insect (e.g., budworm, armyworm, diamondback moth, loopers, codling moth, grape berry moth, and certain leaf rollers) and a range of other insect pests, including Colorado potato beetle, cranberry weevil, leafhoppers, sawflies, and tarnished plant bug. The Meeting received a copy of the official label providing information on registered uses of indoxacarb on tea in China relevant to the supervised trial data.

Table 3 Registered field uses of indoxacarb in China. Labels for the following use on tea were available to the Meeting.

Crop	Country or Region	End use product	F/G/I ^a	Application					PHI [days]
				Method	No. per crop season min. max.	Growth stage	Max. Rate (g ai/ha per application)	Max. Water Volume (L/ha)	
Tea	China	EC, 15%	F	spraying	1-2	Shoots with one bud and two leaves	38-49.5	900	10

F = field use, G = glasshouse application, I = indoor application.

RESIDUES RESULTING FROM SUPERVISED TRIALS

The Meeting received information on supervised field trials for indoxacarb uses on tea plant from China.

Crop	commodity	Country	Table No.
Tea		China	Table 4

A total of eight residue trials were carried out according to GAP ($\pm 30\%$) in China in 2010, 2011 and 2012. In all trials, indoxacarb was applied 1–2 times as an EC formulation containing 50–75 g ai/ha as a foliar application to tea. The water rate was about 900 L/ha. The PHI was 10 days. One-bud and two or three-leaf shoot of tea plant were plucked about 2 kg at PHI. Fresh tea leaves were spreaded under room temperature to leaves surface dry and processed into commercial products of tea such as green tea and black tea etc. The residue data from the supervised trials were summarised in Table 4.

Table 4 Results of residue trials with indoxacarb conducted as a foliar application to tea in China in 2010 to 2012.

FATE OF RESIDUES IN STORAGE AND PROCESSING

In storage

The Meeting received information on the fate of indoxacarb residues during the storing and processing of tea.

Table 5 The storage stability of indoxacarb residue in tea during storage under 25 °C

Tea sample	Remaining in tea (mg/kg)	Residues(mg/kg) of indoxacarb in tea during storage (days)			Remaining (%)		
		30	60	180	30	60	180
1	28.969	28.362	28.023	27.054	97.9	96.7	93.4
2	1.197	1.180	1.166	1.116	98.6	97.4	93.2

4	0.457	0.442	0.432	0.426	96.7	94.5	93.2

In Processing

The brewing rate of indoxacarb pesticide residue from tea to tea infusion has been carried out for 16 samples. Weighs up 3.0 g crushed and blended tea sample (supervised trials) in the 250 mL round beaker, add 150 mL boiling water and wait for 20 minutes, remove the infusion in 1000mL separator funnel, repeat two more times and combine all infusion together. The brewing rates of indoxacarb from tea to tea infusion were summarized in Table 6.

Table 6 Processing factors of indoxacarb from tea to tea infusion

Sample No.	Residue mg/kg	First tea infusion		Second tea infusion		Third tea infusion		Total Processing factor %
		Residue mg/kg	Brewing rate %	Residue mg/kg	Brewing rate %	Residue mg/kg	Brewing rate %

APPRAISAL

Indoxacarb was previously evaluated by the JMPR in 2005 (T, R), 2007 (R), 2009 (R) and 2012 (R), the Meeting established an ADI of 0–0.01 mg/kg bw and an ARfD of 0.1 mg/kg bw. At the Forty-fifth Session of the CCPR, indoxacarb was scheduled for the evaluation by the current Meeting for the additional use on tea (REP13/PR-Appendix XIV).

Definition of the residue for compliance with the MRL for all commodities and for estimation of dietary intake for plant commodities is sum of indoxacarb and its R enantiomer. Definition of the residue for estimation of dietary intake for animal commodities is sum of indoxacarb, its R enantiomer and methyl 7-chloro-2,5-dihydro-2-[[[4-(trifluoromethoxy)phenyl]amino]carbonyl]indeno[1,2-e][1,3,4]oxadiazine-4a(3H)-carboxylate, expressed as indoxacarb. The residue is fat soluble.

Methods of analysis

The Meeting received descriptions and validation data for analytical methods for residues of indoxacarb in tea and tea infusion samples.

Fresh tea leaf or tea leaf sample was extracted with water, acetonitrile and ammonia, with the addition of NaCl before centrifugation. The supernatant underwent clean-up with SPE cartridge, and centrifuged again. The supernatant was filtered and analysed by UPLC-MS/MS.

Crushed and blended tea leaves were added into boiling water, and filtered. Cool tea infusion was cleaned up with SPE cartridge and analysed with UPLC-MS/MS.

Recoveries ranged from 95.7% to 107% and validated LOQs were 0.0004 mg/kg for tea infusions, 0.01 mg/kg for fresh tea leaves and 0.02 mg/kg for tea.

Stability of residues in stored analytical samples

The Meeting received information on the stability of residues in tea.

The storage test showed that residues of indoxacarb in tea sample under -18 °C were stable for at least 6 months.

Results of supervised residue trials on tea

The Meeting received supervised trials data for indoxacarb uses on tea plants.

Eight trials were conducted on tea in China (maximum GAP: 0.050kg ai/ha, 2 applications, 10-day PHI) in 2010, 2011 and 2012. Two green tea trials and six black tea trials were available from Zhejiang, Hunan and Fujian, respectively. In the total of eight trials conducted at the maximum Chinese GAP, residues in tea leaves, median underlined, were: 0.13, 0.14, 0.33, 0.40, 0.42, 0.45, 1.97 and 2.60 mg/kg. The Meeting estimated a maximum residue level and an STMR value for indoxacarb in Tea, green, black (black, fermented and dried) of 5 and 0.41 mg/kg.

Fate of residues during storage and processing

The Meeting received information on the fate of indoxacarb residues during the storing and processing of tea.

Residues of indoxacarb stored under -25 °C were stable for at least 6 months.

The processing factor for tea infusion (0.062) was applied to the STMR of tea (0.41 mg/kg) to estimate an STMR-P value for tea infusion of 0.025 mg/kg.

RECOMMENDATIONS

On the basis of the data from supervised trials, the Meeting concluded that the residue concentrations listed below are suitable for establishing MRLs and for assessing IEDIs.

Definition of the residue for compliance with the MRL for all commodities and for estimation of dietary intake for plant commodities: *sum of indoxacarb and its R enantiomer*.

Definition of the residue for estimation of dietary intake for animal commodities: *sum of indoxacarb, its R enantiomer and methyl 7-chloro-2,5-dihydro-2-[[[4-(trifluoromethoxy)phenyl]amino]carbonyl]indeno[1,2-e][1,3,4]oxadiazine-4a(3H)-carboxylate, expressed as indoxacarb*.

The residue is fat soluble.

CCN	Commodity	MRL, mg/kg	STMR or STMR-P, mg/kg
DT 1114	Tea, green, black (black, fermented and dried)	5	0.41
-	Tea infusion	-	0.025

DIETARY RISK ASSESSMENT

Long-term intake

The Meeting noted that the new estimation for tea did not result in a significant change in long-term dietary intake and concluded that the long-term intake of residues of indoxacarb resulting from the uses of indoxacarb considered by the present JMPR is unlikely to present a public health concern.

Short-term intake

The IESTI of indoxacarb calculated on the basis of the recommendations of tea made by the JMPR 1% of the ARfD (0.1 mg/kg bw) for child and general population.

The Meeting therefore concluded that the short-term intake of indoxacarb residues in tea, when used in ways that have been considered by the JMPR, is unlikely to present a public health concern.

ISOXAFLUTOLE (268)

First draft prepared by Ms T. van der Velde-Koerts and K.M. Mahieu, Centre for Food, Prevention and Health Services, National Institute of Public Health and the Environment, The Netherlands

EXPLANATION

Isoxaflutole was scheduled for evaluation as a new compound by 2013 JMPR at the 44th session of the CCPR (2012).

Isoxaflutole is a synthetic compound of the isoxazole group of chemicals used as an herbicide. The mode of action of isoxaflutole is the inhibition of the enzyme 4-hydroxyphenylpyruvate dioxygenase (HPPD), thereby inhibiting pigment formation, and causing bleaching of the developing tissues of the target plants. Isoxaflutole controls a wide spectrum of grasses and broadleaf weeds by bleaching emerging or emerged weeds following herbicide uptake via the root system.

The Meeting received information from the manufacturer on identity, metabolism, storage stability, residue analysis, use pattern, residues resulting from supervised trials on sweet corn, chickpeas, glyphosate/HPPD tolerant soya beans, maize, sugar cane and poppy seed, fate of residue during processing, and livestock feeding studies.

IDENTITY

ISO common name: isoxaflutole

Chemical name

IUPAC: 5-cyclopropyl-4-(2-methylsulfonyl-4-trifluoromethylbenzoyl)-isoxazole

CAS: (5-cyclopropyl-4-isoxazolyl)[2-(methylsulfonyl)-4-(trifluoromethyl)phenyl]-methanone

CAS Registry No: 141112-29-0

CIPAC No: 575

Synonyms and trade names: RPA 201772; AE B197278; AE B197278; RPA 591428; 94 BCS-AH21981 IFT

Structural formula:

Molecular formula: C₁₅H₁₂F₃NO₄S

Relative Molecular weight: 359.3

Structure confirmed by: UV-VIS (aq MeOH), IR (KBr pellet), ¹H-NMR (250 MHz, CDCl₃), ¹³C-NMR (62.9 MHz, CDCl₃), EI-MS [Guesnet *et al.*, 1994, M-189749-01-1]

PHYSICAL AND CHEMICAL PROPERTIES

Formulations

Isoxaflutole has not been evaluated by JMPS and therefore no FAO specifications for technical and formulated isoxaflutole have been published.

The following formulations with isoxaflutole are commercially available: SL formulations (479 g ai/L), WG formulations (750 g ai/kg), SC formulations (240 g ai/L, 479 g ai/L and 480 g ai/L), SC formulations (44 g ai/L and 240 g ai/L) in combination with a safener cyprosulfamide, SC formulations (50 g ai/L and 225 g ai/L) in combination with a safener cyprosulfamide and a herbicide thien carbazon-methyl.

METABOLISM AND ENVIRONMENTAL FATE

The Meeting received information on the fate of isoxaflutole in livestock, plant commodities, soil and rotational crops. In all these studies isoxaflutole was uniformly labelled with ^{14}C in the phenyl ring (Figure 1).

Figure 1 Position of [^{14}C]- radiolabel in isoxaflutole

Animal metabolism

The Meeting received information on the fate of isoxaflutole in ruminants (lactating goat) and poultry (laying hens). The metabolism in laboratory animals was summarized and evaluated by the WHO panel of the JMPR in 2013.

Lactating goats

Radiolabelled [$\text{U-}^{14}\text{C}$ -phenyl]-isoxaflutole was administered orally by gavage to four lactating goats (British Saanen) twice daily for 7 consecutive days at a nominal dose of 1 (goat 001F), 10 (goat 002F and goat 003F) or 50 (goat 004F) mg/kg feed assuming a daily intake of 2 kg dry matter [Lappin, 1995b, M-166744-01-2]. Animals were dosed in the morning and afternoon prior to feeding and after milk and excreta collections. The mean actual concentrations were 1.084, 10.04, 12.98 and 63.92 mg ai/kg dry feed for goat 001F, 002F, 003F and 004F, respectively. In terms of mg ai/animal, the corresponding daily means were 2.00, 20.1, 20.1 and 100 mg ai/animal. Goats were less than 8 years of age. Body weights were 63 to 87 kg on arrival, 64 to 78 kg at the start of acclimatisation and 61 to 73 kg at the end of the study. It is noted that the animals lost weight during the acclimatisation

period. Recovery occurred in three of the four animals. Average daily feed consumption during application was 1.848, 2.00, 1.545, and 1.566 kg/animal/day for goat 001F, 002F, 003F and 004F, respectively. Average daily milk production during application was 1.628, 2.199, 1.638, and 1.745 kg for goat 001F, 002F, 003F and 004F, respectively, and was not affected by the administration of isoxaflutole. The goats were sacrificed *ca* 23 hours after administration of the last dose. Selected tissues (skeletal muscle, renal and omental fat) and organs (liver and kidney) were removed. In addition the gastrointestinal tract and its contents were analysed in the case of animals 003F and 004F.

The total radioactive residue (TRR) was assessed by LSC or combustion/LSC. Results are shown in Table 2 and Table 3. The total recovered radioactivity amounted to 96.64% TAR in goat 001F, 88.00% TAR in goat 002F, 77.72% TAR in goat 003F and 72.64% TAR in goat 004F. The majority of the radioactivity was recovered from urine (27 to 54% TAR) and faeces (26 to 31% TAR). Levels of radioactivity in milk were not detectable in the low dose goat (001F) and low in the other three animals (0.57, 0.60 and 0.54% TAR in goat 002F, 003F and 004F, respectively). Moderate levels of radioactivity were found in the tissues (including skin), 11.3, 7.49, 9.66 and 8.83% TAR in goat 001F, 002F, 003F and 004F, respectively).

The total radioactive residues (TRR) in tissues and milk were 0.536 to 3.946 mg/kg eq in liver, 0.164–2.123 mg/kg eq in kidney, 0.011 to 0.235 mg/kg eq in omental fat, 0.037 to 0.927 mg/kg eq in muscle, and reaching a maximum of 0.060, 0.095 and 0.350 mg/kg eq in milk for the three highest dose levels (10, 10 and 50 mg ai/kg dry feed), respectively. A steady state was apparent 48 to 96 hours after the first dose for the two low dose levels (1 and 10 mg ai/kg dry feed) with steady state levels of 0.053 mg/kg eq and 0.076 mg/kg eq, respectively. For the high dose group, a steady state was observed by 120 hours after first dosing with a mean concentration of 0.338 mg/kg eq. No separation of the milk in skimmed milk and cream was performed.

Samples were stored at *ca* -20 °C and analysed within 6 months after sampling. Storage stability was established by a comparison of the nature of radiolabelled residues in urine collected from animal 002F in three HPLC systems over an 18 month period, demonstrating no notable qualitative or quantitative differences in the profiles.

For further characterisation and identification the homogenates of the tissues of goat 003F and milk of goat 002F (10 mg ai/kg dry feed group) were subjected to further analysis.

Milk was mixed with chloroform and MeOH and partitioned. The aqueous MeOH fraction was removed and partitioned against chloroform. Chloroform fractions were pooled and reduced to low volume. The pellet from the initial extraction partition procedure was extracted with MeOH, which was pooled with the other MeOH fractions and then admixed with the concentrated chloroform extracts. This was subjected to SPE and eluted with MeOH. The aqueous residue was reconstituted with water prior to analysis by HPLC and HPLC-MS.

Kidney and liver homogenate was extracted sequentially with K_2HPO_4 buffer pH 7.5. Extracts were pooled and mixed with ACN and concentrated. The liver extract was reconstituted in mobile phase prior to HPLC and the kidney extract to HPLC. These initial analyses did not yield the requested results. Hence the extracts were further treated by mixing with ACN and particulate matter and precipitated salts were removed by centrifugation during concentration of the extract using nitrogen convection. The extracts were reconstituted in mobile phase prior to HPLC and HPLC-MS analysis.

Muscle homogenate was extracted sequentially with K_2HPO_4 pH 7.5 buffer and NH_4Ac pH 4.0 buffer. Extracts were pooled and mixed with ACN and concentrated. The extract was mixed with mobile phase and analysed by HPLC. A desalting procedure was undertaken as performed for kidney tissue, but the procedure had little effect on the HPLC chromatography. Fresh tissue sample was extracted in K_2HPO_4 pH 7.5 buffer. The extract was diluted 40 times with 2% aqueous formic acid and applied to a SPE column. Radioactivity was eluted from the column using 2% formic acid in acetone. Eluent was dried by nitrogen convection and reconstituted in HPLC mobile phase and analysed by HPLC. One minute fractions were collected and analysed by LSC.

A sample of the muscle extract was digested with protease in a similar manner as was done for the solid phase (see below). Further purification was performed by dilution with 2% aqueous formic acid and applying SPE as described above. The acetone eluent was reconstituted in HPLC mobile phase and analysed by HPLC. One minute fractions were collected and analysed by LSC.

Further processing of the solids was conducted by re-suspension in K_2HPO_4 buffer pH 7.5 with protease, incubation overnight (37 °C), freeze drying and mixing with mobile phase and ACN. The sample was concentrated and cleaned prior to reconstituting the extract with mobile phase and analysis by HPLC and HPLC-MS.

Renal fat was homogenised with hexane and mixed with K_2HPO_4 buffer pH 7.5. The mixture was centrifuged and organic and aqueous fractions removed. The procedure was repeated twice with the resultant pellet. The hexane fractions were combined, but not further characterized. The aqueous fractions were combined and the excess buffer removed by freeze drying. The resultant residue was mixed with ACN and excess particulate matter removed using centrifugation. The sample was concentrated and cleaned. The resultant residue was reconstituted in mobile phase prior to analysis by HPLC and HPLC-MS.

Omental fat was extracted in the same manner as renal fat. In addition, another extraction method was applied to a second sample, where omental fat was extracted sequentially with ACN (3×), MeOH, and acidified MeOH (2×). The resulting residue was mixed with hexane and partitioned sequentially against ACN, MeOH, acidified MeOH (3×), and water (2×). All extracts (excluding the hexane fraction) were combined, excess solvent removed and cleaned of particulate matter. The remaining aqueous sample was then analysed directly by HPLC.

The nature and identity of the residues in extracts (solvent and/or protease hydrolysates) of milk, kidney, muscle, omental fat and renal fat sampled from animals 002F and 003F were investigated using HPLC and HPLC-MS. Characterisation and/or identification in extracts were based on co-chromatography of reference standards IFT-DKN, IFT-BA, RPA 207048, and RPA 205834.

Results are shown in Table 4. Parent IFT was not found in any of the animal commodities. Three degradation products were identified in the different goat matrices. In milk, muscle, liver, kidney and fat, the metabolite IFT-DKN was the most abundant component of the residues (25–86% TRR or 0.015–1.80 mg/kg eq), followed by the metabolite RPA 207048 (12–26% TRR or 0.009–0.261 mg/kg eq) in all matrices and metabolite RPA 205834 (8.1–18.3% TRR or 0.005–0.011 mg/kg eq) in milk and omental fat only. Several unknown residues were characterized (2.66% TRR to 24.2% TRR or 0.007–0.050 mg/kg eq) in muscle, renal fat, omental fat and milk. Metabolite IFT-BA was not found in any fraction.

The solids remaining after initial extraction in kidney and muscle were treated with protease hydrolysis, resulting in a release of more IFT-DKN and RPA 207048 in muscle (respectively 0.061 mg/kg eq (23.2% TRR) and 0.009 mg/kg eq (3.8% TRR). Part of the radioactivity could not be attributed to any of the known metabolites (0.050 mg/kg eq (5.6% TRR) in kidney and 0.041 mg/kg eq (15.6% TRR) in muscle).

Table 4 Characterisation of residues in goat 002F (milk) and goat 003F (tissues) receiving 10 mg ai/kg dry feed

Tissue	TRR mg/kg eq	IFT-DKN mg/kg eq (%TRR)	RPA 207048 mg/kg eq (%TRR)	RPA 205834 mg/kg eq (%TRR)	Unk 1 mg/kg eq (%TRR)	Unk 2 mg/kg eq (%TRR)	Unk 3 mg/kg eq (%TRR)	PES mg/kg eq (%TRR)	Total %TRR

TRR: total recovered residue; Unknown 1 in aqueous fraction of omental fat and renal fat and in protease hydrolysate of muscle; Unknowns 2 in hexane fraction of omental fat and renal fat and in protease hydrolysate of muscle; Unknown 3 after protease hydrolysis of muscle solids

^a Composed of at least six radiolabelled metabolites (highest peak 0.009 mg/kg eq and < 10%TRR).

^b Released following protease hydrolysis of solids

^c Composed of at least two radiolabelled metabolites (highest peak 0.011 mg/kg eq, but < 10% TRR)

^d Composed of at least three radiolabelled metabolites in the aqueous fraction (highest peak 0.008 mg/kg eq, 12.1% TRR).

^e Partitioned into hexane, not further characterized. Taken into account the low residue levels and the common metabolism between plant and animals, this fraction is not expected to contain any toxicologically relevant residues.

^f Composed of at least three radiolabelled metabolites in the aqueous fraction (highest peak 0.011 mg/kg eq, 15.9% TRR)

Laying hens

Ten laying hens (*ISA Warren* strain) were orally dosed by gavage once daily with [U-¹⁴C-phenyl]-isoxaflutole at a nominal dose rate of 1 (group A) and 10 (group B) mg ai/kg dry feed (based on an assumed feed intake of 150 g dry matter) for 14 consecutive days [Lappin, 1995a, M-170844-01-1]. The nominal dose is equivalent to 0.15 mg ai/animal for group A and 1.5 mg ai/animal for group B. Average body weights were 1.78 and 1.82 kg at the start of the study for group A and B, respectively and 1.80 for both groups at necropsy (range 1.67–2.0 kg). The mean actual dose administered, based on the actual mean food consumption of 0.134 kg diet/day, was 1.135 and 11.35 mg ai/kg dry feed for dose group A and B, respectively. The eggs were collected twice daily and excreta in 24 hr intervals. Eggs were kept refrigerated and separated in egg yolks and egg whites prior to radio analysis. Approximately 23 hours after the last dose, the hens were sacrificed and the tissues (fat, muscle and skin) and organs (kidney and liver) were removed. Samples were stored at -20 °C.

The collected samples were analysed by combustion LSC. The total recovery of radioactivity was found to be 117.1% in dose group A. Radioactivity from the excreta and cage wash amounted to 112.4% of the total radioactivity administered. Negligible radioactivity was recovered in egg yolk (0.15% TAR) or tissues (1.7%). Levels of radioactivity were not detected in egg white. The total recovery of radioactivity in dose group B was found to be 92%. The majority of the radioactivity was recovered in the excreta (88.5%), negligible radioactivity was recovered in the egg yolk (0.10%), egg white (0.02%) or tissues (0.20%). Results are shown in Table 5.

Table 5 Distribution and recovery of total administered radioactivity (% TAR) in laying hens dosed with isoxaflutole

Matrix	1 mg ai/kg dry feed (n=5)	10 mg ai/kg dry feed (n=5)
Excreta	112.4	88.5
Cage wash	2.83	3.24
Egg white	nd	0.10
Egg yolk	0.15	0.02
Tissues (combined)	1.71	0.20
Muscle	< LOD	0.035 mg/kg eq
Fat	< LOD ^a	0.028 mg/kg eq
Liver	0.845 mg/kg eq	0.935 mg/kg eq
Kidney	0.055 mg/kg eq	0.155 mg/kg eq
Skin	0.008 mg/kg eq	0.068 mg/kg eq
Total	117.1	92.01

nd = not detected (limits of detection were calculated on the basis of the levels of the control samples and were between 0.002 and 0.007 mg/kg eq for all tissues)

^a except for one animal

In the low dose group (A) the concentrations of radioactivity in egg whites were below the limit of detection, < 0.002–0.003 mg/kg eq, at all-time points, and above the limit of detection in egg yolk (0.002–0.003 mg/kg eq) as from day 4, with maximum mean concentration of 0.028 mg/kg eq on day 10 and a steady state within 7 days after the first dose (*ca* 0.022 mg/kg eq). In the high dose group (B) the concentration of radioactivity in egg whites reached a maximum of 0.015 mg/kg eq after 10 days of exposure. A steady state (*ca* 0.010 mg/kg eq) in egg white was reached within 4 days of exposure. The levels of radioactivity in egg yolk were up to 16 times higher, with a maximum of 0.152 mg/kg eq after 12 days of exposure and a steady state concentration of *ca* 0.137 mg/kg eq within 7 days of exposure.

The highest radioactivity concentrations in edible tissues were found in the liver (0.845 and 0.935 mg/kg eq for dose group A and B, respectively) and kidney (0.055 and 0.155 mg/kg eq, respectively for A and B. Radioactivity concentrations in fat and muscle were only observed in the high (B) dose group, being 0.028 and 0.035 mg/kg eq, respectively. Some radioactivity was found in skin (0.008 and 0.068 mg/kg eq in dose groups A and B, respectively).

The nature of the radioactive residues was investigated in excreta and tissues of the animals of dose group B (10 mg/kg feed)

A variety of extraction and clean-up methods were employed to analyse residues in the edible tissues and eggs. Subsamples of eggs and homogenized subsamples of tissues and organs (combined samples of five animals from group B) were generally extracted with MeOH (3–4 times), sometimes followed by sequential extraction with acidified MeOH and water (kidney and skin). The aqueous residue was backwashed using hexane and the hexane wash was backwashed with MeOH. The MeOH wash was combined with the aqueous residue and reduced to low volume prior to analysis by HPLC and HPLC-MS. For kidney the aqueous extracts were freeze dried and reconstituted in MeOH and then pooled with the MeOH residue. Excess MeOH was removed and the residue reconstituted in water prior to analysis by HPLC-MS. Following analysis the remaining residue (kidney and liver) was mixed with MeOH and aqueous ACN, the excess solvent removed and reconstituted in water prior to analysis by HPLC.

Egg yolk was extracted subsequently with hexane, MeOH, ACN, acidified MeOH and water. Further extraction using ACN, EtOAc, acidified water and acidified EtOAc did not release any further radioactivity and were therefore not included. Other extracts were combined and excess solvent removed and cleaned up by hexane backwashes and centrifugation to remove participated particulate matter. The resultant residue was reconstituted in mobile phase prior to analysis by HPLC and HPLC-MS.

Egg white was extracted sequentially with ACN, MeOH, EtOAc, acidified MeOH, water and ACN. Quantitative recovery of radioactivity was not achieved following this exhaustive solvent extraction.

Remaining solids of kidney, skin, muscle and egg yolk and white were further subjected to protease digestion (48 hr, 37 °C) and subsequently to acid hydrolysis (6 M HCl at 95 °C for 7 days). The remaining pellets were analysed for residual radioactivity by combustion. For skin the only [¹⁴C] residue levels in the protease hydrolysate were greater than 0.010 mg/kg eq and for the muscle and egg yolk the levels in the acid hydrolysate were greater than 0.010 mg/kg eq. These fractions were further prepared for analysis by HPLC and HPLC-MS.

All fractions were analysed by LSC. The identification and quantification of metabolites in the various fractions was accomplished by HPLC and LC-MS. Characterisation and/or identification in extracts was based on co-chromatography of reference standards for IFT-DKN, IFT-BA, RPA 207048, and RPA 205834. Identification and characterisation of isoxaflutole related residues is shown in Table 6.

In egg yolk metabolites IFT-DKN (26.3% TRR, 0.036 mg/kg eq) and RPA 205834 (27.7%, 0.038 mg/kg eq) were identified. In the metabolic organs liver and kidney the majority of the radioactivity represented IFT-DKN (93.1% TRR and 73.6% TRR, respectively, equivalent with 0.887 mg/kg eq and 0.114 mg/kg eq). The same applies for the skin (61.8% TRR or 0.042 mg/kg eq, being the sum of the findings in the extractable residue and release after protease and acid hydrolysis). In muscle the main metabolite identified was RPA 207048, 48.5% TRR or 0.017 mg/kg eq (combined results of extractable residue and acid hydrolysate). In fat the main metabolites identified were IFT-DKN (28.6% TRR or 0.008 mg/kg eq) and RPA 207048 (21.4% TRR or 0.006 mg/kg eq).

Samples were stored at *ca* –20 °C and analysed within 6 months after sampling. Storage stability was established by a comparison of the nature of radiolabelled residues in excreta collected from animal 006F (group A) and 010F (group B) in three HPLC systems over an 18 month period, demonstrating no notable qualitative or quantitative differences in the profiles.

Note: More than 50% of the radioactivity in egg yolk could not be identified (12.4% TRR in solvent extract) and 46% TRR after acid hydrolysis.

No radiolabelled metabolites were released following protease treatment.

Overview metabolic pathway in livestock

Isoxaflutole was transformed to a number of metabolites after administration to ruminants and poultry. The proposed metabolic pathway of isoxaflutole in livestock involves the opening of the oxazole ring and the formation of the diketo-nitrile derivative (IFT-DKN) or the diketo-amine derivative (RPA 205834). Further degradation occurs through deamination to form the diketo-hydroxy derivative (RPA 207048) or through further cleavage to form the benzoic acid derivative (IFT-BA). Further metabolism involves conjugation of IFT-DKN, RPA 207048 and/or IFT-BA with proteins or acid cleavable compounds. The pathway is shown schematically in Figure 2.

Figure 2 Proposed metabolic pathway of isoxaflutole in livestock

Plant metabolism

The Meeting received information on the uptake and metabolic fate of isoxaflutole in cereals (maize and wheat), pulses/oilseeds (soya beans, poppy seeds) and sugar cane. Further the Meeting received information on the effect of the addition of the safener cyprosulfamide on isoxaflutole related residues. The test item used in all studies was [U-¹⁴C-phenyl]-isoxaflutole (see Figure 1).

Study 1

The metabolic fate and distribution of isoxaflutole was studied outdoors in maize (*Zea mays L*) after either a pre-plant incorporated (PPI) or pre-emergence (PRE) application [Hampton and Pettaway, 1995, M-162883-01-1]. The total amount applied was 0.209 or 0.657 kg ai/ha for the PPI application and 0.227 or 1.075 kg/ha for the PRE application. The test item used was [U-¹⁴C-phenyl]-isoxaflutole. The soil characteristics were: sandy loam, pH 5.3, 1.43% om, 2.94 meq/100 g CEC. The active ingredient was applied on day 1 to the soil either before planting (PPI) or after planting (PRE) as dosing solution using pipettes and applying it in a criss-cross pattern to the soil. For the PPI treatment

the application was subsequently incorporated in the soil with a rake to the depth of approximately 2.5 cm, before planting. Plants were harvested at immature and mature stages (one plant of the container for the forage harvest and one for fodder and grain harvest). Forage was harvested at 41 DAP/DAT (BBCH growth stage not reported, plants were 51–61 cm tall) and comprised of the combined leaves and stems. The mature plants were harvested at 122 DAP/DAT (leaves and ears) and at 138 DAP/DAT (remaining stems). Fodder samples comprised the leaves, stems, husks, shanks, silks and cob. Grain samples consisted of the shelled grain only. The frozen samples were stored at -20 °C.

Homogenised samples were analysed by combustion LSC. Samples with TRRs greater than 0.01 mg/kg eq were extracted sequentially with hexane/EtOAc (9:1 v/v); ACN; H₂O (pH 5.5); and ACN/0.2M HCl (1:1 v/v). Remaining solids in forage and fodder were digested enzymatically by cellulase (6–72 hrs for forage and 24–120 hrs for fodder, 37 °C, pH 4.8). The digests were acidified (pH < 2) and partitioned against EtOAc. Extracts and remaining solids were quantified by LSC or combustion LSC. All aqueous extracts were acidified and partitioned against EtOAc. All organic extracts and EtOAc layers were concentrated. The concentrated extracts were analysed by HPLC and TLC using reference substances for IFT, IFT-DKN and IFT-BA. The identity of the parent and metabolites was confirmed by HPLC-MS-MS.

The total radioactive residues based on combustion of maize forage, grain and fodder are shown in Table 7. Exaggerated dose rates exhibited greater phytotoxicity. The exaggerated rate treatments were not further taken into account for determining extractability and identification of metabolites.

Table 7 Mean radioactive residues in maize forage, fodder, and grain after normal and exaggerated doses

		1.075	0.528

The calculated TRR values were used as 100% TRR for all further calculations. Extractability ranged from 81.3% in fodder to 102.1% TRR in forage. Enzymatic digests of forage and fodder contributed to another 4.0% and 6.5% TRR. Remaining solids in forage, fodder and grain were on average 1.5%, 10.7% and 6.5% TRR. The total accountability ranged from 90.9% to 103.3% TRR. The results are shown in Table 8 and Table 9. Approximately 70–80% of the TRR was identified as IFT-DKN and IFT-BA. Calculations showed an identification rate of 64–89% of the TRR comprising of metabolite IFT-BA, typically greater than 90% of the extracted radioactive residue, representing 64–89% of the TRR. Small amounts of IFT-DKN were found in enzyme treated fractions of forage (*ca.* 0.5% TRR) and in the ACN fraction of grain (7.5% TRR). The parent IFT was not detected in any maize RAC.

Storage stability of the stored treated maize forage, fodder and grain was tested at 0, 96 and 253 days. HPLC profiles were nearly identical to the spiking solution. Some breakdown of the parent compound to IFT-DKN occurred (up to 27%), but is considered not critically relevant for the study, as the parent was not found in the forage samples and IFT-DKN is relatively stable in storage.

Table 8 Extractability of radioactivity in maize treated pre-plant incorporated (PPI) or pre-emergence (PRE) soil applications at normal field use rate

^a Represents the results of the organic layer from partitioning with EtOAc, since the results from the aqueous layer were either not analysed or no radioactivity was observed.

^b The H₂O organic and acid organic extracts were combined prior to analysis due to insufficient radioactivity.

^c ACN, water- and ACID-organic extracts were combined prior to analyses due to low levels of radio activity.

^d Total extracted and total identified was calculated by the reviewer, based on reported values for individual extracts and individual compounds respectively. The % TRR for metabolites was calculated by the reviewer, based on mg/kg eq values.

Study 2

The metabolic fate and distribution of isoxaflutole was studied outdoors in maize (*N7070 BT*) after a post emergence application in combination with safener cyprosulfamide (equal weight fractions). Maize plants were treated with an SC formulation of [U-¹⁴C-phenyl]-isoxaflutole at an application rate of 0.211 kg ai/ha [Meyer and Ripperger, 2006, M-268739-01-2]. The soil characteristics were: sandy loam, pH 6.4, 1.7% om, 9.9 meq/100 g CEC. The active ingredient was applied 13 DAP at growth stage V2 (BBCH growth stage not reported) by hand-held pump sprayer. Plants were harvested for forage and sweet corn (kernels and cob with husks removed) on DAT 75 and for fodder and grain on DAT 106. For sweet corn and grain the ears of all the plants were combined. All samples were homogenized and stored frozen at –20 °C (for 4–10 days until extraction and for 4–33 days until analysis).

Aliquots of homogenised samples were combusted to determine the total radioactive residues (TRR) levels. Samples with TRRs greater than 0.01 ppm were extracted sequentially with ACN (3×), ACN/water (4:1) and ACN/water (1:1). Filtered extracts were combined. Extracts and solids were analysed by (combustion) LSC. After a clean-up through C18 SPE, the eluate was concentrated and adjusted to pH 2 with HCl and then partitioned with EtOAc. The EtOAc layer was concentrated and partitioned between hexane and MeOH/water (9:1). In case of forage and sweet corn, this layer was further fractionated by C18 solid-phase extraction. For forage and fodder, the aqueous fractions arising from the EtOAc partitioning were treated with 1 M NaOH (17 hours, 50 °C) and subsequently partitioned with DCM at both basic and acidic pH. The solids remaining after ACN/water extractions of fodder were subjected subsequently to ASE (Accelerated Solvent Extraction) with 0.5 N H₂SO₄/ACN (1:1) and aq NH₄OH/ACN (1:1). The extracts were sampled for LSC and the solids were sampled for drying and combustion. Identification and quantification in those extracts with sufficient radioactivity was performed by reverse-phase HPLC and confirmation by HPLC-MS-MS. Reference substances IFT, IFT-DKN, IFT-BA and RPA 205834 were used.

TRR (sum of extracts and solids) in forage accounted for 0.134 mg/kg eq, in sweet corn 0.010, fodder 0.10 and grain 0.015 mg/kg eq. TRR in the extracts ranged from 77.3 (grain)–96.3

(kernels + cobs with husks removed (K + CWHR)) % TRR (see Table 10). The TRR in the solids ranged from 3.7 (K + CWHR) to 22.7 (grain) %TRR, but were all < 0.01 mg/kg eq. Identification results are shown in Table 11. The residues in all the RACs were identified primarily as metabolite IFT-BA (61–67% TRR). A second metabolite, IFT-DKN, was found in the fractions of sweet corn, maize fodder and maize grain, accounting for the remaining identified radioactivity (< 10% TRR and ≤ 0.005 mg/kg eq). Parent IFT was not found.

Storage stability was not addressed as the samples were analysed within 33 days.

^c Water soluble 6.1% (< 0.001 mg/kg eq), Methanol soluble 14.3% (0.001 mg/kg eq), Other soluble 5.3% (< 0.001 mg/kg eq).

^d Residues remaining after exhaustive extractions.

^e Fibre further extracted with acid (4.3%), and base (1.5%). Remaining PES 6.3% (0.008 mg/kg eq)

^f Accountability = (TRR extracts + TRR solids)/(TRRs from combustion analysis) × 100.

Study 3

The metabolic fate and distribution of isoxaflutole was studied under field conditions in wheat (*Triticum aestivum*) [Unsworth and Clarke, 2000, M-211481-01-1]. [^{14}C -phenyl]-isoxaflutole was applied as a solution to immature plants (Zadoks growth stage 30, i.e. early stem elongation, pseudo stem erect - third node on the main stem) at a field rate of 0.055 kg ai/ha or at an exaggerated rate of 0.105 kg ai/ha. Only the results of the intended field rate were provided. The soil characteristics were: loam, pH 7.4, 3.3% om, 15.1 meq/100 g CEC. Plants were harvested at interim (hay) at growth stage Z58-Z73 (Zadoks) at DAT 41 or at final harvest at DAT 93 for grain and straw. All samples were homogenised and stored frozen at -20°C . Plant parts were weighed and homogenised. TRRs were determined by combustion.

The total radioactive residues (TRR) ranged from 0.058–0.172 mg/kg in hay, grain and straw (see Table 12). Samples were extracted by maceration with ACN and ACN/water. A total of 92.4% TRR, 96.5%TRR and 86.0% TRR were extracted from hay, grain and straw, respectively. For wheat straw, solids were soxhlet extracted with DCM/glacial acetic acid (4 hr) and an additional 3.0% TRR could be released. Following concentration, the combined extracts were subjected to quantitative and qualitative analyses by reverse-phase HPLC with radiodetection. Metabolite identification was confirmed by HPLC-MS-MS. Reference substances IFT, IFT-DKN, and IFT-BA were used.

The major metabolite in hay, grain and straw is IFT-BA, accounting for 65%TRR (0.112 mg/kg eq), 95.8%TTR (0.055 mg/kg eq) and 79.1% TRR (0.084 mg/kg eq), respectively. In hay and grain also metabolite IFT-DKN was found; representing 20.9%TRR (0.036 mg/kg eq) and 9.9%TRR (0.011 mg/kg eq), respectively. IFT was only found in hay (interim harvest), accounting for 6.5%TRR (0.011 mg/kg eq). Parent IFT was not found in grain and straw. A small fraction of the metabolites in straw might be attributed to conjugates, because 3% TRR was released through acid reflux. However, since the primary and refluxed extracts were mixed, this fraction cannot be indicated.

Storage stability was not addressed as the samples were analysed within 6 months (< 90 days) and the plant parts were stored frozen ($\leq -20^{\circ}\text{C}$) prior to extraction and refrigerated (4°C) between handling steps).

Study 4

The metabolic fate and distribution of isoxaflutole were studied under greenhouse conditions in HPPD (p-hydroxyphenyl pyruvatedioxygenase) tolerant soya bean (FG72 Glytol soya bean) for pre-plant and foliar applications [Nguyen, 2010, M-368555-01-1]. [^{14}C -phenyl]-isoxaflutole was applied via hand-held sprayer as an SC formulation at an application rate of 0.330 kg ai/ha either directly to the soils prior to planting or applied uniformly to the soya bean plants at the full flowering stage (BBCH 65 or 57 DAP). The soil characteristics were: silty clay loam, pH 7.1, 1.7% om, 21.5 meq/100 g CEC. Plants were harvested for forage (BBCH 75), hay (BBCH 99) and seed (BBCH 99). All samples were homogenised and stored frozen at $\leq -20^{\circ}\text{C}$ prior to extraction.

Aliquots of homogenised samples were combusted to determine the total radioactive residues (TRR) levels. Samples were extracted several times with ACN/water (4:1) and filtered. The combined extracts were cleaned up with SPE. The remaining hay solids and soya bean seed solids were extracted with MeOH (reflux overnight) and subsequently treated with 1 M NaOH overnight at room temperature. Extracts and solids were analysed by (combustion) LSC. Identification and quantification of residues was accomplished by using reverse phase HPLC and confirmation by HPLC-MS-MS. Reference substances IFT, IFT-DKN, IFT-BA were used.

The total radioactive residues (TRR) in the RACs ranged from 0.149–0.268 mg/kg eq in pre plant RACs and from 0.259–13.128 mg/kg eq in post emergence application samples (Table 13 and Table 14).

The residues in the RACs of the pre-plant treated soya beans (Table 13) were identified primarily as metabolites IFT-amide (8–53%TRR), IFT-BA (27–66%TRR) and IFT-DKN (13–17%TRR). In hay an additional unidentified metabolite was detected (9%TRR (0.042 mg/kg eq)). Parent IFT was not found. A total of 91–93%TRR was identified.

The residues in the forage samples of the post-emergence treated soya beans (Table 14) were identified primarily as IFT (72%TRR, 7.757 mg/kg eq), and metabolites IFT-DKN (18%TRR, 1.943 mg/kg eq), IFT-BA (6%TRR, 0.627 mg/kg eq) and an unidentified metabolite PE-F4 (3%TRR, 0.352 mg/kg eq). The residues in the hay samples of the post-emergence treated soya beans were identified primarily as metabolites IFT-BA (38%TRR, 0.608 mg/kg eq), IFT-DKN (21%TRR, 0.334 mg/kg eq), and IFT (25%TRR, 0.411 mg/kg eq) and IFT-amide (3%TRR, 0.055 mg/kg eq). In seed samples metabolites IFT-BA (62%TRR, 0.160 mg/kg eq), IFT-DKN (24%TRR, 0.061 mg/kg eq) and IFT-amide (8%TRR, 0.020 mg/kg eq) were identified. Parent IFT was not found.

Storage stability was not addressed as the samples were stored frozen immediately and analysed within 33 days.

Study 5

The metabolic fate and distribution of isoxaflutole was studied under field conditions in poppies (*Papaver somniferum*, cultivar Mieszko) after a pre-emergence spray application, 3 DAS [Klempner, 2009, M-360799-01-1]. [^{14}C -phenyl]-isoxaflutole was applied as an SC formulation in combination with a non-radiolabelled safener cyprosulfamide via hand-held sprayer at an actual application rate of 0.108 kg ai/ha directly to bare soil. The soil characteristics were: sandy loam, pH 6.9, 2.12% om, 8.1 meq/100 g CEC. Poppy seeds, seed bolls with upper stem and poppy straw were harvested at maturity (BBCH stage 89–92) at DAT 110. All samples were homogenised and stored frozen at -18°C .

Aliquots of homogenised samples were combusted and radio assayed by LSC to estimate the total radioactive residues (TRR) levels. The total radioactive residues (TRR) in the RACs were 0.056, 0.779 and 0.725 mg/kg eq in seeds, seed bolls & upper stem, and straw, respectively (see Table 15).

Samples were extracted three times with ACN/water (8:2, v/v) and filtered. The solids were dried and analysed for radioactive residues by combustion and LSC. The extracts were radio assayed (LSC). The combined extracts were cleaned up with SPE. The eluate was collected and analysed by LSC. Less polar fractions were eluted with MeOH/tetrahydrofuran (1/1, v/v) and analysed by LSC.

The metabolic profiles of all extracts were analysed by radio-HPLC using reverse phase HPLC. Identification was mainly achieved by isolation of the metabolites from poppy extract by HPLC, followed by HPLC-MS and by HPLC and/or co-chromatography with reference substances IFT, IFT-DKN, IFT-BA and RPA 205834.

A total of 91.5–97.8% of the TRR was extracted. The residues in the RACs of the pre-plant treated soya beans were identified primarily as metabolite IFT-BA, being 6%TRR (0.037 mg eq/kg) in poppy seed, 94.3%TRR (0.734 mg/kg eq) in seed bolls & upper stem, and 88.7%TRR (0.643 mg eq/kg) in poppy straw). In seed bolls, upper stem and poppy straw minor amounts of AE 202248 were found (2.1%TRR and 3.6%TRR, respectively). This metabolite was not detected in poppy seed. In addition four minor, unidentified metabolites were detected in poppy seeds, two of them in seed bolls & upper stem, and one in poppy straw (range 1.0–5.4%TRR, 0.001–0.029 mg eq/kg). As they accounted for < 10% TRR, further analysis of these metabolites was not performed. Parent IFT was not found. A total of 66–96.4%TRR was identified.

Storage stability was not addressed as the samples were extracted and analysed within 14 days and 16 days (seed bolls with upper stem and poppy seeds, respectively) and 12 weeks (straw).

Study 6

The metabolic fate and distribution of isoxaflutole was studied under field conditions in sugar cane (variety *SP 79-1011*) [Unsworth, 1999, M-211498-01-1]. [^{14}C -phenyl]-isoxaflutole was applied as a solution either to soil just after sugar cane planting (pre-emergence) or on emerged sugar cane (foliar, 47 days after planting). The actual field rates were 0.210 kg ai/ha and 0.133 kg ai/ha, respectively, for pre-emergence and post-emergence treatments. The soil characteristics were: sandy clay, pH 6.2, 2.2% om, 8.1 meq/100 g CEC. Plants were harvested at DAT 81, 95 and 365 for pre-emergence application and at DAT 40, 95 and 365 for post emergence application. Whole plants were bagged and stored frozen until processing, except for the final harvest samples, where the leaves were separated from the cane. Plant parts were weighed and homogenized. All samples were stored frozen prior to homogenisation.

TRRs were determined by combustion and quantified by LSC. Results are shown in Table 16. Total radioactive residues in the DAT 365 samples were < 0.0001 mg/kg eq and in the DAT 95 samples after post emergence application 0.0065 mg/kg eq and therefore not further extracted. Only the DAT 40 (post-emergence), DAT 81 (pre-emergence) and DAT 95 (pre-emergence) samples were extracted. Extraction with ACN released 65.88%, 78.69% and 84% TRR, respectively in these samples. Remaining solids were sequentially soxhlet extracted with ACN (all samples) or ACN/water (80:20 vv, DAT 40 and DAT81). The solids remaining in the DAT 40 samples were extracted further with ACN/water (50:50, vv), 0.1 M HCl, 0.1 M ammonia, 0.1 M HCl at 60 °C, 0.1 M ammonia at 60 °C, reflux in 0.1 M HCl, reflux in 0.1 M ammonia. Extracts and solids were analysed by (combustion) LSC. A total of 90.4% TRR, 95.7%TRR and 93.5% TRR could be extracted in the DAT 40, DAT 81 and DAT 95 samples, respectively.

Following concentration, the combined extracts were subjected to quantitative and qualitative analyses by reverse-phase HPLC. Parent and metabolite identification was confirmed by HPLC-MS. Certified reference standards for IFT, IFT-DKN and IFT-BA were used.

The major metabolite in sugar cane is IFT-BA, accounting for 66.5%TRR (0.117 mg/kg eq) in DAT 40 plants treated with a post emergence application of isoxaflutole. It was also the major metabolite in DAT 81 and 95 sugarcane samples (pre-emergence application): 86–94%TRR, or 0.102 and 0.138 mg/kg eq at 81 DAT or 95 DAT harvested plants, respectively. IFT-DKN was only detected in the 40 DAT harvested sugar cane plants that had received a post emergence application (2.2%TRR or 0.004 mg/kg eq). Parent IFT was not found in any of the samples. Unknown compounds (9.8–10.8%TRR) were detected in the DAT 40/81 samples (pre- and post-emergence application), but were not detected in the DAT 95 or DAT 365 samples.

Storage stability was not addressed as the samples were analysed within 6 months after extraction and the plant parts were stored frozen ($\leq -20^{\circ}\text{C}$) prior to extraction and refrigerated (4°C) between handling steps). It is noted that it took 6 months between harvest and extraction and an additional month for HPLC extraction. Isoxaflutole degrades after 3 months to IFT-DKN (see section on storage stability). This could pose a problem. As the main metabolite in this case is IFT-BA, which is stable, it is not expected that the longer storage of the samples will have influenced the results of this study significantly.

Table 16 Characterisation of residues in sugar cane following a single pre- or post-emergence application of isoxaflutole

Study 7

A study was conducted to demonstrate the effects of the safener cyprosulfamide (AE 0001789) on the metabolism of isoxaflutole in maize [Schulte, 2002, M-210791-01-1]. Three day old seedlings of Zea mays (maize variety: Lorenzo) plants were transferred with their primary roots into 3.5 ml vials. The roots were exposed to a nutrient solution containing $0.5\text{ }\mu\text{g ai/mL}$ as $[\text{U-}^{14}\text{C-phenyl}]\text{-isoxaflutole}$ alone or in combination with safener cyprosulfamide ($1\text{ }\mu\text{g/mL}$). Pure radio-labelled IFT was used without formulation. The safener cyprosulfamide was applied as WP20 formulation. The seedlings were incubated for 24 hr. During that time roots and shoots approximately duplicated their weight and an uptake of 1 ml to 2 ml of the application solution was observed. After 24 hr incubation the seedlings were transferred into beakers filled with nutrient solution (without IFT or safener). In these beakers plants grew for further 3 days in the plant chamber.

Plants treated with isoxaflutole alone had partially bleached leaves at DAT = 3, whereas the maize plants previously incubated with isoxaflutole in combination with the safener showed a clear reduction of leaf damage.

Plants were harvested at 3 DAT and material from 50 plants (shoots, seeds and roots) was used for preparation of one sample. The samples were homogenized and filtered subsequently with ACN/water (80/20, v/v), ACN/water (50/50), mixed with trifluoroacetic acid (TFA), and partitioned three times in EtOAc (shoot and root extracts only). The filtrates or acetyl extracts were subjected to radio-TLC. Metabolites were separated by their R_f values and their radioactivity was measured. The extracts were analysed to determine the levels of the two known IFT metabolites IFT-DKN and IFT-BA by combustion and LSC.

Distribution of radioactivity is shown in Table 17. After three days radioactive distribution over the plant is different for the isoxaflutole and isoxaflutole/safener combination. Planted seeds incorporated more radioactivity than shoots and roots.

Parent IFT was not found due to the rapid conversion to the IFT-DKN metabolite. Additionally plants treated with the isoxaflutole/safener combination show a lower ratio of the IFT-DKN/IFT-BA metabolites in the shoots compared to those plants treated with isoxaflutole alone (factor 2.3, see Figure 3). In seeds and roots no differences in the ratios between the IFT metabolites could be demonstrated and only small enzymatic degradation of IFT-DKN to the inactive IFT-BA metabolite was observed.

To check whether mono-oxygenase inhibitors 1-aminobenzotriazole (ABT) and piperonyl butoxide (PBO) antagonise safener activity of cyprosulfamide also treatment solutions containing ABT or PBO were tested. After treatment the seedlings of those inhibitor-treated plants were transferred to nutrient solution which also contained ABT or PBO. The addition of mono-oxygenase inhibitors did not reduce the safener effects, indicating that mono-oxygenases are not involved in the safener effects of cyprosulfamide.

The reduced uptake of radioactivity in the shoots of plants treated with the safener combination suggests that at least one of the protective effects of the safener might be due to a reduced translocation of IFT-DKN from the root system into the shoot.

Note: Compared to the roots relatively much radioactivity is observed in the planted seeds. According to the manufacturer the radioactivity is mainly located in the transition area between root and shoot and only a small distribution in the endosperm. The accumulation in the transition area between roots and shoots could be caused by the changes in the arrangement of the vascular bundles between roots and shoots [Bayer, 2013].

Table 17 Distribution of the radioactivity (sum of IFT, IFT-DKN and IFT-BA) between the different plant parts

	Isoxaflutole only treatment (% TAR)	Isoxaflutole + Safener treatment (% TAR)
Shoots	30.2	25.5
Seeds	42.1	48.3
Roots	27.8	26.2

Figure 3 Ratio of IFT-DKN/IFT-BA for isoxaflutole and isoxaflutole/safener treatment

Overview metabolic pathway of isoxaflutole in plants

The same metabolic pathway of isoxaflutole was observed in the various metabolism studies on primary crops and rotational crops. The first hydrolytic step is the opening of the isoxazole ring to form IFT-DKN. Further hydrolytical cleavage of the carbonyl bridge and loss of the complete isoxazole moiety leads to the corresponding benzoic acid derivative (IFT-BA). The corresponding aminolysis to IFT amide could only be observed in the glyphosate/HPPD-tolerant soya beans. Application of a safener cyprosulfamide affects the breakdown of IFT-DKN to IFT-BA. The pathway is shown schematically in Figure 4.

Figure 4 Proposed metabolic pathway of isoxaflutole in plant commodities

Environmental fate in soil

The Meeting received information on aerobic degradation in soil, photolysis on soil, and confined and field rotational crop studies. The fate and behaviour of isoxaflutole in the environment was investigated using [U-¹⁴C-phenyl]-isoxaflutole (see Figure 1).

Aerobic degradation in soil - laboratory studies

Study 1

The rate of aerobic degradation of isoxaflutole in a sandy loam soil at a temperature of 20 °C was investigated [Burr, 1996, M-240821-01-1]. Soil characteristics are reported in Table 18. Soils were stored aerobically at the test facility at 4 °C. The surface of a soil was then treated with [U-¹⁴C-phenyl]-isoxaflutole at a nominal rate of 0.2 mg ai/kg dry soil, corresponding with a field application rate of 0.20 kg ai/ha. Soil samples were incubated under aerobic conditions in the dark at 20 ± 2 °C and soil moisture of 45% of the maximum water holding capacity for up to 365 days.

Samples were taken at 0, 3 and 6 hours and at DAT = 1, 2, 3, 7, 14, 28, 59, 92, 120, 181, 273 and 365. All samples generated during the study were analysed as soon as possible, within a few days (maximum of 10 days) after generation.

The soil samples were extracted at ambient temperature using ACN/water followed by extraction with acidified (pH 3) ACN/water. Starting by day 59, samples were extracted with EtOAc in addition. Extracts were concentrated under reduced pressure by rotary evaporation at approximately

30 °C followed by reversed phase HPLC analysis and [^{14}C]-flow-through detection as primary and TLC as confirmatory analytical method.

Isoxaflutole was degraded rapidly to form IFT-DKN and IFT-BA as major metabolites. Degradation was accompanied by the formation of minor metabolites including solids (9.13% TAR at study end, day 365) and volatile components and ^{14}C -CO₂ (1.76% TAR after 365 days of incubation). The distribution of radioactive residues is summarized in Table 19. Mass balances ranged between 94.3 and 103.8%.

Best fit DT_{50} and DT_{90} values of isoxaflutole and its metabolite IFT-DKN were calculated using multi-compartment kinetic models while other approaches (i.e. linear regression analysis, Timme-Frehse) resulted in poor fits to experimental data. The data are summarized in Table 20.

Table 20 Best fit values of half-lives and DT_{90} of isoxaflutole and its metabolites in sandy loam soil 95/04

Compound	Multi compartment kinetic model		
	DT_{50} (days)	DT_{90} (days)	Fit ^a
Isoxaflutole	2.5	8.9	-0.999
IFT-DKN	19.5	218.6	-0.997
IFT-BA	— ^b	— ^b	— ^b

^a A value of ± 1.000 would represent a perfect fit to the experimental data

^b No calculation possible due to low extent of degradation observed under conditions of the test

Study 2

The rate of aerobic degradation of isoxaflutole in two soils at a temperature of 20 °C was investigated [Ferreira *et al.*, 1994, M-158435-01-1]. Soil characteristics are reported in Table 21. Soils were stored aerobically at the test facility at 4 °C. The surface of a soil was then treated with [U - ^{14}C -phenyl]-isoxaflutole at a nominal rate of 0.2 mg ai/kg dry soil, corresponding with a field application rate of 0.20 kg ai/ha. Soil samples were incubated under aerobic conditions in the dark at 21 ± 1 °C and soil moisture of 75% of the moisture holding capacity at 0.33 bar for up to 12 months. Samples were taken at 0, 2 and 6 hours and after 1, 2, 3, 7, 14 days and 1, 2, 3, 4, 6, 9 and 12 months of incubation after treatment (DAT). All samples generated during the study were analysed as soon as possible, within a few days (maximum of 10 days) after generation.

The soil samples were extracted at ambient temperature using ACN/water followed by extraction with acidified (pH 3) ACN/water. Starting by day 3 (clay soil) or after 1 month (sandy loam) samples were successively Soxhlet-extracted with EtOAc and hexane. Extracts were concentrated under reduced pressure by rotary evaporation at approximately 30 °C followed by reversed phase HPLC analysis and [^{14}C]-flow-through detection as primary and TLC as confirmatory analytical method.

Mass balances ranged between 90.7% and 108.0% of TAR for sandy loam soil 93/7 and 90.8% to 102.9% TAR for clay soil 93/6. Results for the extraction, distribution and identification of radioactivity are given in Table 22 and Table 23.

In both test soils the isoxaflutole degraded rapidly to form IFT-DKN and IFT-BA as major metabolites. Degradation was accompanied by the formation of minor metabolites including solids (15.44% TAR for sandy loam, 22.28% for clay after 12 months of incubation) and ¹⁴C-CO₂ (14.14% for sandy loam, 36.70% for clay loam after 12 months). Other volatile components were observed to a negligible extent. The distribution of radioactive residues is summarized in Tables 22 and 23.

Study 3

The rate of aerobic degradation of isoxaflutole in three soils at a temperature of 20 °C was investigated [Ferreira *et al.*, 1996, M-240822-01-1]. Soil characteristics are reported in Table 25. Soils were stored aerobically at the test facility at 4 °C. The surface of a soil was then treated with [U-¹⁴C-phenyl]-isoxaflutole at a nominal rate of 0.2 mg ai/kg dry soil, corresponding with a field application rate of 0.20 kg ai/ha. Soil samples were incubated under aerobic conditions in the dark at 20 ± 2 °C and soil moisture of 45% of the maximum moisture holding capacity. Samples of loam 95/02 soil were removed for analysis after 0, 1, 3, 5, 8, 16, 33, 64, 101 and 120 days of incubation while samples of loamy sand 95/06 were removed after 0, 0.25, 0.75, 1.67, 7, 15, 30, 63, 91 and 120 days. Finally, samples of clay loam 95/05 were removed after 0, 0.125, 0.25, 0.375, 3, 7, 17, 46, 82 and 120 days.

Soil samples of loam 95/02 and loamy sand 95/06 were extracted by using ACN/0.01 M aqueous calcium chloride followed by extraction with acidified (pH 3) ACN/water at ambient temperature. In case radioactive residues in extracted soil were > 10% TAR, samples were successively Soxhlet-extracted with acidified (pH 3) ACN/water and EtOAc. Samples of loamy sand 95/06 and incubated for 30 days were additionally extracted with aqueous 0.01 M diaminoethanetetraacetic acid (EDTA) solution at ambient temperature. Soil samples of clay loam 95/05 were extracted by using ACN/0.01 M aqueous calcium chloride at ambient temperature. In case radioactive residues remaining solids were > 10% TAR, samples were extracted with aqueous 0.01 M EDTA solution at ambient temperature followed by Soxhlet extraction with EtOAc. Extracts were concentrated under reduced pressure by rotary evaporation at approximately 30 °C followed by reversed phase HPLC analysis and [¹⁴C]-flow-through detection as primary and TLC as confirmatory analytical method. Selected soil extracts were investigated by HPLC-MS.

^d Equivalent to pF = 0

The total recovery of radioactivity ranged 97.4–104.6% of TAR for soil loam 95/02, 91.6–102.5% for soil loamy sand 95/06 and 90.6–102.9% for soil clay loam 95/05 (mean values of two replicates).

In all test soils the isoxaflutole degraded rapidly to form IFT-DKN as a major metabolite. The further conversion proceeded via formation of IFT-BA as a major metabolite in soils loam 95/02 and loamy sand 95/06. In soil clay loam 95/05, IFT-BA was observed as a minor component (7.13% TAR by day 7 in maximum) along with the formation significant amounts of solids (31.22% by day 120) and ¹⁴C-CO₂ (34.62%, day 120).

Degradation was accompanied by the formation of minor metabolites including RPA 205834. In soils loam 95/02 and loamy sand 95/06, formation of solids (9.02% for loam 95/02, 4.09% for loamy sand 95/06 after 120 days of incubation) and ¹⁴C-CO₂ (1.26% for loam 95/02, 0.70% for loamy sand 95/06 after 120 days) was less pronounced indicating a slow transformation of isoxaflutole residues beyond IFT-BA under the conditions of the test. The distribution of radioactive residues is summarized in Table 26 to Table 28.

Half-lives of isoxaflutole in the three soils were calculated using linear regression analysis assuming simple first order kinetics. For metabolites IFT-DKN and IFT-BA values for half-lives and DT₉₀ in aerobic soil were calculated, where possible, by using the software Kinetic Modelling (KIM). The results are summarized in Table 29.

Table 29 Half-lives and DT₉₀ of IFT and its metabolites IFT-DKN and IFT-BA in soils clay loam 95/02, loamy sand 95/06 and loam 95/05

Soil photolysis

The rate of photolysis was investigated on a 93/22/1 sandy loam soil [Ferreira, 1994, M-158351-01-1]. The soil was surface-treated with [U-¹⁴C-phenyl]-isoxaflutole at an exaggerated rate of 36.5 µg/sample, equivalent to 0.645 kg ai/ha. Soil samples were irradiated under aerobic conditions at 25 ± 1 °C and soil moisture of 75% of the moisture holding capacity at 0.33 bar. Another set of soil samples was incubated under aerobic conditions in the dark at 25 ± 1 °C and soil moisture of 75% of the moisture holding capacity at 0.33 bar to serve as dark controls. Samples of irradiated soil and dark controls were removed for analysis after 0, 0.125, 0.25, 0.67, 1, 2, 7, 14, 21 and 31 days of incubation. The characteristics of the test soils are given in Table 30.

Soil samples were extracted with aqueous ACN (day 0 samples) followed by extraction with acidified (pH 3) ACN/water at ambient temperature (samples of day 1, 2, 7, 14, 21 and 31). Dark controls of day 31 were Soxhlet-extracted using EtOAc, followed by hexane and 1 M HCl. Extracts were concentrated at approximately 31 °C followed by reversed phase HPLC analysis and ¹⁴C-flow-through detection as primary and TLC as confirmatory analytical method. Selected soil extracts were investigated by HPLC-MS.

^a Classification according to United States Department of Agriculture

^b Organic matter calculated from organic carbon content × 1.7

The total recovery of radioactivity ranged from 88.5–101.4% of TAR for irradiated soil samples and from 91.6–101.5% for dark controls (mean values of two replicates). Isoxaflutole degraded rapidly to form IFT-DKN and IFT-BA as major metabolites in irradiated samples as well as in dark controls. Both metabolites have been observed as transformation products in aerobic soil degradation, IFT-DKN being the result of (abiotic and biotic) hydrolysis and IFT-BA to result from microbial degradation of IFT-DKN. In irradiated samples, solids were formed to a low extent (7.63% by day 31) accompanied by insignificant levels of ¹⁴C-CO₂ (0.13%, day 31). For dark controls

formation of solids and mineralisation to $^{14}\text{C-CO}_2$ was also low being at a similar level as observed for irradiated samples (NER: 4.02%, $^{14}\text{C-CO}_2$: 0.06%, both day 31).

Since the decline of parent compound and the extent of formation of metabolites observed in this experiment was virtually the same for both, i.e. irradiated samples and dark controls, there was no observation of components formed specifically from photo-transformation processes. This allows for the conclusion that the extent of photolytic degradation was insignificant. The distribution of radioactive residues is summarized in Table 31 for irradiated samples and in Table 32 for dark controls.

Table 31 Isoxaflutole related residues in irradiated samples of loam soil 93/22 (% of TAR, mean values of two replicates)

Half-lives of isoxaflutole derived from irradiated soil and after incubation in the dark were calculated using linear regression analysis assuming simple first order kinetics. The results are summarized in Table 33.

Table 33 Half-lives of isoxaflutole in irradiated and dark control samples in soil sandy loam 93/22

Compound	IFT		
	DT ₅₀	DT ₉₀	r ²
Irradiated	22.8 hours	— ^a	not reported
Dark controls	19.7 hours	— ^a	not reported

Proposed degradation pathway of isoxaflutole in/on soil

The first hydrolytic step in the aerobic degradation in soils is the opening of the isoxazole ring to form IFT-DKN. Further hydrolytical cleavage of the carbonyl bridge and loss of the complete isoxazole moiety leads to the corresponding benzoic acid derivative (IFT-BA). The proposed route of degradation is shown schematically in Figure 5. These same metabolites are also found in primary and rotational crops, as a result of uptake from the soil or metabolism within the plant.

Figure 5 Proposed route of degradation of isoxaflutole in/on soil under aerobic conditions

Confined rotational crop studies

The metabolism of isoxaflutole was investigated in rotational crops that were sown in pre-treated soil [Hampton and Pettaway, 1995b, M 192308-01-1]. The treatment and cultivation of crops were conducted in an outdoor fenced facility in Lucama, NC, USA in 1993–1994. The application was done as soil surface pre-emergence or as pre-plant incorporated application, at actual application rates of 0.213 kg ai/ha as [U-¹⁴C-phenyl]-isoxaflutole. Each treatment (control, soil surface or incorporated application) was performed with an isoxaflutole solution in ACN/water (1/1, v/v) in a tank filled with a lower layer of gravel and a supernatant layer (35–45 cm) of sandy loam soil (1.8% om, pH 6.3, CEC 7.9 meq/100 g, 14.6% MWHC at 1/3 bar). Radish (var White Icicle), lettuce (var Butter crunch), grain sorghum (var Pioneer Hybrid 8222), mustard (var Southern Giant Curled) and winter wheat (var Pioneer 2548) were planted in the tanks. Radish, lettuce and grain sorghum were planted at PBI 34 days, radish, mustard and winter wheat at PBI 123 days and radish, lettuce and grain sorghum at PBI

365 days. Lettuce at the last rotational interval needed replanting at 375 days due to a seedling infectious disease which reduced the stand. Prior to each planting, the soil was tilled to depth of 5–10 cm. In each rotation, one sample was taken at immature (1 to 3 weeks before maturity) and mature stages of the plants. Mature wheat and sorghum was separated in grain and straw/fodder. Radish plants were shaken to remove adhering soil and subsequently separated in roots and tops. Sample sizes were: 0.048–0.23 kg immature lettuce, 0.19–0.68 kg immature radish leaf, 0.038–0.084 kg immature radish roots, 1.1–1.4 kg sorghum forage, 0.3–1.0 kg mature lettuce, 3.3–4.6 kg mature radish leaf, 2.2–4.0 kg mature radish root, 0.69–1.0 sorghum grain, 2.4–3.2 kg sorghum fodder. Soil sample cores of 0–15 and 15–30 cm depth were sampled at the time of application and at each planting. Soil and plant samples were stored at -3 °C or lower for 434–741 days.

Total radioactive residues (TRR) were determined in homogenised samples of crops and soil by combustion and LSC. Crop samples with TRRs greater than 0.01 mg/kg eq were subsequently extracted with hexane/EtOAc (9:1 v/v), ACN, water (pH 5.5) and ACN/0.2 M HCl (1:1 v/v). The pH for the water extraction was adjusted to pH 5.5, because at this pH hydrolysis of IFT or isoxaflutole related conjugates did not occur. Radioactive residues in extracts and remaining solids were quantified by (combustion) LSC. For samples with appropriate levels of radioactivity, the water and ACN/0.2 M HCl extracts were partitioned against EtOAc and both layers again analysed by LSC. Organic layers containing > 10% TRR or > 0.01 mg/kg eq were concentrated and subsequently analysed by HPLC with radioactive detection and co-chromatography of standards for IFT, IFT-DKN and IFT-BA. Parent and metabolites were confirmed by HPLC-MS-MS with APCI when feasible using standards for IFT, IFT-DKN, IFT-BA and RPA 205834.

Based on application rate, expected levels are 0.11 mg/kg eq in the top 0–15 cm soil. The TRR in the top 0–15 cm treated soil significantly decreased with time from 0.07–0.08 mg/kg eq at day 0 to a plateau of 0.02–0.03 mg/kg eq. The concentration at 15–30 cm was fairly stable at 0.01 mg/kg eq indicating very minor leaching of radioactivity. Radio-activity was not further characterized.

The results in rotational crops are shown in Table 34 (pre-plant incorporated) and Table 35 (pre-emergence). The highest total radioactive residue (TRR) of 0.24 mg/kg eq was found in sorghum forage of the first rotation after pre-plant incorporated soil application.

The metabolic profile was similar in all crops of the study. IFT was detected by HPLC-MS-MS in trace amounts (< 0.001 mg/kg eq) in radish leaves, sorghum grain and sorghum fodder of the first rotation (34 days) and wheat forage of the second rotation (123 days). IFT-BA represented the major compound and was present in the RACs of the first (34 days), second (123 days) and third rotation (365 days) at levels between < 0.001–0.11 mg/kg eq. IFT-DKN was only found in radish leaves and sorghum grain at levels up 0.005 mg/kg eq in the first rotation (34 days). RPA 205834 was detected by HPLC-MS-MS in trace amounts (< 0.001 mg/kg eq) in mature lettuce of the first rotation (34 days). A fourth metabolite (U1) was found in the RACs of the first (34 days), second (123 days) and third rotation (365 days) at levels between < 0.001–0.022 mg/kg eq. This metabolite was analysed by HPLC-MS-MS after extensive purification and a relative molecular weight of 192 was determined. The polarity of this metabolite, as evidenced by its relative retention time, suggests it is a carboxylic acid degradation product of IFT-BA with the structural formula $\text{CF}_3\text{-C}_6\text{H}_4\text{-COOH}$ (4-trifluoromethyl benzoic acid).

Based on storage stability study 6, it was concluded that after 23 months of storage at -20 °C, IFT partially converts to IFT-DKN and RPA 203328 in sorghum forage, sorghum fodder, sorghum grain, lettuce, radish leaves and radish roots. Total residues (sum of IFT, IFT-DKN and IFT-BA) remained stable for at least 23 months in each matrix tested. Results from the aerobic soil degradation studies showed that isoxaflutole had a short half-life (30 hrs) in sandy loam soil and that IFT-BA was the predominant residue in soil after 1 month. These findings suggest that the likelihood that isoxaflutole was present in the soil in the PBI 34 day is low and that IFT-BA is the main metabolite present for plant uptake.

Field rotational crop studies

A study was conducted in the USA during the 1997–1999 growing seasons to determine the isoxaflutole related residues in rotational crops [Mickelson, 2000, M-240710-01-1]. One trial was established in Illinois and one in Ohio. In each trial isoxaflutole was applied once at a rate of 0.154–0.161 kg ai/ha in a minimum spray volume of 93.5 L/ha to bare ground as pre-plant or pre-emergence application of the primary crop (maize). Maize plants were harvested and/or removed from the plots prior to the planting of the rotational crops [Bayer, 2013]. The study was designed to investigate three representative rotational crop groups (leafy vegetables (mustard and soya bean), root crops (sugar beet, turnip, and radish) and small grains (winter wheat and sorghum)) at four plant-back intervals (30 days, 100–120 days, 150–180 days and 365 days). Each test site selected the variety best suited for the growing area within each crop group. Replicate field samples of the following commodities were sampled for residue analysis: mustard (leaves), sugar beet (top and root), turnip (top and root), radish (top and root), wheat (forage, hay, straw and grain), soya bean (forage, hay, wheat and grain) and sorghum (forage, hay, wheat and grain). Sample sizes were at least 0.5 kg for hay, straw and fodder and at least 1 kg for grains, seeds and cereal forage (except 0.45–0.68 kg for wheat grain). Sample sizes were 1.1–3.0 kg for mustard leaves, 1.4–3.6 kg for turnip roots + tops, 0.45–2.5 kg for radish roots + tops, 2.5–18 kg for sugar beets + tops, but the number of items was not indicated. All samples were stored at –5 °C or lower for a maximum period of 721 days (24 months).

IFT, IFT-DKN and IFT-BA were determined according to modification A and B of HPLC-MS-MS method CAL#019-03. Average concurrent recovery data for modification A (n=1/level, at 0.01–0.05–0.5 mg/kg) were within 70–120% for all analytes in wheat hay, wheat grains, wheat straw, soya bean seeds, soya bean hay, sorghum grains, sorghum fodder. Recoveries are not satisfactory for IFT-BA in wheat hay (62%, n=1, 0.01 mg/kg), wheat straw (68%, n=1, 0.01 mg/kg) and soya bean seeds (64%, n=1, 0.01 mg/kg). No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control samples. Average concurrent recovery data for modification B were within (at n=1/level, 0.01–0.05–0.5 mg/kg) were within 70–120% for all analytes in mustard leaves, turnip roots, turnip tops, wheat forage, soya bean forage, radish roots, radish tops and sorghum forage. Recoveries are not satisfactory for IFT-BA in turnip tops (69%, n=1, 0.01 mg/kg) and wheat forage (69%, n=1, 0.01 mg/kg). No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control samples.

The average sample results are summarized in Table 36. None of the analysed samples showed IFT or its metabolite IFT-DKN greater than the LOQ of 0.01 mg/kg. The same applies to metabolite IFT-BA, except that it was found in samples of soya bean hay (0.010 mg/kg) and soya bean forage (0.038 mg/kg) in one trial in Ohio.

Table 36 Results of field rotational crop trials conducted with isoxaflutole in the USA

Environmental fate in water/sediment systems

No data submitted. Not relevant for the present intended use.

RESIDUE ANALYSIS

The Meeting received information on enforcement/monitoring methods for the determination of isoxaflutole and its metabolites in plant and animal commodities. In addition the Meeting received information on analytical methods for the determination of isoxaflutole and its metabolites as used in the various study reports (supervised residue trials, storage stability studies, processing studies, feeding studies). The analytical residue methods have been evaluated according to the guidance provided by OECD (Series on Pesticides number 39) as indicated on page 25 of the FAO manual 2009.

Validation results are required for every commodity submitted for MRL-setting: at least one full validation for a commodity within the five defined crop groups (high acid content, high water content, high oil content, high protein content, high starch content) and a reduced validation for every other commodity within a certain crop group. Where validation results do not meet the criteria given below, this is indicated.

When the analytical method is validated according to a full validation scheme, it means that:

- at least five recovery experiments per level were conducted on at least two levels (LOQ and $10\times$ LOQ) and average recovery per level was shown to be between 70–120% and the relative standard deviation (RSD_r or CV) per level was shown to be $< 20\%$
- at least two control samples were analysed and were shown to be below $0.3\times$ LOQ
- the calibration was conducted with at least five single points or at least three duplicate points and was shown to be linear (either standards in solvent or matrix matched standards).

When the analytical method is validated according to a reduced validation scheme, it means that:

- a full validation is available for a crop in the same crop group (high acid content, high water content, high oil content, high protein content, high starch content)
- at least three recovery experiments per level were conducted on at least two levels (LOQ and $10\times$ LOQ) and the average recovery per level was shown to be between 70–120% and the relative standard deviation (RSD_r or CV) per level was $< 20\%$
- at least two control samples were analysed and shown to be below $0.3\times$ LOQ
- the calibration was conducted with at least five single points or at least three duplicate points and was shown to be linear (only relevant for matrix matched standards; standards in solvent are already covered by full validation).

Analytical methods for enforcement in plant commodities

HPLC-MS-MS method 01021

HPLC-MS-MS method 01021 is intended as enforcement method for the determination of parent isoxaflutole and its diketone nitrile metabolite IFT-DKN in/on plant material [Schoening, 2007, M-282394-02-1]. Plant material was extracted with MeOH/1% formic acid solution (9/1, v/v) using a blender. After filtration of the extract the solution was made up to volume, diluted and subjected to HPLC-MS-MS. Isoxaflutole and IFT-DKN were quantified against external matrix-matched mixed standards. Two MRM transitions were monitored for each analyte and each matrix tested (m/z 360 $\rightarrow$ 251 for quantification and m/z 360 $\rightarrow$ 220 for confirmation of IFT and m/z 358 $\rightarrow$ 79 for quantification and m/z 358 $\rightarrow$ 64 for confirmation of IFT-DKN). Analyte levels were expressed as IFT equivalents.

HPLC-MS-MS Method 01021 was validated according to the full validation scheme for commodities with high acid content (orange fruit), high water content (tomato fruit), high starch content (wheat grains) and high oil content (rape seeds) [Schoening, 2007, M-282394-02-1]. The validation was performed for the quantification transition ions as well as for the confirmation transition ions. Mixed analyte solutions were used for fortification of samples. Average recoveries at 0.01 mg/kg and 0.1 mg/kg were within 70–120% limits and RSDs were within 20%. Linearity was observed in a range from 0.125–5.00 $\mu\text{g/L}$ on all mass transitions (equivalent concentration in the samples not stated). The correlation coefficients for a $1/\times$ weighted regression were $r > 0.99$ using five triplicate matrix matched standards. No interfering peaks $> 0.3\text{LOQ}$ (i.e. 0.003 mg/kg) were detected in any of the control extracts. The valid LOQ was 0.01 mg/kg for each commodity.

HPLC-MS-MS Method 01021 was validated according to the full validation scheme by an independent laboratory (ILV) for tomato fruit and wheat grain [Class, 2007, M-286476-01-1]. Slight modifications were introduced: 0.1% formic acid was used instead of 1% formic acid. The validation was performed for the quantification transition ions as well as for the confirmation transition ions.

Mixed analyte solutions were used for fortification of samples. Average recoveries at 0.01 mg/kg and 0.1 mg/kg were within 70–120% limits and RSDs were within 20%. Linearity (coefficient of correlation $r > 0.99$) was observed in the range of 0.050–5.0 ng/mL for each analyte using six single matrix matched standards. The equivalent concentration in the samples was not stated. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control samples. The valid LOQ was 0.01 mg/kg for each commodity.

Conclusion: The method is considered valid for use as enforcement method in plant material with an LOQ of 0.01 mg/kg for isoxaflutole and IFT-DKN.

Analytical methods for enforcement in animal commodities

QuEChERS multi-residue method

The official multi-residue method QuEChERS was validated for the individual determination of isoxaflutole and its metabolite IFT-DKN in animal commodities. No multiresidue methods were available for determination of isoxaflutole related residues in plant commodities.

In the QuEChERS method (also named BCS method 01300/M009) animal commodities were extracted with acetonitrile and water (1:1, v/v) [Winter and Amann, 2013, M454397-01-1]. Samples with low water content ($< 80\%$) require the addition of water before the initial extraction to get a total of approximately 10 g of water. After addition of magnesium sulphate, sodium chloride and buffering citrate salts, the mixture was shaken intensively and centrifuged for phase separation. An aliquot of the extract was taken, diluted and subjected to HPLC-MS-MS. Two MRM transitions were monitored for isoxaflutole: 358.0 to 277.9 for quantification and 358.0–78.9 for confirmation. Two MRM transitions were monitored for IFT-DKN: 358.0 to 277.9 for quantification and 358.0–78.9 for confirmation.

The validation was conducted on milk, eggs, bovine meat, bovine fat, bovine liver and bovine kidney [Winter and Amann, 2013, M454397-01-1]. To avoid the degradation of the isoxaflutole parent compound, hydrochloric acid was added to the bovine meat matrix before spiking and extraction of the samples. Matrix effects of $\geq 20\%$ were measured for isoxaflutole and IFT-DKN in kidney and for isoxaflutole in liver. For milk, eggs, meat, fat and liver (IFT-DKN only) minor matrix effects ($< 20\%$) were detected. Therefore, for all tested matrices, quantification was performed with matrix-matched standards. Average recoveries at 0.01 and 0.10 mg/kg (five replicates per level) were within 70–120% limits and RSDs were within 20% for each analyte and for both MRM transitions. Linearity was observed in the range of 0.25–60 ng/mL for IFT and IFT-DKN matrix matched standards. The equivalent concentration in the samples was not stated. The coefficient of determination was $R^2 > 0.99$ using six single matrix matched standards. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts. The valid LOQ was 0.01 mg/kg in milk, eggs, meat, fat, liver and kidney. Two MRM transitions were validated for all matrices and therefore an additional confirmatory method is not necessary.

Conclusion: The method is considered valid for use as enforcement method in animal commodities with an LOQ of 0.01 mg/kg for isoxaflutole and IFT-DKN.

HPLC-UV method AR 109-95

HPLC-UV method AR 109-95 is intended as enforcement method for the determination of isoxaflutole, its diketonitrile metabolite IFT-DKN and its benzoic acid metabolite IFT-BA in animal commodities (fat, kidney, milk and eggs) [Guillet, *et al.*, 1995, M-213160-01-1; Le Gren, 1995a/b/c, M-213162-01-1, M-262409-01-1, M-213164-01-1].

Milk residues were extracted by macerating with a mixture of 0.1% trifluoroacetic acid acidified water/ACN. The extract was purified using an Octyl cartridge, IFT and IFT-DKN being eluted in the same fraction.

Fat residues were extracted by macerating with a mixture of 0.1% trifluoroacetic acid acidified water/ACN. The extract was purified using an Octyl cartridge followed by a Diol cartridge.

IFT-BA was eluted directly on the Octyl cartridge and IFT and IFT-DKN were eluted consecutively on the Diol cartridge.

Kidney residues were extracted by macerating with ACN. The extract was purified using an Octyl cartridge for IFT-DKN and additionally using a Diol cartridge for IFT. For determination of IFT-BA, the extract was purified using a Diol cartridge first followed by the purification using an Rdx cartridge.

Egg residues were extracted by macerating with ACN. The extract containing IFT-DKN was purified using an Octyl cartridge followed by a Diol cartridge for IFT-DKN. Attempts to analyse IFT in eggs were not successful, even with acidified extraction solvent, because IFT rapidly degrades onto IFT-DKN in presence of a basic matrix like eggs (pH around 9).

Quantification was carried out by HPLC-UV on a C18 column at 270 or 300 nm. Quantification of residues was done by external calibration using standards in solvent. Analyte levels were expressed as the corresponding analyte.

HPLC-UV Method AR 109-95 was validated according to a reduced validation scheme for bovine fat, bovine kidney, cow milk and hen eggs [Guillet, *et al.*, 1995, M-213160-01-1; Le Gren, 1995a/b/c, M-213162-01-1, M-262409-01-1, M-213164-01-1]. Mixed analyte solutions were used for fortification of samples. Average recoveries at 0.01 mg/kg (milk), 0.02 mg/kg (eggs, tissues) and 0.1 mg/kg were within 70–120% limits and RSDs were within 20% for each analyte. Linearity was observed in the range of 10–1000 ug/L for IFT and IFT-DKN and in the range 25–1000 ug/L for IFT-BA. The equivalent concentration in the samples was not stated. The coefficient of correlation was $r > 0.99$ using 4–7 duplicate solvent standards. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg in milk, 0.006 mg/kg in eggs, fat and kidney) were detected in any of the control extracts. The valid LOQ was 0.01 mg/kg in milk (IFT, IFT-DKN), 0.02 mg/kg in eggs (IFT-DKN) and 0.02 mg/kg in fat and kidney (IFT, IFT-DKN and IFT-BA).

Conclusion: HPLC-UV method AR 109-95 is considered insufficiently validated for use as enforcement method, since a reduced validation scheme is used ($n=3/\text{level}$), a confirmation method is not available and no validation is available for muscle/meat and liver.

HPLC-UV method RPAC #45532

HPLC-UV method RPAC #45532, version 2.0, 4 March 1998, is intended as enforcement method for the determination of IFT, IFT-DKN and RPA 205834 in animal commodities (milk, eggs and tissues) [Lopes *et al.*, 1998, M-166734-01-2].

Milk (50 g) was extracted by macerating with a mixture of 0.1% aqueous trifluoroacetic acid and ACN (5:18 v/v). The extract was purified using a C-8 cartridge column. The cartridge is eluted subsequently with water/ACN (90:10, v/v) and water/ACN (50:50, v/v). The first fraction contains IFT-BA and this fraction is discarded. Isoxaflutole, IFT-DKN and RPA 205834 were eluted and collected together in the second fraction.

Eggs were extracted with ACN. The extract was purified using a C-8 cartridge column, IFT-DKN being collected in the second fraction.

Tissues were analysed by a common moiety technique. Kidney, liver and muscle (10 g) were extracted using 0.1% aqueous trifluoroacetic acid. For beef fat or chicken skin with adhering fat (10 g) the extraction solvent was a 2:1 mixture of hexane and water. The fat hexane extracts were partitioned against an 18:5 mixture of ACN and water. The ACN-water phase was added to the aqueous extract and evaporated to remove all ACN. Isoxaflutole was converted to IFT-DKN by treatment of the extract with 10% NaOH. Trace enrichment/purification was obtained using a C-18 cartridge. IFT-DKN was eluted from the C-18 cartridge and collected in the second fraction.

All residue analyses were accomplished by HPLC-UV on a C-8 column at 270 or 300 nm. Quantification of residues was done by external calibration using standards in solvent. Analyte levels in milk and eggs were expressed as the corresponding analyte. For the animal tissue analysis the isoxaflutole related residues were determined as IFT-DKN but were reported as isoxaflutole. The

molecular weight of isoxaflutole and IFT-DKN are the same, therefore, a correction factor for differences in molecular weight is not necessary.

HPLC-UV method RPAC #44882 is identical to HPLC-UV method RPAC #45532 for milk, except that fraction 1, containing IFT-BA, was analysed as well. HPLC-UV method RPAC #44882 was validated according to a full validation scheme for cow milk for IFT, IFT-DKN, RPA 205834 and IFT-BA [Shaffer, 1995, M-192304-01-2]. Two trials were required to optimize the method. Trial 1 was not successful due to low and highly variable recoveries of IFT-DKN. The retention times shifted significantly when the pH of the final solution was changed from 2.13 to 2.07. A second milk trial, incorporating the developer's suggestions and taking care to mix the sample extract well, was successful. Mixed analyte solutions were used for the fortification of milk. Average recoveries at 0.02 and 2.0 mg/kg were within 70–120% limits and RSDs were within 20% for each analyte and matrix tested. Linearity (coefficient of correlation $r > 0.9999$) was observed in the range of 20–100 ng/mL using five single or duplicate standards in solvent. Equivalent concentrations in the samples were not stated. No interfering peaks > 0.3 LOQ (i.e. 0.006 mg/kg) were detected in any of the control samples. The valid LOQ was 0.02 mg/kg for IFT, IFT-DKN, RPA 205834 and IFT-BA.

HPLC-UV method RPAC #44933 (identical to HPLC-UV method RPAC #45532 for eggs) was validated according to a full validation scheme for IFT-DKN in hen eggs [Tew, 1995b, M-192317-01-1, Lowder, 1996, M-192281-01-2-01]. Average recoveries at 0.05 mg/kg ($n=8$) and 0.25 mg/kg ($n=6$) were within 70–120% limits and RSDs were within 20% for IFT-DKN in eggs. Linearity (coefficient of determination $R^2 > 0.999$) was observed in the range of 20–200 ng/mL using six single standards in solvent. Equivalent concentrations in the samples were not stated. No interfering peaks $>$ LOQ (i.e. 0.05 mg/kg) were detected in any of the control extracts ($n > 2$). The valid LOQ was 0.05 mg/kg in eggs for IFT-DKN.

HPLC-UV method RPAC #45532 was validated by an independent laboratory according to a full validation scheme for milk, eggs, meat and kidney [Kaune, 2002, M-213302-01-1]. Validation was conducted for IFT, IFT-DKN and RPA 205834 in milk, IFT-DKN in eggs and IFT, IFT-DKN in meat and kidney. Animal origin for the tissues is not indicated for these samples. Separate solutions for each individual analyte were used for fortification of eggs and tissues. Mixed analyte solutions were used for fortification of milk. Average recoveries at 0.01–0.1 mg/kg for milk and eggs or 0.2–2.0 mg/kg for tissues were within 70–120% limits and RSDs were within 20% for each analyte and matrix tested. The calibration curve was not linear: a curve of the type $y = a + bx + cx^2$ was applicable over the tested range of 5 to 50 ng (0.05 to 0.5 mg/L) using 4–5 single or duplicate standards in solvent. Equivalent concentration in the samples was not stated. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts. The valid LOQ was 0.01 mg/kg in milk (IFT, IFT-DKN and RPA 205834), 0.01 mg/kg in eggs (IFT-DKN), 0.2 mg/kg in meat and kidney (IFT, IFT-DKN).

Conclusion: HPLC-UV method RPAC #45532 is considered insufficiently validated for use as enforcement method, since a confirmation method is not available, the method for tissues is a common moiety method and no validation is available for fat and liver.

HPLC-UV method RPAC #45532 is considered valid for use as pre-registration analytical method in the range 0.02–2.0 mg/kg IFT, IFT-DKN, RPA 205834 and IFT-BA in milk and at 0.05–0.25 mg/kg IFT-DKN in eggs when using a linear calibration curve. The LOQ may be lowered to 0.01 mg/kg in milk and eggs when using a second order calibration curve.

HPLC-UV method RPAC #45532 is considered not suitable for use as pre-registration analytical method since the residues are analysed as a common moiety.

Analytical methods used in study reports in plant commodities

GC-MS method 00473 and its modifications

GC-MS method 00473, version January 1995, code HWI 6224-215, is a common moiety method for the determination of isoxaflutole related residues (sum of IFT, IFT-DKN and IFT-BA) in plant

commodities [Nandihalli, 1995, M-020184-01-1]. Homogenised samples (25 g) were extracted by maceration with MeOH (3× 125 mL). Combined extracts were filtered. After addition of 2% NaOH solution isoxaflutole was hydrolysed to IFT-DKN in 1 hr at room temperature. The MeOH was evaporated off and 10 mL saturated NaCl was added to the low volume aqueous phase. The aqueous phase was washed subsequently with DCM and petroleum ether. Acidification (12 M HCl, pH 1.0) of the aqueous phase then allowed liquid-liquid partition of both IFT-DKN and IFT-BA into DCM (3×). The DCM phase was drained through anhydrous Na₂SO₄ and evaporated to dryness. The residue was re-dissolved in 1 M methanolic NaOH solution and heated for 1 hr at 100 °C, whereby residues of IFT-DKN were hydrolysed to IFT-BA. Acidification (12 M HCl, pH 1.0) of the aqueous phase then allowed liquid-liquid partition of IFT-BA into DCM (3×). The DCM phase was drained through anhydrous Na₂SO₄ and evaporated to dryness. The residue was redissolved in DCM and IFT-BA was methylated to RPA 204497 using diazomethane (1 hr 30 °C). Excess diazomethane was destroyed by addition of HAc. Residues of the ester derivative RPA 204497 are detected by GC-MS at m/z 251 (quantification) and m/z 267 (confirmation). Residues are quantified as RPA 204497, but are expressed as isoxaflutole equivalents in the trials.

GC-MS method 00473 was used in maize storage stability studies [Nandihalli, 1996, M-089371-01-1]. GC-MS method 00473 was validated according to a full validation scheme for maize forage, maize silage, maize grain and maize fodder [Nandihalli, 1995, M-020184-01-1]. Samples were fortified separately with IFT, IFT-DKN or IFT-BA. Average recoveries at 0.01 and 0.05 mg/kg (n=6 each) were within 70–120% limits, except IFT-BA in maize grain (0.01/0.05 mg/kg, average 67%/64%, n=6 each). Individual recoveries and RSDs were not reported. Additional recovery data from the storage stability study indicated that average recoveries at 0.2 mg/kg in maize silage and maize fodder and at 0.1 mg/kg in maize grain were within 70–120% limits (n=12, each analyte, each matrix) and RSD at this level was within 20%. Linearity (coefficient of correlation $r > 0.9999$) was observed in the range of 0.01–0.5 mg/L using six single solvent standards. The equivalent concentration in the samples was not stated. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts. The valid LOQ is 0.01 mg/kg for isoxaflutole related residues, expressed as isoxaflutole.

GC-MS-MS modification A of method 00473 was used in the Australian sugarcane supervised residue trials & storage stability studies (dated April 1999) [Davis and Keats, 1999a/b/c/d/e/f, M-284383-01-1, M-284347-01-1, M-284356-01-1, M-284369-01-1, M-284408-01-1 M-284324-01-1]. Modifications involved changes in sample types, extraction volumes, conditions for hydrolysis, diazomethane methylation and MS conditions. Homogenised samples of sugarcane billets (25 g) or sugarcane forage (25 g) were extracted with 2× 80 mL MeOH. Further sample preparation was identical to the original method except that an aliquot equivalent to 5 g sample matrix was taken for further analysis. The hydrolysis of IFT-DKN to IFT-BA was conducted at a lower temperature of 60 °C. Diazomethane was directly added to the last DCM phase and IFT-BA was methylated to RPA 204497 (30 min, room temperature). Excess diazomethane was destroyed by addition of HAc and toluene was added to the extract. The extract was then reduced to the toluene phase. The toluene phase was filtered using a 0.45 µm PTFE filter and clean-up on a Florisil cartridge. The analytes were eluted with a toluene/acetone mixture (90:10, v/v). Residues of the ester derivative of RPA 204497 are detected by GC-MS-MS at m/z 251 and m/z 252 (parent ions as well as quantification ions).

GC-MS-MS modification A of method 00473 was partially validated for sugarcane billets and sugarcane forage [Davis and Keats, 1999a/b/c/d/e/f, M-284383-01-1, M-284347-01-1, M-284356-01-1, M-284369-01-1, M-284408-01-1 M-284324-01-1]. Samples were fortified separately with IFT, IFT-DKN or IFT-BA. Average recoveries at 0.01 mg/kg (n=5) for each compound were within 70–120% limits. Additional recovery data from the storage stability study indicated that average recoveries at 0.1 mg/kg in maize silage and maize fodder and at 0.1 mg/kg in maize grain were within 70–120% limits (n=12, each analyte, each matrix) and RSD at this level was within 20%. Recoveries at 10× LOQ were not verified. However, since residue levels in the trials were $< \text{LOQ}$, this is considered acceptable. Linearity (coefficient of correlation $r > 0.9999$) was observed in the range of 0.01–0.1 mg/L using three duplicate solvent standards. The equivalent concentration in the samples

was not stated. No interfering peaks > LOQ were detected in any of the control extracts ($n > 2$, each matrix). The valid LOQ is 0.01 mg/kg for isoxaflutole related residues, expressed as isoxaflutole.

GC-MS-MS modification B of method 00473 was used in the 1999 chickpea supervised residue trials & storage stability studies (dated December–February 2000) [Lynch and Keats, 1999a/b, M-432364-01-1, M-432374-01-1, Lynch and Keats, 2000a/b/c, M-432434-01-1, M-432441-01-1, M-432444-01-1]. Modifications involved changes in sample types, extraction volumes, conditions for hydrolysis, diazomethane methylation and MS conditions. Homogenised chickpea seeds (25 g), chickpea forage (25 g) or chickpea straw (10 g) were extracted with 2×100 mL MeOH. Further sample preparation was identical to the original method except that an aliquot equivalent to 5 g sample matrix was taken for further analysis and aqueous phases were washed with diethyl ether instead of petroleum ether. The hydrolysis of IFT-DKN to IFT-BA was conducted at a lower temperature of 60 °C. The last DCM phase was drained through anhydrous Na_2SO_4 . After addition of diazomethane IFT-BA was methylated to RPA 204497 (30 min, room temperature). Excess diazomethane was removed by nitrogen at 30–35 °C and ACN was added to the extract. The extract was then reduced to 1 mL of ACN, made up to 5 mL with ACN and filtered using a 0.45 μm PTFE filter cartridge. Residues of the ester derivative of RPA 204497 are detected by GC-MS-MS at m/z 251 (parent ion) and m/z 189 and m/z 221 (quantification ions).

GC-MS-MS modification B of method 00473 was validated for chickpea seeds, chickpea forage and chickpea straw [Lynch and Keats, 1999a/b, M-432364-01-1, M-432374-01-1, Lynch and Keats, 2000a/b/c, M-432434-01-1, M-432441-01-1, M-432444-01-1]. Samples were fortified separately with IFT, IFT-DKN or IFT-BA. Average recoveries at 0.01 and 0.1 mg/kg ($n=3$ or 6) for each compound were within 70–120% limits. Individual recoveries and RSDs were not reported. Linearity was not observed: a second order calibration curve (correlation coefficient $r > 0.99$) was fitted to the data in the range 0.005–0.5 mg/L using six triplicate solvent standards. The equivalent concentration in the samples was not stated. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts ($n > 2$, each matrix). The valid LOQ is 0.01 mg/kg for isoxaflutole related residues, expressed as isoxaflutole.

GC-MS modification C of method 00473 was used in the Brazilian sugarcane supervised residue trials (dated March 2000) [Tornisielo, 2000a/b, M-287038-01-1, M-287041-01-1]. Modifications involved changes in sample types, extraction volumes and diazomethane methylation. Homogenised sugarcane billets (20 g) were extracted by maceration with 2×95 mL MeOH. Further sample preparation was identical to the original method. The last DCM phase was reduced to 5 mL. After addition of diazomethane, IFT-BA was methylated to RPA 204497 (time and temperature not stated) and the sample was evaporated to dryness. The residue was redissolved in hexane.

GC-MS modification C of method 00473 was validated for sugarcane billets [Tornisielo, 2000a/b, M-287038-01-1, M-287041-01-1]. Samples were fortified with IFT only. Average recoveries at 0.01 and 0.02 mg/kg ($n=3$, each) were within 70–120% limit and RSD was within 20% at these levels. Recoveries at $10 \times$ LOQ were not verified. However, since residue levels in the trials were < LOQ, this is considered acceptable. Linearity (coefficient of determination $R^2 > 0.999$) was observed in the range of 0.02–0.15 ng/mL using five single solvent standards. The equivalent concentration in the samples was not stated. No interfering peaks > LOQ were detected in any of the control extracts ($n=2$). The valid LOQ is 0.01 mg/kg for isoxaflutole related residues, expressed as isoxaflutole.

GC-MS modification D of method 00473 was used in the Mexican sugarcane supervised residue trials (dated November 2000) [Gough, 2000, M-238729-01-1]. Modifications involved changes in sample types and diazomethane methylation. Homogenised samples of sugarcane billets (12.5 g) were extracted with 3×125 mL MeOH (3×125 mL). The last DCM phase was drained through anhydrous Na_2SO_4 . After addition of diazomethane, IFT-BA was methylated to RPA 204497 (30 min, room temperature) and the sample was evaporated to dryness. The residue was redissolved in DCM and cleaned-up on a Florisil cartridge. The analytes were eluted with an EtOAc/DCM (1:1, v/v). The eluent was evaporated to dryness and redissolved in DCM.

GC-MS modification D of method 00473 was validated for sugarcane billets [Gough, 2000, M-238729-01-1]. Samples were fortified separately with IFT, IFT-DKN or IFT-BA. Only limited

validation results are available. Average recoveries at 0.01, 0.02, 0.05, 0.1 mg/kg analyte were within 70–120% limits (n=1–4 each), except for IFT at 0.01 mg/kg (128%, n=2) and IFT-DKN at 0.01 mg/kg (122%, n=2). The RSD was within 20% at 0.02 mg/kg IFT and at 0.01 mg/kg IFT-DKN or IFT-BA; the RSD was not verified at other levels. This is considered acceptable, since the residue levels in the trials are at LOQ. Linearity was not verified, since this is covered by the original method. No interfering peaks > LOQ (i.e. 0.01 mg/kg) were detected in any of the control extracts (n > 2). The valid LOQ is 0.01 mg/kg for isoxaflutole related residues, expressed as isoxaflutole.

Overall, GC-MS method 00473 and its modifications are considered fit for purpose:

- The original method is considered valid at 0.01–0.2 mg/kg total residues in maize forage, maize grain and maize fodder.
- Modification A is considered valid at 0.01 mg/kg total residues in sugarcane billets and sugarcane forage.
- Modification B is considered valid at 0.01–0.1 mg/kg total residues in dry chickpea seeds, chickpea forage and chickpea straw. However, since residue values for chickpea forage in the supervised trials ranged from < 0.01–0.19 mg/kg, validation at higher levels is desirable.
- Modification C is considered valid at 0.01–0.02 mg/kg total residues in sugarcane billets.
- Modification D is considered valid at 0.01–0.02 mg/kg total residues in sugarcane billets.

HPLC-MS-MS method CAL#19-03 and its modifications

HPLC-MS-MS method CAL#019-03, revision 1, issued 29 December 1998, allows the individual determination of IFT and its metabolites IFT-DKN and IFT-BA in plant commodities [Wickremesinhe, 1998a, M-286215-01-1]. Revision 1 differs from the original version (issued on August 18, 1998) in that it includes the results from the validation study [Wickremesinhe, 1998b, M-240820-01-1]. Homogenised samples (10 g) were mixed with 10 mL 1% formic acid and left for 5–10 min (to hydrate dry matrices and to stabilize isoxaflutole). The sample mixture was extracted with 90 mL MeOH and homogenised. The filtered extract was acidified (1 M HCl) and 10% NaCl was added. The extract was purified by liquid-liquid partitioning into methylene chloride. After acidification with 1% formic acid, the methylene chloride phase was evaporated to the aqueous remainder. The residue was diluted with 1% formic acid and further purified by solid-phase extraction (RP 102 column) using 40–70% ACN in water. Two fractions were collected: fraction 1 contained IFT-DKN and IFT-BA and fraction 2 contained IFT. Fractions were adjusted to 100 mL with ACN and water to contain 40% ACN in water. Quantification was performed by HPLC-MS-MS analysis. A turbo-ion interface (atmospheric pressure ionization) was used for the analysis of fraction 1 (with IFT-DKN and IFT-BA), whereas a heated nebulizer interface was used for the analysis of fraction 2 (with IFT, to avoid matrix suppression). The mass transitions monitored were m/z 358 → 79 for IFT-DKN and m/z 267 → 159 for IFT-BA (fraction 1) and m/z 358 → 79 for IFT (fraction 2). For all analytes quantification was done using external calibration with standards in solvent.

HPLC-MS-MS method CAL#019-03, revision 1, was used in the 1998 supervised residue trials on maize in the US [Mickelson, 1999a, M-240663-01-1]. HPLC-MS-MS method CAL#019-03, was validated according to the full validation scheme for maize grains, maize flour, wheat straw and mustard leaves [Wickremesinhe, 1998b, M-240820-01-1]. Samples were fortified with a mixture of IFT, IFT-DKN or IFT-BA. Average recoveries at 0.01 and 0.10 mg/kg (n=5 each) were within 70–120% limits and RSDs were within 20% for each analyte and matrix. An exception is wheat straw at 0.10 mg/kg IFT-BA with an average recovery of 65% (n=5, range 62–72%). Additional limited validation data are available in the supervised residue trials [Mickelson, 1999a, M-240663-01-1]. Average recoveries at 0.01, 0.1 and 10 mg/kg (n=2 each) in maize forage and maize fodder were within 70–120% limits for each analyte. Linearity (correlation coefficient $r > 0.99$) was observed in the range of 0.5–5 ng/mL using four duplicate standards in solvent. A 0.5–5 ng/mL standard is equivalent to 0.005–0.05 mg/kg in the sample. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control samples. The valid LOQ is 0.01 mg/kg for each analyte. After validation, the validation results were included in the method description and the method became revision 1.

Modification A of HPLC-MS-MS method CAL#019-03 was used in the field rotational crop study for matrices with low moisture content (fodder, hay, straw and grains) [Mickelson, 2000, M-240710-01-1]. Modifications involved changes in extraction. Low moisture samples (5 g) were extracted with 20 mL 1% formic acid and 100 mL MeOH (20:100, v/v). The extract was cleaned up as described in revision 1 of the method. Final fractions were adjusted to 50 mL instead of 100 mL. Only limited concurrent recovery data (n=1/level, at 0.01–0.05–0.5 mg/kg, within 70–120%, all analytes) are available for wheat hay, wheat grains, wheat straw, soya bean seeds, soya bean hay, sorghum grains and sorghum fodder. Recoveries are not satisfactory for IFT-BA in wheat hay (62%, n=1, 0.01 mg/kg), wheat straw (68%, n=1, 0.01 mg/kg) and soya bean seeds (64%, n=1, 0.01 mg/kg). No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control samples.

Modification B of HPLC-MS-MS method CAL#019-03 was used in the field rotational crop study on fresh commodities [Mickelson, 2000, M-240710-01-1]. Modifications involved only minor changes in the RP102 clean-up part of the method. Only limited concurrent recovery data are available for mustard leaves, turnip roots, turnip tops, wheat forage, soya bean forage, radish roots, radish tops, sorghum forage (at n=1/level, 0.01–0.05–0.5 mg/kg, within 70–120%, all analytes). Recoveries are not satisfactory for IFT-BA in turnip tops (69%, n=1, 0.01 mg/kg) and wheat forage (69%, n=1, 0.01 mg/kg). Linearity (coefficient of correlation $r > 0.99$) was observed in the range of 0.5–5 ng/mL using four single standards in solvent. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control samples.

Modification C of HPLC-MS-MS method CAL#019-03 was used in the 2005 and 2006 Canadian and US supervised field trials on maize [Fischer and Helfrich, 2007, M-285889-01-1; Vaughn and Cosgrove, 2007, M-286216-02-1]. Modifications involved changes in extraction, addition of internal standards and omission of the RP 102 clean-up step and a different MS system. Homogenised samples (5 g) were extracted with 10 mL 1% formic acid and 90 mL MeOH. Mixed internal standards ($^{13}\text{C}_6$ -IFT, $^{13}\text{C}_6$ -IFT-DKN, $^{13}\text{C}_6$ -IFT-BA, and 0.025 mg/L each) were added together with the HCl solution. After liquid-liquid partition, the DCM phase was acidified with 1% formic acid and evaporated to 1 mL. The sample was diluted with 1% aqueous formic acid solution and ACN (50:50 or 60:40, v/v, 100 mL). A 0.1 mL aliquot was used for injection. HPLC-MS-MS with electrospray ionization was used for the analysis of IFT, IFT-DKN and IFT-BA. The mass transitions monitored were m/z 358 $\rightarrow$ 79 for IFT, m/z 358 $\rightarrow$ 79 for IFT-DKN and m/z 267 $\rightarrow$ 159 for IFT-BA as well as the mass transitions for their ^{13}C isotopes.

Modification C of HPLC-MS-MS method CAL#019-03 was validated according to a reduced scheme for maize forage, maize grains and maize fodder [Fischer and Helfrich, 2007, M-285889-01-1]. Samples were fortified separately with IFT, IFT-DKN or IFT-BA. Average recoveries at 0.01 mg/kg (n=14–22) and 0.20 mg/kg (n=3, IFT) or 0.27 mg/kg (n=3, IFT-DKN, IFT-BA) were within 70–120% limits for each analyte. The RSD was within 20%, except for IFT-DKN and IFT-BA at 0.01 mg/kg in maize forage (24%, 21%) and for IFT-BA at 0.01 mg/kg in maize fodder (27%). Linearity (1/ $\times$ weighted, correlation coefficient $r > 0.99$) was observed in the range of 0.002–2.0 mg/kg using seven duplicate standards in solvent with internal standards. No interfering peaks > LOD (i.e. 0.003 mg/kg IFT, 0.005–0.007 mg/kg IFT-DKN, 0.006–0.01 mg/kg IFT-BA) were detected in any of the control extracts (n> 2), except 0.007 mg/kg IFT-BA in maize grain. Based on these results, the valid LOQ is 0.01 mg/kg for IFT, 0.02 mg/kg for IFT-DKN and 0.03 mg/kg for IFT-BA.

Conclusion: HPLC-MS-MS method CAL#19-03 is generally insufficiently validated. Modification C needs adaption of LOQs to 0.02 mg/kg for IFT-DKN and 0.03 mg/kg for IFT-BA. Additional validation data are needed for commodities analysed in the field rotational crop study:

- Revision 1 is considered valid at 0.01–0.10 mg/kg IFT, IFT-DKN and IFT-BA in maize grains, maize flour, mustard leaves, maize forage and maize fodder. The method is not valid in wheat straw. Since IFT-BA levels in the supervised trials on maize forage were in the range < 0.01–0.15 mg/kg, validation at higher levels is desirable.
- Modification A is considered insufficiently validated. Additional validation data for the commodities analysed in the field rotational crop study are needed.

- Modification B is considered insufficiently validated. Additional validation data for the commodities analysed in the field rotational crop study are needed.
- Modification C is considered valid at 0.01–0.2 mg/kg IFT, 0.02–0.3 mg/kg IFT-DKN and 0.03–0.3 mg/kg IFT-BA in maize forage, maize grains and maize fodder. Results below 0.02 mg/kg IFT-DKN and below 0.03 mg/kg IFT-BA in the supervised field trials need to be reported as < 0.02 mg/kg IFT-DKN and < 0.03 mg/kg IFT-BA.

HPLC-MS-MS method 00985/M001

HPLC-MS-MS method 00985/M001, version 13 November 2006, was developed to determine individual residues of IFT and its metabolites IFT-DKN and IFT-BA in plant materials [Schoening and Wolters, 2006, M-280607-01-1]. Samples (10 g) were extracted with MeOH/1% formic acid (90:10, v/v). After filtering, the corresponding $^{13}\text{C}_6$ labelled analytes were added. The solution was made up to volume with water (pH 3, using formic acid) and MeOH. An aliquot of the extract was 5× diluted with water/ACN (90/10, v/v, pH 3 using formic acid), filtered and subjected to HPLC-MS-MS analysis with electrospray ionisation. For quantification external calibration with standard solutions was used quoting the peak area ratio of the analytes and the corresponding isotopically labelled internal standards. Quantification was carried out by monitoring the ion transitions m/z 360/366 → 251/257 (IFT), m/z 358/364 → 79/79 (IFT-DKN) and m/z 267/273 → 159/165 (IFT-BA).

HPLC-MS-MS method 00985/M001 was used in the EU maize and poppy seed trials [Zimmer and Wieland, 2007, M-282674-01-1; Wolters and Erler, 2007a/b, M-284416-01-1, M-284423-01-1; Wolters, 2007a/b, M-285005-01-1, M-285014-01-1; Zimmer, 2006, M-281611-01-1; Billian and Reinecke, 2010, M-360144-02-1; Billian and Krusell, 2010a/b, M-364166-01-1, M-360114-02-1; Noss and Reinecke, 2010, M-366025-01-1]. HPLC-MS-MS method 00985/M001 was validated according to the full validation scheme for maize grains, maize forage and sweet corn (cobs without husks) [Schoening and Wolters, 2006, M-280607-01-1] and poppy seeds [Billian and Reinecke, 2010, M-360144-02-1]. Grinding of poppy seeds led to residues about a factor 2 higher compared to non-grinded seeds. Therefore, poppy seeds need to be grinded prior to extraction (e.g. 30 sec using an IKA A11 basic mixer or pestling by hand). Samples were fortified with a mixture of IFT, IFT-DKN or IFT-BA. Average recoveries at 0.01 mg/kg and 0.10 mg/kg were within 70–120% limits and RSDs were within 20% for each analyte and matrix. Linearity (coefficient of correlation $r > 0.99$ for $1/\times$ weighted) was observed in the range of 0.01–50 ng/mL standards using nine single solvent standards and internal standards at 1 ng/mL. Equivalent concentrations in the samples were not stated. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts. The valid LOQ is 0.01 mg/kg for each analyte in all matrices tested.

Conclusion: HPLC-MS-MS method 00985/M001 is considered valid at 0.01–0.10 mg/kg IFT, IFT-DKN and IFT-BA in maize grains, maize forage, sweet corn (cobs without husks) and poppy seeds (which need to be grinded prior to extraction). Additional validation data are needed for maize fodder. Since IFT and IFT-DKN levels in the supervised residue trials on maize forage ranged from < 0.01 –13 mg/kg and < 0.01 –2.6 mg/kg, respectively, validation at higher levels is desirable.

HPLC-MS-MS method IS-004-P10 and its modifications

HPLC-MS-MS method IS-004-P10-01, issued 18 February 2010, was developed for the analysis of IFT and IFT-DKN in plant matrices [Stoughton, 2010a, M368825-01-1]. Homogenized samples (5 g) were extracted by blending with a 1% aqueous formic acid/MeOH (5:20, v/v) solution. The extraction was repeated with MeOH. The extract was filtered using a Bond Elute cartridge. An isotopic internal standard mixture ($^{13}\text{C}_6$ -IFT, $^{13}\text{C}_6$ -IFT-DKN, 1 mg/L each) was added to the extract. An aliquot of the sample was then diluted 1:1 with 0.1% formic acid in water. The sample was analysed by HPLC-MS-MS for IFT and IFT-DKN. Quantification was based on the use of internal standards and comparisons of peak areas with those of known standards. The detection by MS-MS was performed with a turbo ion spray interface operated in positive ion mode and multiple reaction monitoring (MRM): m/z 360 to 251 for IFT and m/z 358 to 79 for IFT-DKN.

HPLC-MS-MS method IS-004-P10-01 was used in soya bean residue trials [Dallstream and Fisher, 2010, M-368661-01-1; Beedle and Dallstream, 2010, M-368669-01-1]. HPLC-MS-MS method IS-004-P10-01 was validated according to the full validation scheme for soya bean seed [Stoughton, 2010c, M-368828-01-1]. Samples were fortified with a mixture of IFT and IFT-DKN. Average recoveries at 0.01 mg/kg and 0.10 mg/kg were within 70–120% limits and RSDs were within 20% for each analyte in soya bean seeds. Linearity (coefficient of determination $R^2 > 0.99$) was observed in the range of 0.12–9.0 ng/mL using seven duplicate solvent standards. Equivalent concentrations in the samples were 0.0024–0.180 mg/kg. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts. The valid LOQ is 0.01 mg/kg for each analyte. On completion of the validation study, method IS-004-P10-01 was updated to include the confirmatory MRM transitions m/z 358 to 64 for IFT and m/z 358 to 64 for IFT-DKN. The updated method was issued and assigned a method number of IS-004-P10-02 (dated 12 May 2010) [Stoughton 2010b, M368826-01-1].

Modification A of HPLC-MS-MS method IS-004-P10-01 was used in soya bean processing studies [Fischer, 2010, M-368662-01-1]. The modification involved changes in sample type and sample weight. Samples of 5 g soya bean seed, soya bean meal, soya bean hulls, soya bean oil, soymilk or 1.0 g for soya bean aspirated grain fractions were homogenised before extraction.

Modification A of HPLC-MS-MS method IS-004-P10-01 was validated according to a reduced validation scheme for soya bean seed, soya bean meal, soya bean hulls, soya bean oil, soymilk and soya bean aspirated grain fractions [Fischer, 2010, M-368662-01-1]. Samples were fortified with a mixture of IFT and IFT-DKN. Average recoveries at 0.01 mg/kg ($n=3$) and 0.10 mg/kg ($n=3$) or 0.5 mg/kg ($n=2$, aspirated grain fractions) were within 70–120% limits and RSDs were within 20% for each analyte and matrix. Linearity (correlation coefficient $r > 0.99$) was observed in the range of 0.0–9.0 ng/mL using seven duplicate solvent standards. Equivalent concentrations in the samples were 0.0–0.180 mg/kg. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts. The valid LOQ is 0.01 mg/kg for each analyte and matrix.

Modification B of HPLC-MS-MS method IS-004-P10-01 was used in storage stability studies [Klasmeier, 2012, M-442915-01-1]. The modification involved changes in extraction and addition of filtration steps. Homogenized samples (5 g) were extracted by blending once with a 1% aqueous formic acid/MeOH (10:40, v/v) solution. The extract was filtered on glass wool. Just prior to analysis the sample was filtered with 0.45 μ m Nylon filter. The detection by MS-MS was performed with a turbo ion spray interface operated in positive ion mode at m/z 360.1 to 250.9 and 219.8 for isoxaflutole and in negative ion mode at m/z 358.0 to 79.0 and 64.0 for IFT-DKN for quantification and confirmation.

Modification B of HPLC-MS-MS IS-004-P10-01 was partially validated for oranges, soya bean seeds, dry pinto beans and sugarcane billets [Klasmeier, 2012, M-442915-01-1]. Samples were fortified separately with isoxaflutole or IFT-DKN. Average recoveries at 0.1 mg/kg ($n=3$) were within 70–120% limits for each analyte. The RSD was within 20%. Recoveries at the LOQ were not verified, but this is considered acceptable for the storage stability studies at 0.1 mg/kg. Linearity ($1/\times$ weighted, correlation coefficient $r > 0.99$) was observed in the range of 0.12–9.0 ng/mL using five single standards in solvent with internal standards. No interfering peaks $> LOD$ (i.e. 0.003 mg/kg) were detected in any of the control extracts ($n > 2$).

Conclusion: HPLC-MS-MS method IS-004-P10 and its modifications are considered fit for purpose:

- The original method is considered valid at 0.01–0.1 mg/kg in dry soya bean seed.
- Modification A is considered valid at 0.01–0.1 mg/kg in dry soya bean seed, soya bean meal, soya bean hulls, soya bean oil, soymilk and 0.01–0.5 mg/kg in soya bean aspirated grain fractions.
- Modification B is considered valid at 0.1 mg/kg in oranges, dry soya bean seeds, dry pinto beans, and sugarcane billets.

HPLC-MS-MS method ATM-0054.01

HPLC-MS-MS method ATM-0054.01, version August 2011, was developed to determine individual residues of IFT, IFT-DKN and IFT-BA in plant materials [Ellis, 2012, M-425905-02-1]. Homogenised samples (10 g) were extracted with 20:80 water:ACN. An aliquot of the extract was reduced to dryness and reconstituted in water acidified with 0.22% formic acid. The reconstituted sample was then filtered and subjected to analysis by HPLC-MS-MS. Quantitation was achieved using matrix matched analytical standards and $^{13}\text{C}_6$ -labelled internal standards for isoxaflutole, diketonitrile metabolite and the benzoic acid metabolite. The monitored ion transitions were m/z 360 $\rightarrow$ 251 for IFT, m/z 358 $\rightarrow$ 79 for IFT-DKN and m/z 267 $\rightarrow$ 159 for IFT-BA. The metabolites are not expressed as isoxaflutole equivalents.

HPLC-MS-MS method ATM-0054.01 was validated according to the full validation scheme for oat grain, lupin seed, and mung bean forage [Ellis, 2012, M-425905-02-1]. Samples were fortified with a mixture of IFT, IFT-DKN and IFT-BA. Average recoveries at 0.01 mg/kg and 1.0 mg/kg were within 70–120% limits and RSDs were within 20% for each analyte and matrix. Linearity (coefficient of correlation $r > 0.999$ for $1/\times$ weighted) was observed in the range of 0.5–150 $\mu\text{g/L}$ using five single matrix matched standards. Equivalent concentrations in the samples were not stated. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control samples. The valid LOQ is 0.01 mg/kg for each analyte and matrix tested.

Modification A HPLC-MS-MS method ATM-0054.01 was used in the Australian chickpea trials [Ellis, 2012, M-425905-02-1]. The method modification involved using less sample material (5 g), increased extraction volumes and modified aliquots for further analysis.

Modification A was validated according to a full validation scheme for chickpea seeds and chickpea straw and a reduced validation scheme for chickpea forage [Ellis, 2012, M-425905-02-1]. Samples were fortified with a mixture of IFT, IFT-DKN or IFT-BA. Average recoveries at 0.01 mg/kg and 1.0 mg/kg were within 70–120% limits and RSDs were within 20% for each analyte and matrix. Linearity (coefficient of correlation $r > 0.999$ for $1/\times$ weighted) was observed in the range of 0.5–150 $\mu\text{g/L}$ using six single matrix matched standards. Equivalent concentrations in the samples were not stated. No interfering peaks were detected in any of the control samples (< 0.01 mg/kg for each analyte). The valid LOQ is 0.01 mg/kg for each analyte and matrix tested and 0.03 mg/kg for total residues.

Conclusion: HPLC-MS-MS method ATM-0054.01 and its modifications are considered fit for purpose:

- The original method is considered valid at 0.01–0.1 mg/kg in oat grain, lupin seed, and mung bean forage.
- Modification A is considered valid at 0.01–0.1 mg/kg in dry chickpea seeds, chickpea forage and chickpea straw. Since IFT-BA levels in the supervised trials on chickpea forage ranged from < 0.01 –0.55 mg/kg and in chickpea straw ranged from < 0.01 –0.12 mg/kg, validation at higher levels is desirable.

*Analytical methods used in study reports in animal commodities**HPLC-UV method RPAC #44882*

HPLC-UV method RPAC #44882, version 2.0, 27 October 1995, was developed to determine individual residues of IFT and its metabolites IFT-DKN, RPA 205834, and IFT-BA in milk [Tew, 1995a, M-192311-01-1]. The method was used in dairy cow feeding studies [Tew, 1995a, M-192311-01-1] and storage stability studies in milk [Lowder, 1996, M-192281-01-2-01]. The method is identical to HPLC-UV method RPAC #45532 for milk except that fraction 1, containing IFT-BA, is kept. Validation results for IFT, IFT-DKN, RPA 205834 and IFT-BA are available in the section describing method RPAC #45532.

HPLC-UV method RPAC #44933

HPLC-UV method RPAC #44933, version 2.0, 17 November 1995 was developed to determine metabolite IFT-DKN in eggs [Tew, 1995b, M-192317-01-1]. The method is identical to HPLC-UV method RPAC #45532 for eggs and was used in laying hen feeding studies [Tew, 1995b, M-192317-01-1] and storage stability studies in eggs [Lowder, 1996, M-192281-01-2-01]. Validation results for IFT-DKN are available in the section describing method RPAC #45532.

HPLC-MS-MS method RPAC #44996 and its modifications

HPLC-MS-MS method RPAC #44996, version 1.0, 4 December 1995, was developed to determine RPA 207048 in animal tissues [Tew, 1995a/b, M-192311-01-1, M-192317-01-1, Lowder, 1996, M-192281-01-2-01]. Samples (25 g) were extracted twice with 0.1% aqueous trifluoroacetic acid and ACN (25:90, v/v). The combined filtered extracts were washed with hexane. A portion of the extract was reduced by evaporation and then diluted with NaCl solution. Residues are then partitioned into DCM and drained through anhydrous Na₂SO₄. The DCM phase was evaporated and the remaining residue was dissolved in water/ACN (80:20) prior to quantification by HPLC-MS-MS. Matrix matched standards were used to compensate for any matrix effects that may enhance or depress the analyte signal. The ion transitions monitored were 361/79 (RPA 207048).

HPLC-MS-MS method RPAC #44996, version 1.0 also provided good results for the parent compound and metabolites IFT-DKN and RPA 205834. Therefore the method was rewritten as HPLC-MS-MS method RPAC 44996, version 2.0, 29 January 1996, to incorporate these metabolites as well [Hudson *et al.*, 1996, M-262714-01-1]. The ion transitions monitored were 358/79 (IFT), 361/79 (RPA 207048), 358/79 (IFT-DKN), and 360/79 (RPA 205834). During sample extraction and clean-up, parent IFT is partially degraded to IFT-DKN. Parent IFT is only stable at pH 2; metabolite RPA 207048 is unstable at pH 2. Since the method measures IFT and IFT-DKN, any degradation of IFT is measured as increased IFT-DKN, so that the entire amount of residue in the original sample is measured even though the character of the residue may have changed. For this reason, separate samples need to be prepared for verification of recovery for IFT, since residues will appear as IFT and its metabolite IFT-DKN.

HPLC-MS-MS method #44996 was used during the conduct of the dairy cow feeding studies, the laying hen feeding studies and storage stability studies in animal tissues [Tew, 1995a/b, M-192311-01-1, M-192317-01-1, Lowder, 1996, M-192281-01-2-01]. The method was validated by either fortifying IFT alone, or a mixture of IFT-DKN, RPA 207048, and RPA 205834. The recoveries for IFT were measured by summing up residues of IFT and IFT-DKN. Concurrent recovery results from the cow and hen feeding studies are summarized in the validation report [Hudson *et al.*, 1996, M-262714-01-1]. Only limited recovery data (n=1–2/level, within 70–120%) are available for IFT, IFT-DKN, RPA 205834 and RPA 207048 in bovine liver (0.05, 0.25 and 2.0 mg/kg), bovine kidney (0.05, 0.45 and 0.60 mg/kg), bovine muscle (0.05 mg/kg only), bovine fat (0.05 mg/kg only), chicken liver (0.05, 0.45, 0.60 and 1.0 mg/kg), chicken muscle (0.05 mg/kg only) and chicken skin plus fat (0.05 and 0.45 mg/kg). An RSD within 20% was found for IFT in bovine liver at 0.05 mg/kg (n=3) and for IFT-DKN in chicken liver at 0.05 mg/kg (n=3). Additional recovery and precision data are available from the storage stability study. Average recoveries at 0.25 mg/kg for each analyte were within 70–120% limits and RSDs were within 20% for each analyte and matrix. Linearity (coefficient of correlation $r > 0.99$) was observed in the range of 0–150 ng/mL or 0–75 ng/mL using 6–7 single matrix matched standards. Equivalent concentrations in the samples were not stated. No interfering peaks were detected in any of the control samples (< 0.05 mg/kg for each analyte). The reported LOQ is 0.05 mg/kg for each analyte and matrix tested, but precision data at this level are not available (except in chicken and bovine liver).

Conclusion: HPLC-MS-MS method #44996 is considered suitable for determination of IFT, IFT-DKN, RPA 205834 and RPA 207048 in animal tissues. However, the method is considered insufficiently validated. Validation is sufficient at 0.25 mg/kg for each analyte and each tissue. Additional validation data are needed for muscle, kidney, and fat in order to establish precision at the

reported LOQ of 0.05 mg/kg, since only 1–2 recoveries were available. Isoxaflutole is partly degraded because of extraction conditions, but is measured as an increased amount of IFT-DKN.

Since residue levels in the feeding studies ranged from < 0.05–0.503 mg/kg for IFT-DKN in bovine kidney, < 0.05–1.84 mg/kg for IFT-DKN in bovine liver, 0.123–0.645 mg/kg for IFT-DKN in hen liver, < 0.05–0.810 mg/kg for RPA 205834 mg/kg in bovine liver, additional validation at higher levels is desirable for kidney and liver.

Because the extraction solvent resembles the extraction solvent used in HPLC-UV method RPAC #45532 for milk and eggs, the method is possibly also suitable for milk and eggs; validation data on these commodities are desirable.

Stability of pesticide residues in stored analytical samples

The Meeting received information on storage stability of parent and its metabolites IFT-DKN and IFT-BA in plant commodities. In addition the Meeting received information on storage stability of parent and its metabolites IFT-DKN, RPA 205834 and RPA 207048 in animal commodities.

Study 1

Storage stability was investigated in maize commodities [Nandihalli, 1996, M-089371-01-1]. Homogenized untreated sample materials (25 g each) were independently spiked with IFT, IFT-DKN and IFT-BA. Fortification levels were 0.210 mg/kg for maize forage and maize fodder, 0.105 mg/kg for maize grain. The samples were stored at –10 °C or lower for 15 months. Samples were analysed in duplicate at various intervals using GC-MS method 00473 (common moiety method), where IFT, IFT-DKN and IFT-BA are converted into RPA 204497 (and expressed as spiked analyte). Average concurrent recoveries at 0.21 mg/kg for maize silage and maize fodder and at 0.105 mg/kg for maize grain were within 70–120%. Levels in control samples were < 0.003 mg/kg (0.3 LOQ).

During the storage period the temperature increased to –5.5 to –3.9 °C on two consecutive days, –0.4 to +2.0 °C on two consecutive days and –8.2 to –2.2 °C on four consecutive days. Since the samples remained frozen, this deviation did not significantly affect the results of the study. Storage stability results and concurrent recoveries are shown in Table 37. The presented results for the stored samples are not corrected by the concurrent (freshly spiked) recoveries.

Conclusion: The storage stability results indicate that there were no significant losses of total isoxaflutole residues (sum of IFT, IFT-DKN and IFT-BA) in maize grains, maize forage and maize fodder stored at –10 °C for at least 15 months. Any degradation from IFT to IFT-BA or from IFT-DKN to IFT-BA remains undetected, because of the common moiety method used.

Table 37 Storage stability of 0.1–0.2 mg/kg IFT, IFT-DKN or IFT-BA in frozen maize commodities at –10 °C

Study 2

Storage stability was investigated in chickpea commodities [Lynch and Keats, 1999b, M-432374-01-1, Lynch and Keats, 2000a, M-432434-01-1]. Homogenized untreated sample materials of chickpea forage, chickpea seeds and chickpea straw were independently spiked with IFT, IFT-DKN and IFT-BA at a fortification level of 0.10 mg/kg. The samples were stored at -20°C for 11 months. Samples were analysed in triplicate at various intervals using GC-MS-MS modification B of method 00473 (common moiety method), where IFT, IFT-DKN and IFT-BA are converted into RPA 204497 (and expressed as spiked analyte). Average concurrent recoveries at 0.01 mg/kg were within 70–120% for each analyte and matrix. Levels in control samples were < 0.003 mg/kg (0.3 LOQ).

Storage stability results and concurrent recoveries are shown in Table 38. Presented results for the stored samples are not corrected by the concurrent (freshly spiked) recoveries.

Conclusion: The storage stability results indicate that there were no significant losses of total isoxaflutole residues (sum of IFT, IFT-DKN and IFT-BA) in chickpea forage, chickpea seeds or chickpea straw stored at -20°C for at least 11 months. Any degradation from IFT to IFT-BA or from IFT-DKN to IFT-BA remains undetected, because of the common moiety method used.

Table 38 Storage stability of 0.1 mg/kg IFT, IFT-DKN or IFT-BA in chickpea commodities at -20°C

Commodity	Storage time	IFT % remaining mean, n=3	IFT concurrent recovery mean, n=3	IFT-DKN %remaining, mean, n=3	IFT-DKN concurrent recovery mean, n=3	IFT-BA % remaining mean, n=3	IFT-BA concurrent recovery, mean, n=3
Chickpea forage	3 days	78	79	78	75	78	81
	11 months	73	95	73	72	73	99
Chickpea grain	3 days	76	78	76	76	76	82
	11 months	78	80	78	75	78	87
Chickpea straw	3 days	73	79	73	77	73	76
	11 months	74	80	74	82	74	87

Study 3

Storage stability was investigated in sugarcane commodities [Davis and Keats, 1999e/f, M-284408-01-1, M-284324-01-1] Homogenised untreated samples of sugarcane billets and sugarcane forage were independently spiked with IFT, IFT-DKN and IFT-BA at a fortification level of 0.10 mg/kg eq. The samples were stored at -20°C for a period of 20 months. Samples were analysed in duplicate at various intervals using GC-MS modification A of method 00473 (common moiety method), where IFT, IFT-DKN and IFT-BA are converted into RPA 204497 and residues were expressed as isoxaflutole equivalents. Average concurrent recoveries at 0.01 mg/kg eq were within 70–120% for each analyte and matrix. Levels in control samples were < 0.01 mg/kg (LOQ).

Storage stability results and concurrent recoveries are shown in Table 39. The presented results for the stored samples are not corrected by the concurrent (freshly spiked) recoveries.

Conclusion: The storage stability results indicate that there were no significant losses of total isoxaflutole residues (sum of IFT, RPA 202238 and IFT-BA) in sugarcane billets or sugarcane forage stored at -20°C for at least 20 months. Any degradation from IFT to IFT-BA or from IFT-DKN to IFT-BA remains undetected, because of the common moiety method used.

Table 39 Storage stability of IFT, IFT-DKN and IFT-BA in sugarcane commodities

Commodity	Storage time months	IFT % remaining mean, n=2-4 ^a	IFT concurrent recovery mean, n=5	IFT-DKN % remaining mean, n=2-4 ^a	IFT-DKN concurrent recovery, mean, n=5	IFT-BA % remaining mean, n=2-4 ^a	IFT-BA concurrent recovery, mean, n=5

^a mean of two replicates for sugarcane, mean of four replicates for forage

Study 4

Storage stability was investigated in oranges, soya bean seeds, dry pinto beans, and sugarcane billets [Klasmeier, 2012, M-442915-01-1]. Homogenized untreated sample materials were individually spiked with IFT and IFT-DKN at a fortification level of 0.1 mg/kg. The samples were stored at -10°C or lower for a period of 6 months. Samples were analysed in duplicate at various intervals using modification B of HPLC-MS-MS method IS-004-P10-01. Average concurrent recoveries for mixtures of IFT and IFT-DKN each at 0.1 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.003 mg/kg (0.3 LOQ).

Storage stability results and concurrent recoveries are shown in Table 40. The presented results for the stored samples are not corrected for the concurrent (freshly spiked) recoveries.

Additional results for this storage stability are available covering a storage period of 374-377 days (see Table 40) but there is no corresponding report available yet [Bayer, 2013].

Conclusion: After 3 months of storage at -10°C , IFT partially converts to IFT-DKN in dry pinto beans while this conversion was observed at 6 months for oranges, soya bean seeds and sugarcane billets. Total residues (sum of IFT and IFT-DKN) and IFT-DKN alone remained stable for at least 1 year in each matrix tested. Storage stability of IFT-BA alone or further degradation of IFT or IFT-DKN to IFT-BA was not verified, but this is considered desirable.

No storage stability studies have been conducted on chickpea seeds, chickpea forage, chickpea straw, sweetcorn, maize forage, maize grains and maize fodder. Most of these commodities can be extrapolated from the present data: dry chickpea seeds vs dry pinto beans, chickpea forage vs sugarcane billets, sweetcorn vs sugarcane billets and maize forage vs sugarcane billets. Storage stability data on chickpea straw, maize grains and maize fodder cannot be extrapolated; these are desirable. Since maize forage, maize grains, maize fodder in the supervised residue trials have been stored for 593, 544 and 546 days, respectively, storage stability data for longer periods are desirable.

Table 40 Storage stability of IFT and IFT-DKN in various commodities

Commodity	Storage time days	IFT % remaining mean, n=2	IFT concurrent recovery mean, n=2-3	IFT-DKN % remaining mean, n=2	IFT-DKN concurrent recovery, mean, n=2-3
Oranges	0	-	88	-	73
	31	91	92	71	79
	96	88	93	75	93
	188	74 (IFT) + 21 (IFT-DKN) = 95 ^a	88	70	87
	377 ^b	74 (IFT) + 19 (IFT-DKN) = 93 ^a	89	79	87
Pinto beans	0	-	95	-	81
	36	71	97	80	92
	94	58 (IFT) + 31 (IFT-DKN) = 90 ^a	88	75	90
	184	49 (IFT) + 36 (IFT-DKN) = 85 ^a	71	77	73
	374 ^b	48 (IFT) + 41 (IFT-DKN) = 89 ^a	70	75	74

Commodity	Storage time days	IFT % remaining mean, n=2	IFT concurrent recovery mean, n=2-3	IFT-DKN % remaining mean, n=2	IFT-DKN concurrent recovery, mean, n=2-3
Soya bean seeds	0	—	81	—	74
	35	76	94	66	79
	94	72	84	75	84
	183	58 (IFT) + 24 (IFT-DKN) = 82 ^a	86	78	86
	374 ^b	51 (IFT) + 31 (IFT-DKN) = 82 ^a	72	70	70
Sugarcane billets	0	—	93	—	75
	29	82	80	72	75
	95	94	92	77	92
	185	76 (IFT) + 9.0 (IFT-DKN) = 86 ^a	89	78	88
	375 ^b	78 (IFT) + 12 (IFT-DKN) = 90 ^a	88	81	91

^a Due to apparent partial conversion of IFT to IFT-DKN during storage, the recovery value reflects the sum of IFT and IFT-DKN (in isoxaflutole equivalents)

^b Additional results are available but there is no corresponding report available yet [Bayer, 2013].

Study 5

Storage stability was investigated for incurred residues in poppy seeds and poppy straw [Klempner, 2010, M-366215-01-1-01]. Poppy seeds and straw originated from the poppy metabolism study [Klempner, 2009, M1731775-1] where 100 g [phenyl-UL-14C]-Isoxaflutole per hectare was applied onto the bare soil (pre-emergence application). Samples from this study were stored at -18°C or lower. Samples were extracted and analysed after 16.1 months of storage by HPLC-UV with radiodetection. The method used in the storage stability study was the same method used in the metabolism study.

Aliquots of 20 g of the homogenised samples were extracted three times with a mixture of ACN/water (8/2, v/v). Extracts were combined and filtered by suction. The TRR values of the poppy matrices were determined by summing up the radioactivity determined in the combined extracts and the radioactivity in the remaining solids after extraction. The extracts were subjected to a clean-up step using an SPE RP 18 cartridge (Varian Mega Bond Elut C18). The flow-through fraction (percolate) was collected and mixed with emulsifier and/or defoamer and evaporated to the aqueous remainder (= final extract). The final extracts were analysed by HPLC-UV with radiodetection. Storage stability was assessed IFT-DKN and IFT-BA, because parent IFT was not detected in poppy matrices.

Comparison of the metabolic profiles of the poppy seeds and poppy straw from the metabolism study (extraction after 16 days of storage for seeds and 12 weeks of storage for straw) and at 16.1 months showed that the distribution of components did not significantly change during this storage period. No significant transformation of compounds was found in this storage period. Residue results from both studies are shown in Table 41.

Conclusion: The reference time point for this storage stability study is the first analysis day in the metabolism study: 16 days for poppy seeds and 12 weeks for poppy straw. Since the reference point for poppy seeds is shortly after harvest, levels of IFT-DKN and IFT-BA in poppy seeds can be considered stable for a period of at least 16 months. No conclusion can be drawn for the storage stability in poppy straw, since residues have not been measured shortly after harvest. Consequently it is not clear, whether the analytes had already been degraded to a plateau level at the start of the analysis (i.e. 12 weeks after harvest). No storage stability information is available for IFT, but this is considered desirable.

Table 41 Storage stability of incurred residues of IFT-DKN and IFT-BA in poppy seeds at -18 °C

Matrix	Storage period (days)	Origin	TRR mg/kg eq	IFT-DKN (mg/kg eq)	IFT-DKN % remaining ^a	IFT-BA (mg/kg eq)	IFT-BA % remaining ^a
Poppy seeds	16	metabolism study	0.056	–	–	0.037	–
	482	storage stab study	0.056	–	–	0.039	105
Poppy straw	84	metabolism study	0.725	0.026	–	0.643	–
	482	storage stab study	0.721	0.027	104	0.630	98

^a The concentrations found for isoxaflutole equivalent residue in the metabolism study were set to 100%.

Study 6

Homogenised samples of sorghum forage, sorghum fodder, sorghum grain, lettuce, radish leaves and radish roots were fortified with a mixture of 14C IFT, 14C-IFT-DKN and 14C-RPA203328 as total 2 mg/kg eq per sample [Hampton, 1996; M-192325-01-1]. Samples were stored at –20 °C for 700 days. Duplicate samples were subsequently extracted with hexane/EtOAc (9:1 v/v), ACN, water (pH 5.5) and ACN/0.2 M HCl (1:1 v/v). The pH for the water extraction was adjusted to pH 5.5, because at this pH hydrolysis of parent compound or conjugates did not occur. Radioactive residues in extracts were quantified by HPLC with radiodetection and co-chromatography of standards for IFT, IFT-DKN and IFT-BA.

Results are shown in Table 42. Extraction of day 0 spiked samples demonstrated a TRR of 99.3% present on average as 49% IFT, 33% IFT-DKN and 18% IFT-BA. After 700 days of storage the mean recovered TRR was 93.7% compared to 99.3% at day 0. The composition of the TRR changed. IFT was not sufficiently stable in storage, a decrease from 42.8–54.7% TRR (day 0) to 0.0–29.3% TRR after 700 days of storage was reported depending on matrix. Recovery for the intermediate metabolite IFT-DKN increased from 25.2–40.5% TRR (day 0) to 41.9–57.6% TRR (day 700) for most matrices, while a decrease of 34.2–40.5% TRR (day 0) to 26.4–31.4% TRR (day 700) was found in sorghum forage and sorghum grain. Also amounts of IFT-BA increased from 15.4–23.0% TRR at day 0 to 40.0–59.9% TRR after 700 days suggesting that degradation of Isoxaflutole to RPA202248 and subsequently from IFT-DKN to IFT-BA had occurred.

Conclusion: After 23 months of storage at –20 °C, isoxaflutole partially or completely converts to IFT-DKN and IFT-BA in sorghum forage, sorghum fodder, sorghum grain, lettuce, radish leaves and radish roots. Total residues (sum of IFT, IFT-DKN and IFT-BA) remained stable for at least 23 months. Storage stability of IFT-DKN alone or IFT-BA alone is masked by the isoxaflutole degradation. However, since the amount of IFT-BA increases with time, it indicates that IFT-DKN degrades further to IFT-BA. Storage stability studies with individual fortifications of IFT, IFT-DKN and IFT-BA are desirable.

Table 42 Storage stability of IFT, IFT-DKN and IFT-BA in various commodities

Commodity	Storage time days	TRR	IFT %TRR mean, n=2	IFT %remaining	IFT-DKN %TRR mean, n=2	IFT-BA %TRR mean, n=2	Sum ^a %TRR

^a Sum of IFT, IFT-DKN and IFT-BA

Study 7

Storage stability was investigated in animal commodities purchased from a local food vender [Lowder, 1996, M-192281-01-2]. Milk samples were fortified with IFT, IFT-DKN, RPA 205834 and IFT-BA at 0.1 mg/kg each. Egg samples were fortified with IFT-DKN at 0.25 mg/kg. Bovine liver, kidney, muscle and fat samples were fortified with IFT, IFT-DKN, RPA 205834 and RPA 207048 at 0.25 mg/kg each. The storage samples were spiked individually with each analyte. The samples were stored frozen at -20 °C for up to 4 months. Samples were analysed at various intervals using HPLC-UV method RPAC #44882 for milk, HPLC-UV method RPAC #44933 for eggs and HPLC-MS-MS method RPAC #44996, version 2.0 for tissues. The analyses included a control sample, a freshly fortified control sample and duplicates of the storage samples.

For milk, the freshly fortified (i.e. concurrent recovery) samples were spiked with a mixture of IFT, IFT-DKN, RPA 205834, and IFT-BA at a level of 0.1 mg/kg for each analyte. For egg, the freshly fortified (i.e. concurrent recovery) samples were spiked with IFT-DKN at a level of 0.25 mg/kg. For liver, kidney, muscle, and fat tissues, two freshly fortified (i.e. concurrent recovery) samples were prepared: one with IFT alone, and one with a mixture of IFT-DKN, RPA 205834, and RPA 207048, each at 0.25 mg/kg. The tissue fortification procedure was necessary, because isoxaflutole is partially degraded to IFT-DKN during the tissue extraction procedure of HPLC-UV method RPAC #44996 and recovery of isoxaflutole in tissues can only be calculated as the sum of IFT and IFT-DKN. Levels in control samples were < 0.02 mg/kg (LOQ) in milk and < 0.05 mg/kg (LOQ) in eggs and tissues.

Storage stability results and concurrent recoveries are shown in Table 43 and Table 44. In these tables, the presented results for the stored samples are shown as not corrected and corrected (cr) by the concurrent (freshly spiked) recoveries. The power was off to the freezer for about 40 hours during the storage period. During this outage, temperatures rose to +5 °C. The outage would affect the "4 month" liver and muscle analyses.

Conclusion: The results for milk indicate that IFT-DKN, RPA 205834 and IFT-BA are stable for at least 127–128 days. Parent IFT is stable for a maximum period of 85 days, but degrades significantly thereafter (43% remaining at 127–128 days). The degradation of isoxaflutole on to IFT-DKN has not been verified. Storage stability of RPA 207048 has not been verified.

The results for eggs indicate that IFT-DKN is stable in the egg matrix for at least 129 days. Since parent IFT is immediately converted to IFT-DKN in the egg matrix, no fresh recovery of IFT is possible. Storage stability of metabolites RPA 205834 and RPA 207048 has not been verified.

The results for the tissues indicate that parent IFT and IFT-DKN are stable for at least 130 days in liver, 115 days in kidney, 113 days in fat, 131 days for IFT-DKN in muscle and a maximum period of 85 days for isoxaflutole in muscle. Metabolite RPA 205834 is stable for a period of 113–131 days in kidney, muscle, fat. Metabolite RPA 205834 is stable for a maximum storage period of 94 days in liver and degrades significantly thereafter (36% remaining after 130 days). Metabolite RPA 207048 is not stable in any animal commodity. RPA 207048 degrades instantaneously in kidney to a level of about 45% which is maintained from 13–115 days. RPA 207048 is stable for a maximum storage period of 28 days in muscle (70% remaining), a maximum period of 40 days in liver (74% remaining), and a maximum period of 84 days in fat (100% remaining) and thereafter remains stable at a level of about 50% of the original residue level for a period up to 85–113 days.

^b Data not reported in the study report: poor calibration curve for all analytes ($r^2 < 0.99$) due to shift in detector response during the run

cr = corrected for concurrent method recovery

t = The power was off to the freezer for about 40 hours during the storage period. During this outage, temperatures rose to +5 °C

USE PATTERN

The herbicide isoxaflutole belongs to the chemical class of isoxazoles and acts as a pigment photosynthesis inhibitor of 4-hydroxyphenyl-pyruvate-dioxygenase (4-HPPD). Isoxaflutole controls a wide spectrum of grasses and broadleaf weeds by bleaching emerging or emerged weeds following herbicide uptake via the root system.

Isoxaflutole is a registered herbicide in several countries and the original registered labels in the original language as well as their English translation were submitted for Australia, Canada, France, Hungary, Italy, Spain and the USA. Use patterns were submitted for sweetcorn, chickpeas, maize, sugarcane and poppy seed. An overview is presented in Table 45.

The Australian, Canadian and USA labels warn against crop damage:

- Soils with low organic carbon (OC) and low CEC have a reduced capacity to adsorb the herbicide in the soil, which may result in the herbicide leaching past the weed root zone into the crop root zone. Crop root uptake of isoxaflutole may result in phytotoxicity, which is evident as bleaching of leaves. To minimise the risk of sugarcane root uptake, isoxaflutole is not recommended for use on soil with a CEC below 4.5 meq/100 g, or an OC of 1.0% or less. Chickpeas planted in sandy or gravelly soils or soils low in clay or organic matter may result in crop damage. Maize or IFT-soya beans grown on loamy sands, sandy loams or sands and/or soils with less than 1.5–2.0% om or pH > 7.5 may result in crop damage. US labels have soil specific application rates: lowest dose rate for sand, loamy sand or sandy loam; medium dose rate for loam, silt loam, silt or sandy clay loam; highest dose rate for silty clay loam, clay loam, sandy clay, silty clay, or clay.
- Failure to thoroughly close and firm the seed furrow for chickpeas and maize may allow herbicide to directly contact the seed which may cause crop injury. Maize seeds need to be planted at least 4 cm deep.
- Isoxaflutole is activated by rainfall or irrigation, which is required to carry the herbicide into the root zone of the germinating weeds. Heavy rains after the application of isoxaflutole to chickpeas may cause crop damage, particularly in sandy or gravelly soils.

Table 45 Registered pre-harvest uses of isoxaflutole

Crop	Country	Form g ai/kg g ai/L	Application				PHI, days

SC (suspension concentrate), WG (water dispersible granule), SL (soluble concentrate)

NA: PHI not applicable, because of the restriction in timing of the application

^a This product also contains the safener cyprosulfamide

^b This product also contains the herbicide thiencazuron-methyl.

^c Do not apply with wetting agents, crop oils or adjuvants

^d Do not apply to soils with CEC below 4.5 meq/100 g or < 1.0% organic carbon.

^e Crop oil concentrate or methylated seed oil is recommended when weeds are present at the time of treatment.

^f Either one application with 100% of the recommended rate can be made at the timing period indicated or two split applications can be made with 60% of the recommended broadcast rate applied 15 to 30 days prior to planting (pre-plant surface applied) and the remaining 40% applied at planting.

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received information on supervised residue trials of isoxaflutole for the following crops:

Group	Table	Commodity
Fruiting vegetables other than cucurbits	46	Sweet corn
Pulses	47	Chickpea seeds
	48	Glyphosate/HPPD tolerant soya beans seeds
Cereals	49	Maize grains
Grasses for sugar or syrup production	50	Sugarcane billets
Oilseeds	51	Poppy seeds
Legume animal feeds	52	Chickpea forage
	53	Chickpea straw
Straw, fodder and forage of cereal grains and grasses	54	Maize forage
	55	Maize fodder
Miscellaneous forage and fodder crops	56	sugarcane forage

Application rates and spray concentrations have been rounded to three figures; residues have been rounded to two figures. Residue data are recorded unadjusted for percentage recoveries or for residue values in control samples unless otherwise stated. Unquantifiable residues are shown as below the reported LOQ (e.g. < 0.01 mg/kg). Where multiple samples were taken from a single plot or where multiple analyses were conducted on a single sample, the average value is reported. Where results from separate plots with distinguishing characteristics such as different formulations, crop varieties or treatment schedules were reported, results are listed separately for each plot. Residues from the trials conducted according to critical GAP have been used for the estimation of maximum residue levels, STMR and HR values. Those results are underlined.

The residues presented in the tables are given as individual compound (and expressed as such) or as total residue. The total residue represents the sum of parent + IFT-DKN, expressed as isoxaflutole, unless stated otherwise. Since the relative molecular weight of IFT-DKN is the same as the relative molecular weight of isoxaflutole, no conversion for molecular weight is necessary. Where residues of were < 0.01 mg/kg, these were calculated as being at 0.01 mg/kg (expressed as metabolite).

Sweet corn

Supervised trials on maize were conducted in Spain, Italy, Greece, Portugal, Germany, France, Netherlands and the United Kingdom in 2005 and 2006 [Zimmer and Wieland, 2007, M-282674-01-1, report RA-2587/05; Wolters and Erler, 2007b, M-284423-01-1, report RA-2510/06; Wolters, 2007b, M-285014-01-1, report RA-2615/06; Zimmer, 2006, M-281611-01-1, report RA-2588/05; Wolters and Erler, 2007a, M-284416-01-1, report RA-2511/06; Wolters, 2007a, M-285005-01-1, report RA-2616/06]. Small plots of maize (50–1700 m²) were treated as indicated in Table 46 using knapsack, tractor/ATV mounted or wheelbarrow sprayers with spray volumes ranging from 90–300 L/ha

Four treatment scenarios were tested in the plots:

- a single application of isoxaflutole in combination with the safener cyprosulfamide at BBCH 12–14,
- a single application of isoxaflutole in combination with thienencarbazone-methyl and the safener cyprosulfamide at BBCH 13–14.

- a single bare ground application of isoxaflutole in combination with the safener cyprosulfamide (pre-emergence of the crop) followed by a second application with thiencarbazone-methyl in combination with the safener cyprosulfamide at BBCH 18.

Single field samples of ears without husks were taken as “baby corn” (BBCH 61), as “sweet corn” (milk ripeness, BBCH 79) or as “silage stage corn” (BBCH 85). All sample sizes were at least 2 kg and at least 12 items (in accordance with FAO manual 2009), except for some baby corn samples (0.6–1.2 kg) as indicated in Table 46. All samples were stored frozen with a maximum storage period of 244 days (8 months) at -18 °C.

Isoxaflutole and its metabolites IFT-DKN and IFT-BA were determined using HPLC-MS-MS method 00985/M001. This method is considered valid in the range 0.01–1.0 mg/kg for sweet corn. Average concurrent recoveries at 0.01–1.0 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.01 mg/kg (LOQ) for each analyte. Average concentrations for single field samples are shown in Table 46.

Note: Storage stability studies on commodities with high water content showed that total residues (sum of IFT, IFT-DKN and IFT-BA) were stable for at least 20 months. Storage stability studies on commodities with high water content showed that isoxaflutole converts to IFT-DKN after 3–6 months of storage and IFT-DKN is stable for at least 12 months but converts to IFT-BA within 23 months of storage. Since sweet corn has been stored for less than 12 months residues are considered reliable.

Note: All trials listed in Table 46 on sweet corn have been conducted with the safener cyprosulfamide. The manufacturer submitted summaries of six European trials (three from southern Europe and three from northern Europe) for sweet corn for the use of isoxaflutole in pre-emergence at 0.10 or 0.30 kg ai/ha without the safener cyprosulfamide, where it is shown that the presence of the safener cyprosulfamide does not affect the residue levels of IFT-DKN and IFT-BA. In these additional trials, the residue data were measured using a common-moiety method (sum of isoxaflutole, IFT-DKN and IFT-BA, expressed as isoxaflutole). In all trials, residue levels in the ear/cob harvested at DAT 76–158 were found to be < 0.013 mg/kg eq [Bayer, 2013]. These trials were not further investigated, since they have been conducted with a common moiety method and they confirm the residues found in the studies in Table 46.

Table 46 Isoxaflutole related residues after post-emergent treatment in sweet corn (ears without husks)

GS: BBCH grows stage: GS¹ - at application; GS² - at harvest

Soil: C = Clay, L = loam, Si = silt; Sa = sand; CL = clay loam; CSa = clay sand, CSi = clay silt; LSa = loamy sand; SiC = silty clay; SaCL = sandy clay loam; SiCL = silty clay loam, SiL = silty loam; SaC = sandy clay; SaL = sandy loam, SaSi = sandy silt;

Total = sum of IFT and IFT-DKN, expressed as isoxaflutole equivalents. Since the molecular weight of IFT-DKN is identical to the molecular weight of the parent compound (MW 359.3), no correction for molecular weight is necessary.

^a SC formulation contained 20.4% w/w isoxaflutole and 20.3% w/w cyprosulfamide (safener); or 240 g/L each

^b SC formulation contained 225 g/L isoxaflutole, 150 g/L cyprosulfamide (safener) and 90 g/L thien carbazole-methyl

^c A first spray application was performed with an SC formulation (containing 240 g/L isoxaflutole and 240 g/L cyprosulfamide (safener)) at the pre-emergence stage followed by a second application with an SC formulation (containing 225 g/L thien carbazole-methyl and 225 g/L cyprosulfamide (safener)) at growth stage BBCH 18. Days after last treatment (DAT) are related to the isoxaflutole treatment (i.e. days after the first treatment).

^d Sample sizes were less than the required minimum of 2 kg (in accordance with FAO manual 2009): 0.6–1.1 kg at BBCH 61 (baby corn) in reports RA-2510/06, RA-2615/06, RA-2511/06. Samples are considered not representative and trials cannot be selected for MRL derivation, if according to cGAP.

Pulses

Supervised trials were conducted on chickpeas and glyphosate/HPPD tolerant soya beans.

Chickpea seeds (dry harvested)

Supervised trials on chickpeas were conducted in Australia during the 1999 and 2011 season [Lynch and Keats, 1999a, M-432364-01-1, report AK99054; Lynch and Keats, 1999b, M-432374-01-1, report AK99056; Lynch and Keats, 2000a, M-432434-01-1, report AQ00001; Lynch and Keats, 2000b, M-432441-01-1, report AQ00002; Lynch and Keats, 2000c, M-432444-01-1, report AQ00003; Ellis, 2012, M-425905-02-1, report BCS-0370]. Small plots of chickpeas (20–135 m²) were treated as indicated in Table 47 using a hand held boom sprayer or a small plot sprayer with spray volumes ranging from 50–230 L/ha.

In 1999, different application scenarios were tested on parallel plots. Plots were treated once at different application rates and/or growth stages (before emergence of the crop or at 3 nodes stage).

In 2011, four application scenarios were tested on parallel plots. Isoxaflutole was applied at rates of 0.075 kg ai/ha and 0.150 kg ai/ha to bare soil either as a single fallow application approximately four month before sowing the chickpea crops, or in conjunction with a second application at planting.

Replicate field samples of dry pea seeds were taken at maturity (marketable specimens). In report AK99054, chickpea plots were mechanically harvested and seeds were randomly selected from a harvester bin. In report AK99056, BCS-370 and AQ reports dry pea seeds were sampled by hand, cutting random samples of chickpea pods from at least 10 separate plants from all over the plot. Sample sizes were at least 1 kg in report AQ00003 and AK99054. Sample sizes from all other reports were below the required minimum of 1 kg (in accordance with FAO manual 2009): 0.1 kg in report AK99056, 0.25 kg in AQ00001 and AQ00002, 0.5 kg in BCS-370. Samples were stored frozen with a maximum storage period of 2–21 days at –20 °C (AK99054 and AQ reports), 11 months at –20 °C (AK99056) or 21 days at –8 °C (BCS-370).

In the trials from 1999, samples were analysed for total residues using GC-MS-MS modification B of method 00473 (common moiety method), where IFT, IFT-DKN and IFT-BA are converted into RPA 204497 and total residues are expressed as isoxaflutole equivalents. This method is considered valid in the range 0.01–0.1 mg/kg for dry chickpea seeds. Average concurrent recoveries at 0.01 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.003 mg/kg (0.3LOQ). Average concentrations for duplicate field samples are shown in Table 47.

In the trials from 2011, samples were analysed for IFT, IFT-DKN and IFT-BA using modification A of HPLC-MS-MS method ATM-0054.01. This method is considered valid in the range 0.01–0.1 mg/kg in dry chickpea seeds. Average concurrent recoveries at 0.01–1.0 mg/kg were

within 70–120% for each analyte. Levels in control samples were < 0.003 mg/kg (0.3 LOQ). Average concentrations for duplicate field samples are shown in Table 47.

Note: In the AK and AQ reports, some data (application rate and date of application) were found to be inconsistent between the summary and appendices. The data coming from the field presented in the “residue sample submission form” were considered as being the valid ones.

Note: Storage stability studies on commodities with high protein content showed that total residues (sum of IFT, IFT-DKN and IFT-BA) were stable for at least 11 months. Storage stability studies on commodities with high protein content showed that isoxaflutole converts to IFT-DKN after 3–6 months of storage and IFT-DKN is stable for at least 12 months but converts to IFT-BA within 23 months of storage. Since chickpeas have been stored for a maximum of 11 months in the trials where a common moiety method was used and chickpeas have been stored for less than 3 months in trials where individual compounds have been measured, all results are considered reliable.

Table 47 Isoxaflutole related residues after pre- or post-emergent treatment of chickpeas (dry harvested seeds)

^a Total residue obtained by common moiety method, whereby residues are converted into RPA 204497 and expressed as isoxaflutole equivalent (residue includes IFT, IFT-DKN and IFT-BA)

^b Total residue calculated by summing up residues of IFT and IFT-DKN and expressed as isoxaflutole equivalents. Since the molecular weight of IFT-DKN is identical to the molecular weight of the parent compound (MW 359.3), no correction for molecular weight is necessary.

^c Sample sizes were below the required minimum of 1 kg (in accordance with FAO manual 2009): 0.1 kg in report AK99056, 0.25 kg in AQ00001 and AQ00002, 0.5 kg in BCS-370. However, two samples were taken from each trial plot (each from at least 10 plants in the AK and AQ reports) and the results are the mean of both samples. Therefore results can be considered representative and trials can be selected for MRL derivation, if according to cGAP.

^d Added adjuvant: 0.25% X-77

^e Added adjuvant: Uptake oil

Glyphosate/HPPD tolerant soya beans

Supervised trials on glyphosate/HPPD tolerant soya beans were conducted in the USA and Canada during the 2009 season [Dallstream and Fisher, 2010, M-368661-01-1, study RAISP006; Beedle and Dallstream, 2010, M-368669-01-1, study RAISP010]. Small plots of soya beans (500–1800 ft² or 46–167 m²) were treated as indicated in Table 48 using backpack or tractor mounted sprayers with spray volumes ranging from 9–26 GPA or 84–243 L/ha.

In report RAISP006 three different application scenarios were tested in parallel plots: a) single pre-plant or pre-emergence soil application, b) single foliar application from BBCH 13 (trifoliate leaf on the 3rd node unfolded) to BBCH 15 (trifoliate leaf on the 5th node unfolded) or c) single foliar application from BBCH 51 (first flower buds visible) to BBCH 66 (about 60% of flowers open). The pre-emergent applications occurred within 3 days following planting.

In report RAISP010 two different application scenarios were tested on parallel plots:

- In the first plot a single pre-emergent application of glyphosate-isoxaflutole spray mix was made, followed by two additional foliar applications of glyphosate.
- For the second plot, a single pre-emergent application of glyphosate was made, followed by a single foliar application of glyphosate-isoxaflutole spray mix between growth stages BBCH 51 (first flower buds visible) and BBCH 62 (about 20% of flowers open), and an additional foliar application of glyphosate 8–11 days later.

The pre-emergent applications occurred within 3 days following planting.

Replicate field samples of soya bean seed were collected at earliest commercial harvest (BBCH 89). Seed samples were a composite from at least 12 areas of the plot, avoiding the edges and ends of the plot. Samples sizes were 1 kg (in accordance with FAO manual 2009), except for trial IS007-09DA (0.20–0.44 kg). All samples were stored frozen with a maximum storage period of 188 days at 0 °C (or lower in report RAISP006) or 218 days at –20 °C (or lower in report RAISP010).

Samples were analysed for IFT and IFT-DKN using HPCL-MS-MS method IS-004-P10-01. The method is considered valid in the range 0.01–0.1 mg/kg in dry soya bean seed. Average concurrent recoveries at 0.01 and 0.1 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.003 mg/kg (0.3 LOQ) for each analyte. Average concentrations for duplicate field samples are shown in Table 48.

Note: Storage stability studies on various commodities showed that total residues (sum of IFT, IFT-DKN and IFT-BA) were stable for at least 11–20 months. Storage stability studies on commodities with high oil content showed that isoxaflutole converts to IFT-DKN after 3–6 months of storage and IFT-DKN is stable for at least 16 months but converts to IFT-BA within 23 months of storage. Since dry soya beans have been stored for longer than 6 months, part of the IFT may have degraded to IFT-DKN. Since dry soya beans have been stored for less than 16 months, levels of IFT-DKN are not further degraded to IFT-BA and can be considered reliable. As the residue definition includes both IFT and IFT-DKN, residues can be taken for MRL derivation, if according to cGAP.

Note: Isoxaflutole inhibits the enzyme 4-hydroxyphenylpyruvate dioxygenase (HPPD) while glyphosate inhibits the enzyme 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS). The glyphosate/HPPD tolerant soya bean line (FG72) was produced by direct gene transfer of the transgenic insert to conventional soya bean cells. FG72 soya bean expresses the *hppdPFW336* gene from *Pseudomonas fluorescens* and the *2mepsps* gene derived from maize. These genes confer tolerance to the herbicide isoxaflutole and glyphosate-containing herbicides, respectively [COGEM advice CGM/120104-02].

Note: Crops can be made tolerant against herbicides in two different ways:

- Some tolerant crops are able to detoxify the herbicide via a specific chemical modification of the pesticide which makes it unable to react with its molecular target. The detoxification is usually mediated by an enzyme which is very specific for the herbicide under consideration. Interaction with other pesticides cannot be completely excluded but normally will not occur at high level. Thus a significant impact on the metabolism and residue behaviour of other pesticides is quite unlikely.
- Other crops are made tolerant to herbicides via a modification of the target enzyme which makes the modified enzyme insensitive against the herbicide. The FG72 soya bean variety contains a gene coding for the modified enzyme HPPDW336 which differs only by a single amino acid from the natural HPPD enzyme. While HPPDW336 has the same biological activity as HPPD it is not deactivated by isoxaflutole. The FG72 soya bean variety also contains a gene for the modified enzyme 2mEPSPS which has a biological activity comparable to that of the natural EPSPS but is not deactivated by glyphosate.

Metabolism studies and field trials all have been conducted with the glyphosate/HPPD tolerant soya bean line (FG72). No trials have been conducted with a soya bean variety where only the HPPD tolerant gene is present. Since in the FG72 soya bean variety the tolerance against glyphosate and isoxaflutole is not based on detoxification, the tolerance to glyphosate is not expected to modify the nature and levels of isoxaflutole-derived residues in treated soya beans. Similarly the tolerance to isoxaflutole is not expected to modify the nature and levels of glyphosate residues.

Table 48 Isoxaflutole related residues after pre-emergent or foliar treatment on soya beans (dry harvested seeds)

Soil LSa=loamy sand, SiL = silty loam, CL=clay loam, SaL=sandy loam, L=loam, SiCL=silty clay loam, SaCL=sandy clay loam

GS growth stage, according to BBCH,

NS not stated, NA = not analysed

Total = sum of IFT and IFT-DKN, expressed as isoxaflutole equivalents. Since the molecular weight of IFT-DKN is identical to the molecular weight of the parent compound (MW 359.3), no correction for molecular weight is necessary.

^a spray mix prepared from SC 480 g/L isoxaflutole and SC 480 g/L of the isopropylammonium salt of glyphosate (see introductory text)

^b Additionally, adjuvants were used, which included AMS at 2% w/w, a non-ionic surfactant ranging from 0.5% to 1% v/v, a drift control agent, and if necessary anti-foam.

^c Sample sizes were below the required minimum of 1 kg (in accordance with FAO manual 2009): (200–440 g). Samples are considered not representative and trials cannot be selected for MRL derivation, if according to cGAP.

^d Seeds were planted in an area that received isoxaflutole in the previous growing season. However, this did not affect the results, since no isoxaflutole residues were found in the control samples (< LOQ).

Maize (grains)

Supervised trials on maize were conducted in Spain, Italy, Greece, Portugal, Germany, France, Netherlands and the United Kingdom in 2005 and 2006 and in USA and Canada in 1998, 2005 and 2006 [Zimmer and Wieland, 2007, M-282674-01-1, report RA-2587/05; Wolters and Erler, 2007b, M-284423-01-1, report RA-2510/06; Wolters, 2007b, M-285014-01-1, report RA-2615/06; Zimmer, 2006, M-281611-01-1, report RA-2588/05; Wolters and Erler, 2007a, M-284416-01-1, report RA-2511/06; Wolters, 2007a, M-285005-01-1, report RA-2616/06; Mickelson, 1999a, M-240663-01-1, report AA98714495; Fischer and Helfrich, 2007, M-285889-01-1, report RAUBP008; Vaughn and

Cosgrove, 2007, M-286216-02-1, report RAUBP011]. Small plots of maize (50–1700 m²) were treated as indicated in Table 49 using knapsack, tractor/ATV mounted or wheelbarrow sprayers with spray volumes ranging from 90–300 L/ha

Four treatment scenarios were tested in the plots:

- a single bare ground application of isoxaflutole (pre-emergence of the crop)
- a single application of isoxaflutole in combination with the safener cyprosulfamide at BBCH 12–14,
- a single application of isoxaflutole in combination with thien carbazon-methyl and the safener cyprosulfamide at BBCH 13–14.
- a single bare ground application of isoxaflutole in combination with the safener cyprosulfamide (pre-emergence of the crop) followed by a second application with thien carbazon-methyl in combination with the safener cyprosulfamide at BBCH 18.

Field samples of maize grains were taken as: “immature kernel” (milk ripeness, BBCH 79, sweetcorn kernel) or “field corn” (earliest commercial harvest, mature, BBCH 89). Single field samples were taken in the EU trials, duplicate field samples were taken in the USA trials. All sample sizes were at least 1 kg (in accordance with FAO manual 2009). All samples were stored frozen with a maximum storage period of 244 days at -18 °C (EU trials), 185 days at -10 °C (AA987144495) or 544 days at -15 °C (RAUBP008), 139 days at -20 °C (Canadian trials).

In the EU trials, isoxaflutole and its metabolites IFT-DKN and IFT-BA were determined using HPLC-MS-MS method 00985/M001. This method is considered valid in the range 0.01–0.1 mg/kg in maize grains. Average concurrent recoveries at 0.01–5.0 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.01 mg/kg (LOQ) for each analyte. Average concentrations for single field samples are shown in Table 49.

In the 1998 US trials, isoxaflutole and its metabolites IFT-DKN and IFT-BA were determined using HPLC-MS-MS method CAL#019-03 revision 1. This method is considered valid in the range 0.01–0.10 mg/kg in maize grains. Individual concurrent recoveries at 0.01, 0.1 and 10 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.003 mg/kg (0.3 LOQ). Average concentrations for duplicate field samples are shown in Table 49.

In the 2005 and 2006 Canadian and US trials, isoxaflutole and its metabolite IFT-DKN and IFT-BA were determined using modification C of HPLC-MS-MS method CAL#019-03. Modification C is considered valid in the range 0.01–0.2 mg/kg for IFT, 0.02–0.3 mg/kg for IFT-DKN and 0.03–0.3 mg/kg for IFT-BA in maize grains. Average concurrent recoveries at 0.01, 0.05 and 0.2 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.01 mg/kg (reported LOQ). Average concentrations for duplicate field samples are shown in Table 49. Because of validation results, the LOQs were increased to 0.02 mg/kg for IFT-DKN and 0.03 mg/kg for IFT-BA (indicated by note f).

Note: Storage stability studies on commodities with high starch content showed that total residues (sum of IFT, IFT-DKN and IFT-BA) were stable for at least 15 months. Storage stability studies on various commodities showed that isoxaflutole converts to IFT-DKN after 3–6 months of storage and IFT-DKN is stable for at least 12 months but converts to IFT-BA within 23 months of storage. Since maize grains have been stored for longer than 3 months, part of the IFT may have degraded to IFT-DKN. Except for trials in report RAUBP008, maize grains have been stored for less than 12 months and these results are considered reliable. Samples from report RAUBP008 have been stored for longer than 12 months and part of the IFT-DKN may have degraded to IFT-BA. However, IFT, IFT-DKN and IFT-BA are all below LOQ and degradation remains unnoticed. Therefore, these results are considered reliable as well.

Table 49 Isoxaflutole related residues after pre- or post-emergent treatment in maize grains

Ste- Madeleine, QC, 2006, (Mycogen 2P172) Soil: SaL												011, 15-06H

Soil: C = Clay, L = loam, Si = silt; Sa = sand; CL = clay loam; CSa = clay sand, CSi = clay silt; LSa = loamy sand; SiC = silty clay; SaCL = sandy clay loam; SiCL = silty clay loam, SiL = silty loam; SaC = sandy clay; SaL = sandy loam, SaSi = sandy silt;

GS Mat = mature, R6 = reproductive stage 6, equivalent to BBCH 89, ECH = earliest commercial harvest

Total = sum of IFT and IFT-DKN, expressed as isoxaflutole equivalents. Since the molecular weight of IFT-DKN is identical to the molecular weight of the parent compound (MW 359.3), no correction for molecular weight is necessary.

^a SC formulation contained 20.4% w/w isoxaflutole and 20.3% w/w cyprosulfamide (safener); or 240 g/L each

^b SC formulation contained 225 g/L isoxaflutole, 150 g/L cyprosulfamide (safener) and 90 g/L thien carbazole-methyl

^c A first spray application was performed with an SC formulation (containing 240 g/L isoxaflutole and 240 g/L cyprosulfamide (safener)) at the pre-emergence stage followed by a second application with an SC formulation (containing 225 g/L thien carbazole-methyl and 225 g/L cyprosulfamide (safener)) at growth stage BBCH 18. Days after last treatment (DAT) are related to the isoxaflutole treatment (i.e. days after the first treatment).

^d Trial UB080-05D was repeated in 2006 as UB080-05DA due to improper application timing in the original trial.

^e Individual results for IFT and IFT-DKN not considered reliable, because samples have been stored for longer than 12 months.

^f LOQ for IFT-DKN needs to be increased to 0.02 mg/kg and LOQ for IFT-BA needs to be increased to 0.03 mg/kg. This increase has been taken into account in total residue calculation.

^g kernel immature (milk ripe)

Sugar cane (billets)

Supervised trials on sugarcane were conducted in Australia during the 1996–1998 growing seasons [Davis and Keats, 1999a, M-284383-01-1, Report AK99009; Davis and Keats, 1999b, M-284347-01-1, Report AK99010; Davis and Keats, 1999c, M-284356-01-1, Report AK99011; Davis and Keats, 1999d, M-284369-01-1, Report AK99012; Davis and Keats, 1999e, M-284408-01-1, Report AK99017], in Mexico during the 1999 growing season [Gough, 2000, M-238729-01-1, Report 99717930] and in Brazil during the 1998-1999 growing season [Tornisielo, 2000b, M-287041-01-1 Report USP BRA98R27-1; Tornisielo, 2000a, M-287038-01-1 Report USP BRA98R27-2].

In Australia, small plots of sugar cane (15–40 m²) were treated as indicated in Table 50 using plot boom sprayers or spray bars with spray volumes ranging from 238–265 L/ha. In two parallel plots sugarcane in the 5–8 leaf stage received a single soil application of isoxaflutole at two different application rates.

In Mexico, small plots of sugar cane (210–216 m²) were treated as indicated in Table 50 using commercial ground equipment for broadcast application with spray volumes ranging from 252–411 L/ha. The application was made at the regrowth stage, up to 4 months after harvest of the previous crop, and about 8–10 months before expected crop maturity.

In Brazil, small plots of sugar cane (72–78 m²) were treated as indicated in Table 50 using backpack sprayers with spray volumes of 200 L/ha. Sugarcane was treated twice with isoxaflutole. The first application was performed at pre-emergence and the second one after emergence. In parallel plots, different application rates were tested.

Field samples of whole canes were collected at a harvestable maturity: single field samples in Australia: replicate field samples in Mexico. Samples from each plot were taken from at least 15 whole canes randomly from the entire plot (in accordance with the FAO 2009 manual). The top 30 cm of the whole canes were then cut off using secateurs to provide forage (tops) and cane. The remaining cane was cut into billets of 20–25 cm in length. Equal portions of tops, middle and bottom were

sampled from at least 12 stalks to provide at least 1 kg of whole cane billets. All samples were stored frozen for a maximum storage period of 33 days at -10 °C (Mexican trials), 5 months at -20 °C (AK 99009, AK 99010) or 10 months at -20 °C (AK 99011, AK 99012) or 20 months at -20 °C (AK 99017), 24 months at -10 °C (Brazilian trials).

In the Australian trials, samples were analysed using GC-MS-MS modification A of method 00473 (common moiety method), where IFT, IFT-DKN and IFT-BA are converted into RPA 204497 and total residues are expressed as isoxaflutole equivalents. This method is considered valid at 0.01 mg/kg in sugar cane billets. Average concurrent recoveries at 0.01 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.01 mg/kg (LOQ). Average results of the replicate field samples are reported in Table 50.

In the Mexican trials, samples were analysed using GC-MS modification D of method 00473 (common moiety method), where IFT, IFT-DKN and IFT-BA are converted into RPA 204497 and total residues are expressed as isoxaflutole equivalents. This method is considered valid in the range 0.01–0.02 mg/kg in sugar cane billets. Average concurrent recoveries at 0.01, 0.02, 0.1 mg/kg analyte were within 70–120% limits (n=1–2 each), except for IFT at 0.01 mg/kg (128%, n=2) and IFT-DKN at 0.01 mg/kg (122%, n=2). Levels in control samples were < 0.01 mg/kg (LOQ). Average results of the replicate field samples are reported in Table 50.

In the Brazilian trials, samples were analysed using GC-MS-MS modification C of method 00473 (common moiety method), where IFT, IFT-DKN and IFT-BA are converted into RPA 204497 and total residues are expressed as isoxaflutole equivalents. This method is considered valid in the range 0.01–0.02 mg/kg in sugar cane billets. Average concurrent recoveries at 0.01 and 0.02 mg/kg were within 70–120% for IFT. Recoveries for other metabolites were not verified. Levels in control samples were < 0.01 mg/kg (LOQ). Average results of the replicate field samples are reported in Table 50.

Note: Storage stability studies on commodities with high water content showed that total residues (sum of IFT, IFT-DKN and IFT-BA) were stable for at least 20 months. Since sugarcanes have been stored for 20 months or shorter, all results are considered reliable.

Soil: C = clay, CL = clay loam, SaCL = sandy clay loam, SaL = sandy loam

Total = Total residues of IFT = measured sum of IFT, RPA 20248 and IFT-BA residues, expressed as isoxaflutole equivalents. The total residue is determined via a common moiety method which converts isoxaflutole, IFT-DKN and IFT-BA onto the derivative RPA 204497

TVD = top visible dewlap

CH = commercial harvest (normal crop maturity, marketable specimens)

^a regrowth stage: up to 4 months after harvest of the previous crop

^b first application in pre-emergence followed by a second application post-emergence

^c X-77 wetting agent (250 ml/hL) was added

Poppy seed

Supervised trials on poppy were conducted in France, Spain, Germany, Netherlands and Hungary in 2008 and 2009 [Billian and Reinecke, 2010, M-360144-02-1, Report 08-2095; Billian and Krusell, 2010b, M-360114-02-1, Report 08-2094; Billian and Krusell, 2010a, M-364166-01-1, Report 09-2085; Noss and Reinecke, 2010, M-366025-01-1, report 09-2022]. Small plots of poppy (45–910 m²) were treated as indicated in Table 51 using knapsack or tractor mounted boom sprayers with spray volumes ranging from 300–400 L/ha. Poppy plants were treated with a single application of isoxaflutole in combination with the safener cyprosulfamide at pre-emergence stage of the crop.

In some trials phytotoxicity signs were seen a few weeks after treatment: dead plants, plants with burning damage or symptoms of discoloration, plants with reduced growth, reduced emergence of plants (trial 08-2094-02&03&04, trial 08-2095/02&04). These phytotoxicity problems affected the yield of the poppy seeds.

Single field samples of seed were taken at harvest (BBCH 89). All sample sizes were at least 1 kg (in accordance with FAO manual 2009), except in trials 09-2022/01&02 and 08-2095/02&04 (0.1–0.7 kg) as indicated in Table 51. All samples were stored frozen at –18 °C with a maximum storage period of 111 days (report 0902085), 134 days (report 09-2022) or 447 days (report 08-2094 and 08-2095).

Isoxaflutole and its metabolites IFT-DKN and IFT-BA were determined using HPLC-MS-MS method 00985/M001. This method is considered valid in the range 0.01–0.10 mg/kg in poppy seeds. Average concurrent recoveries at 0.01–0.1 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.01 mg/kg (LOQ) for each analyte. Average concentrations for single field samples are shown in Table 51.

Note: Seeds need to be grinded prior to analyses, since residue levels may increase upon grinding. At first instance seeds were not grinded prior to extraction. In those cases, where residues of IFT-BA were seen, the analysis was repeated by grinding the seeds prior to extraction. All results are therefore considered reliable.

Note: Storage stability studies on various commodities showed that total residues (sum of IFT, IFT-DKN and IFT-BA) were stable for at least 11–20 months. Storage stability studies on commodities with high oil content showed that isoxaflutole converts to IFT-DKN after 3–6 months of storage and IFT-DKN is stable for at least 16 months but converts to IFT-BA within 23 months of storage. Since poppy seeds have been stored for longer than 3 months, part of the IFT may have degraded to IFT-DKN. Since poppy seeds have been stored for less than 16 months, levels of IFT-DKN are not further degraded to IFT-BA and can be considered reliable. If the residue definition includes both IFT and IFT-DKN, residues can be taken for MRL derivation, if according to cGAP.

Soil: C = Clay, L = loam, Si = silt; Sa = sand; CL = clay loam; CSa = clay sand, CSi = clay silt; LSa = loamy sand; SiC = silty clay; SaCL = sandy clay loam; SiCL = silty clay loam, SiL = silty loam; SaC = sandy clay; SaL = sandy loam, SaSi = sandy silt;

total = sum of IFT and IFT-DKN, expressed as isoxaflutole equivalents. Since the molecular weight of IFT-DKN is identical to the molecular weight of the parent compound (MW 359.3), no correction for molecular weight is necessary.

^a SC formulation contained 20.4% w/w isoxaflutole and 20.3% w/w cyprosulfamide (safener); or 240 g/L each

^b Before analysis, the seeds were not grinded.

^c Before analyses, the seeds were grinded/homogenised for 30 sec using a basic mixer. Grinding the seeds leads to residues of IFT-BA about a factor 2 higher compared to non-grinded seeds.

^d Sample sizes were less than the required minimum of 1 kg (in accordance with FAO manual 2009): 0.1–0.9 kg. In plot 082095-02&04, the reduced sample size is due to phytotoxicity effects: bad growing and bad conditions of plants. Samples are considered not representative and trials cannot be selected for MRL derivation, if according to cGAP.

Legume animal feeds

Supervised residue trials were conducted on chickpea forage and chickpea straw.

Chickpea forage

Supervised trials on chickpeas were conducted in Australia during the 1999 and 2011 season [Lynch and Keats, 1999a, M-432364-01-1, report AK99054; Lynch and Keats, 1999b, M-432374-01-1, report AK99056; Lynch and Keats, 2000a, M-432434-01-1, report AQ00001; Lynch and Keats, 2000b, M-432441-01-1, report AQ00002; Lynch and Keats, 2000c, M-432444-01-1, report AQ00003; Ellis, 2012, M-425905-02-1, report BCS-0370]. Small plots of chickpeas (20–135 m²) were treated as indicated in Table 52 using a hand held boom sprayer or a small plot sprayer with spray volumes ranging from 50–230 L/ha.

In 1999, different application scenarios were tested on parallel plots. Plots were treated once at different application rates and/or growth stages (before emergence of the crop or at 3 nodes stage). In 2011, four application scenarios were tested on parallel plots. Isoxaflutole was applied at rates of 0.075 kg ai/ha and 0.150 kg ai/ha to bare soil either as a single fallow application approximately four month before sowing the chickpea crops, or in conjunction with a second application at planting.

Replicate field samples of forage (or green material) were taken at pre-flowering (AK99056) or at 3–4 node stage (AQ reports) or 42–49 DAS (BCS-0370). Forage was sampled by hand with secateurs, cutting random samples of a chickpea plant down to 5 cm above ground level, from at least 10 separate plants from all over the plot. All sample sizes were less than the required minimum of 1 kg (in accordance with FAO manual 2009): 0.10 kg in report AK99056, 0.20 kg in BCS-0370,

0.25 kg in AQ00001 and AQ00003, 0.5 kg in AQ00002. Samples were stored frozen with a maximum storage period of 3–21 days at –20 °C (AQ reports), 11 months at –20 °C (AK99056) or 135 days at –9 °C (BCS-0370).

In the trials from 1999, samples were analysed for total residues using GC-MS-MS modification B of method 00473 (common moiety method), where IFT, IFT-DKN and IFT-BA are converted into RPA 204497 and total residues are expressed as isoxaflutole equivalents. This method is considered valid in the range 0.01–0.1 mg/kg in chickpea forage. Since total residue levels in the supervised trials ranged from 0.01–0.19 mg/kg, validation at higher levels is desirable. Average concurrent recoveries at 0.01 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.003 mg/kg (0.3 LOQ). Average concentrations for duplicate field samples are shown in Table 52.

In the trials from 2011, samples were analysed for IFT, IFT-DKN and IFT-BA using modification A of HPLC-MS-MS method ATM-0054.01. This method is considered valid in the range 0.01–0.1 mg/kg in chickpea forage. Since IFT-BA levels in the supervised trials ranged from 0.01–0.55 mg/kg, validation at higher levels is desirable. Average concurrent recoveries at 0.01–1.0 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.003 mg/kg (0.3 LOQ). Average concentrations for duplicate field samples are shown in Table 52.

Note: In the AK and AQ reports, some data (application rate and date of application) were found to be inconsistent between the summary and appendices. The data coming from the field presented in the “residue sample submission form” were considered as being the valid ones.

Note: Storage stability studies on commodities with high water content showed that total residues (sum of IFT, IFT-DKN and IFT-BA) were stable for at least 20 months. Storage stability studies on commodities with high water content showed that isoxaflutole converts to IFT-DKN after 3–6 months of storage and IFT-DKN is stable for at least 12 months but converts to IFT-BA within 23 months of storage. Since chickpea forages have been stored for a maximum of 11 months in the trials where a common moiety method was used and chickpea forages have been stored for less than 3 months in trials where individual compounds have been measured, all results are considered reliable.

^a Total residue obtained by common moiety method, whereby residues are converted into RPA204497 and expressed as isoxaflutole equivalent (residue includes IFT, IFT-DKN and IFT-BA)

^b Total residue calculated by summing up residues of IFT and IFT-DKN and expressed as isoxaflutole equivalents. Since the molecular weight of IFT-DKN is identical to the molecular weight of the parent compound (MW 359.3), no correction for molecular weight is necessary.

^c All sample sizes were less than the required minimum of 1 kg (in accordance with FAO manual 2009): 0.10 kg in report AK99056, 0.20 kg in BCS-0370, 0.25 kg in AQ00001 and AQ00003, 0.5 kg in AQ00002. However, two samples were taken from each trial plot (each from at least 10 plants in the AK and AQ reports) and the results are the mean of both samples. Therefore results can be considered representative and trials can be selected for MRL derivation, if according to cGAP.

^d added adjuvant: 0.25% X-77

^e added adjuvant: Uptake oil

Chickpea fodder

Supervised trials on chickpeas were conducted in Australia during the 1999 and 2011 season [Lynch and Keats, 1999a, M-432364-01-1, report AK99054; Lynch and Keats, 1999b, M-432374-01-1, report AK99056; Lynch and Keats, 2000a, M-432434-01-1, report AQ00001; Lynch and Keats, 2000b, M-432441-01-1, report AQ00002; Lynch and Keats, 2000c, M-432444-01-1, report AQ00003; Ellis, 2012, M-425905-02-1, report BCS-0370]. Small plots of chickpeas (20–135 m²) were treated as indicated in Table 53 using a hand held boom sprayer or a small plot sprayer with spray volumes ranging from 50–230 L/ha.

In 1999, different application scenarios were tested on parallel plots. Plots were treated once at different application rates and/or growth stages (before emergence of the crop or at 3 nodes stage).

In 2011, four application scenarios were tested on parallel plots. Isoxaflutole was applied at rates of 0.075 kg ai/ha and 0.150 kg ai/ha to bare soil either as a single fallow application

approximately four month before sowing the chickpea crops, or in conjunction with a second application at planting.

Replicate field samples of chickpea fodder were taken at maturity. In report AK99054, chickpea plots were mechanically harvested and fodder was randomly selected from the trash coming out of the back of the harvester. In report AK99056, BCS-370 and AQ reports fodder was sampled by hand with secateurs, cutting random samples of a dry chickpea plant down to 5 cm above ground level, from at least 10 separate plants from all over the plot. Sample sizes were at least 0.5 kg in report BCS-0370, AQ00003 and AK99054. Sample sizes from all other reports were below the required minimum of 0.5 kg (in accordance with FAO manual 2009): 0.1 kg in report AK99056, 0.25 kg in AQ00001 and AQ00002. Samples were stored frozen with a maximum storage period of 2–21 days at -20 °C (AK99054 and AQ reports), or 11 months at -20 °C (AK99056) or 25 days at -8 °C (BCS-0370).

In the trials from 1999, samples were analysed for total residues using GC-MS-MS modification B of method 00473 (common moiety method), where IFT, IFT-DKN and IFT-BA are converted into RPA 204497 and total residues are expressed as isoxaflutole equivalents. This method is considered valid in the range 0.01–0.1 mg/kg in chickpea straw. Average concurrent recoveries at 0.01 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.003 mg/kg (0.3 LOQ). Average concentrations for duplicate field samples are shown in Table 53.

In the trials from 2011, samples were analysed for isoxaflutole, IFT-DKN and IFT-BA using modification A of HPLC-MS-MS method ATM-0054.01. This method is considered valid in the range 0.01–0.1 mg/kg in chickpea straw. Since IFT-BA levels in chickpea straw ranged from < 0.01–0.12 mg/kg validation at higher levels is desirable. Average concurrent recoveries at 0.01–1.0 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.003 mg/kg (0.3 LOQ). Average concentrations for duplicate field samples are shown in Table 53.

Note: In the AK and AQ reports, some data (application rate and date of application) were found to be inconsistent between the summary and appendices. The data coming from the field presented in the “residue sample submission form” were considered as being the valid ones.

Note: Storage stability studies on straw showed that total residues (sum of IFT, IFT-DKN and IFT-BA) were stable for at least 15 months. Storage stability studies on various commodities showed that isoxaflutole converts to IFT-DKN after 3–6 months of storage and IFT-DKN is stable for at least 12 months but converts to IFT-BA within 23 months of storage. Since chickpea straw has been stored for a maximum of 11 months in the trials where a common moiety method was used and chickpea straw has been stored for less than 3 months in trials where individual compounds have been measured, all results are considered reliable.

^a Total residue obtained by common moiety method, whereby residues are converted into RPA204497 and expressed as isoxaflutole equivalent (residue includes IFT, IFT-DKN and IFT-BA)

^b Total residue calculated by summing up residues of IFT and IFT-DKN and expressed as isoxaflutole equivalents. Since the molecular weight of IFT-DKN is identical to the molecular weight of the parent compound (MW 359.3), no correction for molecular weight is necessary.

^c Sample sizes were below the required minimum of 0.5 kg (in accordance with FAO manual 2009): 0.1 kg in report AK99056, 0.25 kg in AQ00001 and AQ00002. However, two samples were taken from each trial plot (each from at least 10 plants in the AK and AQ reports) and the results are the mean of both samples. Therefore results can be considered representative and trials can be selected for MRL derivation, if according to cGAP.

^d added adjuvant: 0.25% X-77

^e added adjuvant: Uptake oil

Forage and fodder of cereal grains and grasses

Supervised residue trials were available for maize forage and maize fodder.

Maize forage

Supervised trials on maize were conducted in Spain, Italy, Greece, Portugal, Germany, France, Netherlands and the United Kingdom in 2005 and 2006 and in USA and Canada in 1998, 2005 and 2006 [Zimmer and Wieland, 2007, M-282674-01-1, report RA-2587/05; Wolters and Erler, 2007b, M-284423-01-1, report RA-2510/06; Wolters, 2007b, M-285014-01-1, report RA-2615/06; Zimmer, 2006, M-281611-01-1, report RA-2588/05; Wolters and Erler, 2007a, M-284416-01-1, report RA-2511/06; Wolters, 2007a, M-285005-01-1, report RA-2616/06; Mickelson, 1999a, M-240663-01-1, report AA98714495; Fischer and Helfrich, 2007, M-285889-01-1, report RAUBP008; Vaughn and Cosgrove, 2007, M-286216-02-1, report RAUBP011]. Small plots of maize (50–1700 m²) were treated as indicated in Table 54 using knapsack, tractor/ATV mounted or wheelbarrow sprayers with spray volumes ranging from 90–300 L/ha

Four treatment scenarios were tested in the plots:

- a single bare ground application of isoxaflutole (pre-emergence of the crop)
- a single application of isoxaflutole in combination with the safener cyprosulfamide at BBCH 12–14,
- a single application of isoxaflutole in combination with thienencarbazone-methyl and the safener cyprosulfamide at BBCH 13–14.
- a single bare ground application of isoxaflutole in combination with the safener cyprosulfamide (pre-emergence of the crop) followed by a second application with thienencarbazone-methyl in combination with the safener cyprosulfamide at BBCH 18.

Field samples of forage (whole plants) were taken at various growth stages: BBCH 13–85 in the EU trials, late milk—dent stage (BBCH 85–87) in the US trials and BBCH 75–85 in the Canadian trials. Forage harvested at growth stage BBCH 85 or later still contains the cobs/kernels, but the material itself will be very dry and is not green anymore. Single field samples were taken in the EU trials, duplicate field samples were taken in the US and Canadian trials. Sample sizes were at least 1 kg (in accordance with FAO manual 2009), except for some DAT = 0 samples (0.1–0.8 kg) as indicated in Table 54. Samples were stored frozen at -18 °C with a maximum storage period of 327 days (EU trials), 185 days at -10 °C (AA987144495) or 593 days at -15 °C (RAUBP008), 189 days at -20 °C (Canadian trials).

In the EU trials, isoxaflutole and its metabolite IFT-DKN and IFT-BA were determined using HPLC-MS-MS method 00985/M001. This method is considered valid in the range 0.01–0.10 mg/kg for maize forage. Since IFT and IFT-DKN levels in the supervised residue trials on maize forage ranged from < 0.01–13 mg/kg and < 0.01–2.6 mg/kg, respectively, validation at higher levels is desirable. Average concurrent recoveries at 0.01–5.0 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.01 mg/kg (LOQ) for each analyte. Average concentrations for single field samples are shown in Table 54.

In the 1998 US trials, isoxaflutole and its metabolite IFT-DKN and IFT-BA were determined using HPLC-MS-MS method CAL#019-03 revision 1. The method is considered valid in the range 0.01–0.10 mg/kg for maize forage. Since IFT-BA levels in the supervised trials on maize forage were in the range < 0.01–0.15 mg/kg, validation at higher levels is desirable. Individual concurrent recoveries at 0.01, 0.1 and 10 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.003 mg/kg (0.3 LOQ). Average concentrations for duplicate field samples are shown in Table 54.

In the 2005 and 2006 Canadian and US trials, isoxaflutole and its metabolites IFT-DKN and IFT-BA were determined using modification C of HPLC-MS-MS method CAL#019-03. This method is considered valid in the range 0.01–0.2 mg/kg IFT, 0.02–0.3 mg/kg IFT-DKN and 0.03–0.3 mg/kg IFT-BA in maize forage. Average concurrent recoveries at 0.01, 0.05 and 0.2 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.01 mg/kg (reported LOQ). Average

concentrations for duplicate field samples are shown in Table 54. Because of validation results, the LOQs were increased to 0.02 mg/kg for IFT-DKN and 0.03 mg/kg for IFT-BA (indicated by note ^g).

Note: Storage stability studies on commodities with high water content showed that total residues (sum of IFT, IFT-DKN and IFT-BA) were stable for at least 20 months. Storage stability studies on commodities with high water content showed that isoxaflutole converts to IFT-DKN after 3–6 months of storage and IFT-DKN is stable for at least 12 months but converts to IFT-BA within 23 months of storage. Since maize forage has been stored for longer than 3 months, part of the IFT may have degraded to IFT-DKN. Except for trials in report RAUBP008, maize forage has been stored for less than 12 months and these results are considered reliable. Samples from report RAUBP008 have been stored for longer than 12 months and part of the IFT-DKN may have degraded to IFT-BA. However, in those trials where IFT, IFT-DKN and IFT-BA are all below LOQ, any degradation remains unnoticed and these results are considered reliable. In a few trials where IFT-BA was found to be above LOQ and where the storage period exceeded 12 months, individual results for IFT and IFT-DKN are not considered reliable. These are indicated by note ^f.

Table 54 Isoxaflutole related residues after pre- or post-emergent treatment in maize forage (whole plant including cobs)

Soil: C = Clay, L= loam, Si = silt; Sa= sand; CL = clay loam; CSa = clay sand, CSi= clay silt; LSa = loamy sand; SiC = silty clay; SaCL=sandy clay loam; SiCL = silty clay loam, SiL = silty loam; SaC = sandy clay; SaL = sandy loam, SaSi = sandy silt;

GS: EaFo = early forage, Fo = forage, LaMi = late milk; EaDo = early dough, Do = dough; LaDo= late dough; EaDe= early dent; De = dent;; ECH = earliest commercial harvest, 75-85 = kernels in the middle of the cob are yellowish white to dough state.

total = sum of IFT and IFT-DKN, expressed as isoxaflutole equivalents. Since the molecular weight of IFT-DKN is identical to the molecular weight of the parent compound (MW 359.3), no correction for molecular weight is necessary.

^a SC formulation contained 20.4% w/w isoxaflutole and 20.3% w/w cyprosulfamide (safener); or 240 g/L each

^b SC formulation contained 225 g/L isoxaflutole, 150 g/L cyprosulfamide (safener) and 90 g/L thienicarbazone-methyl

^c A first spray application was performed with an SC formulation (containing 240 g/L isoxaflutole and 240 g/L cyprosulfamide (safener)) at the pre-emergence stage followed by a second application with an SC formulation (containing 225 g/L thienicarbazone-methyl and 225 g/L cyprosulfamide (safener)) at growth stage BBCH 18. Days after last treatment (DAT) are related to the isoxaflutole treatment (i.e. days after the first treatment).

^d Trials UB088-05HA and UB091-05HA were repeated in 2006 in order to collect early forage samples at DAT = 45.

Trial UB080-05DA was repeated in 2006 due to improper application timing in the original trial.

^e Sample sizes were less than the required minimum of 1 kg (in accordance with FAO manual 2009): 0.1–0.8 kg at DAT = 0 in report RA-2587/05, RA-2510/06 and RA-2588/05. Samples are considered not representative and trials cannot be selected for STMR or HR derivation, if according to cGAP.

^f Individual results for IFT and IFT-DKN not considered reliable, since samples were stored for longer than 12 months.

Maize fodder

Supervised trials on maize were conducted in Spain, Italy, Greece, Portugal, Germany, France, Netherlands and the United Kingdom in 2005 and 2006 and in USA and Canada in 1998, 2005 and 2006 [Zimmer and Wieland, 2007, M-282674-01-1, report RA-2587/05; Wolters and Erler, 2007b, M-284423-01-1, report RA-2510/06; Wolters, 2007b, M-285014-01-1, report RA-2615/06; Zimmer, 2006, M-281611-01-1, report RA-2588/05; Wolters and Erler, 2007a, M-284416-01-1, report RA-2511/06; Wolters, 2007a, M-285005-01-1, report RA-2616/06; Mickelson, 1999a, M-240663-01-1, report AA98714495; Fischer and Helfrich, 2007, M-285889-01-1, report RAUBP008; Vaughn and Cosgrove, 2007, M-286216-02-1, report RAUBP011]. Small plots of maize (50–1700 m²) were treated as indicated in table 55 using knapsack, tractor/ATV mounted or wheelbarrow sprayers with spray volumes ranging from 90–300 L/ha

Four treatment scenarios were tested in the plots:

- a single bare ground application of isoxaflutole (pre-emergence of the crop)
- a single application of isoxaflutole in combination with the safener cyprosulfamide at BBCH 12–14,
- a single application of isoxaflutole in combination with thien carbazon-methyl and the safener cyprosulfamide at BBCH 13–14.
- a single bare ground application of isoxaflutole in combination with the safener cyprosulfamide (pre-emergence of the crop) followed by a second application with thien carbazon-methyl in combination with the safener cyprosulfamide at BBCH 18.

Field samples of maize fodder (plants after removal cobs/kernels) were taken as sweet corn fodder (BBCH 79) or as field corn fodder (mature, BBCH 85–89). Single field samples were taken in the EU trials, duplicate field samples were taken in the USA trials. All sample sizes were at least 1 kg and at least 12 plants (in accordance with FAO manual 2009), except some Canadian trials (0.8–0.9 kg) as indicated in Table 55. All samples were stored frozen with a maximum storage period of 244 days at -18 °C (EU trials), 185 days at -10 °C (AA987144495) or 546 days at -15 °C (RAUBP008), 147 days at -20 °C (Canadian trials).

In the EU trials, isoxaflutole and its metabolite IFT-DKN and IFT-BA were determined using HPLC-MS-MS method 00985/M001. This method is considered valid in the range 0.01–0.01 mg/kg in maize grains and maize forage, but maize fodder has not been validated. Additional validation results for maize fodder are desirable. Concurrent recoveries in maize fodder were not verified, although recoveries for maize grains, sweet corn and maize forage were within 70–120%. Levels in control samples were < 0.01 mg/kg (LOQ) for each analyte. Average concentrations for duplicate field samples are shown in Table 55.

In the 1998 US trials, isoxaflutole and its metabolite IFT-DKN and IFT-BA were determined using HPLC-MS-MS method CAL#019-03 revision 1. This method is considered valid in the range 0.01–0.10 mg/kg for maize fodder. Individual concurrent recoveries at 0.01, 0.1 and 10 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.003 mg/kg (0.3 LOQ). Average concentrations for duplicate field samples are shown in Table 55.

In the 2005 and 2006 Canadian and US trials, isoxaflutole and its metabolites IFT-DKN and IFT-BA were determined using modification C of HPLC-MS-MS method CAL#019-03. This modification is considered valid in the range 0.01–0.2 mg/kg for IFT, 0.02–0.3 mg/kg for IFT-DKN and 0.03–0.3 mg/kg for IFT-BA in maize fodder. Average concurrent recoveries at 0.01, 0.05 and 0.2 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.01 mg/kg (reported LOQ). Average concentrations for duplicate field samples are shown in Table 55. Because

of validation results, the LOQs were increased to 0.02 mg/kg for IFT-DKN and 0.03 mg/kg for IFT-BA (indicated by note ^h).

Note: Storage stability studies on straw showed that total residues (sum of IFT, IFT-DKN and IFT-BA) were stable for at least 15 months. Storage stability studies on various commodities showed that isoxaflutole converts to IFT-DKN after 3–6 months of storage and IFT-DKN is stable for at least 12 months but converts to IFT-BA within 23 months of storage. Since maize fodder has been stored for longer than 3 months, part of the IFT may have degraded to IFT-DKN. Except for trials in report RAUBP008, maize fodder has been stored for less than 12 months and these results are considered reliable. Samples from report RAUBP008 have been stored for longer than 12 months and part of the IFT-DKN may have degraded to IFT-BA. However, in those trials where IFT, IFT-DKN and IFT-BA are all below LOQ, any degradation remains unnoticed and these results are considered reliable. In a few trials where IFT-BA was found to be above LOQ and where the storage period exceeded 12 months, individual results for IFT and IFT-DKN are not considered reliable. These are indicated by note ^g.

Table 55 Isoxaflutole related residues after pre- or post-emergent treatment in maize fodder (plant without cobs, or cobs)

GS mat = mature; R6 = reproductive stage 6, equivalent to BBCH 89, ECH = earliest commercial harvest

total = sum of IFT and IFT-DKN, expressed as isoxaflutole equivalents. Since the molecular weight of IFT-DKN is identical to the molecular weight of the parent compound (MW 359.3), no correction for molecular weight is necessary.

^a SC formulation contained 20.4% w/w isoxaflutole and 20.3% w/w cyprosulfamide (safener); or 240 g/L each

^b SC formulation contained 225 g/L isoxaflutole, 150 g/L cyprosulfamide (safener) and 90 g/L thiencarbazone-methyl

^c A first spray application was performed with an SC formulation (containing 240 g/L isoxaflutole and 240 g/L cyprosulfamide (safener)) at the pre-emergence stage followed by a second application with an SC formulation (containing 225 g/L thiencarbazone-methyl and 225 g/L cyprosulfamide (safener)) at growth stage BBCH 18. Days after last treatment (DAT) are related to the isoxaflutole treatment (i.e. days after the first treatment).

^d Trial UB080-05D was repeated in 2006 as UB080-05DA due to improper application timing in the original trial.

^e Trial UB087-05H was harvested at DAT = 133 for grain and DAT = 134 for straw. Since grain and straw are derived from the same commodity it is assumed that the straw has been left to dry for 1 day in the field before sampling.

^f Sample sizes were less than the required minimum of 1 kg (in accordance with FAO manual 2009): 0.8 kg. Samples are considered not representative and trials cannot be selected for MRL derivation, if according to cGAP.

^g Individual results for IFT and IFT-DKN are not considered reliable because samples were stored for longer than 12 months.

^h Results reported below 0.02 mg/kg IFT-DKN and below 0.03 mg/kg IFT-BA, were reported as < 0.02 mg/kg IFT-DKN and < 0.03 mg/kg IFT-BA because of validation results.

Miscellaneous forage and fodder crops

Supervised trials were available for sugarcane forage.

Sugar cane forage

Supervised trials on sugarcane were conducted in Australia during the 1996–1998 growing seasons [Davis and Keats, 1999a, M-284383-01-1, Report AK99009; Davis and Keats, 1999b, M-284347-01-1, Report AK99010; Davis and Keats, 1999c, M-284356-01-1, Report AK99011; Davis and Keats, 1999d, M-284369-01-1, Report AK99012; Davis and Keats, 1999f, M-284324-01-1, Report AK99013; Davis and Keats, 1999e, M-284408-01-1, Report AK99017], in Mexico during the 1999 growing season [Gough, 2000, M-238729-01-1, Study 99717930] and in Brazil during the 1998–1999 growing season [Tornisielo, 2000b, M-287041-01-1, report USP BRA98R27-1; Tornisielo, 2000a, M-287038-01-1, report USP BRA98R27-2].

In Australia, small plots of sugar cane (15–40 m²) were treated as indicated in Table 56 using plot boom sprayers or spray bars with spray volumes ranging from 238–265 L/ha. In two parallel plots sugarcanes in the 5–8 leaf stage received a single soil application of isoxaflutole at two different application rates.

Single field samples of whole canes were collected at a harvestable maturity at DAT = 133–209. Samples from each plot were taken from at least 12 separate plants. The top 30 cm of the whole canes were then cut off using secateurs to provide forage (tops). At least 1 kg of sample was supplied from each plot (in accordance with the FAO 2009 manual). All samples were stored frozen for a

maximum storage period of 5 months at -20 °C (AK 99009, AK 99010), 10 months at -20 °C (AK 99011, AK 99012) or 19–20 months at -20 °C (AK 99013, AK 99017).

Samples were analysed using GC-MS-MS modification A of method 00473 (common moiety method), where IFT, IFT-DKN and IFT-BA are converted into RPA 204497 and total residues are expressed as isoxaflutole equivalents. This method is considered valid at 0.01 mg/kg in sugarcane forage. Average concurrent recoveries at 0.01 mg/kg were within 70–120% for each analyte. Levels in control samples were < 0.01 mg/kg (LOQ). Average results of the replicate field samples are reported in Table 56.

Note: Storage stability studies on commodities with high water content showed that total residues (sum of IFT, IFT-DKN and IFT-BA) were stable for at least 20 months. Since sugarcane forage has been stored for 20 months or shorter, all results are considered reliable.

Total = Total residues of IFT = measured sum of IFT, RPA 20248 and IFT-BA residues, expressed as isoxaflutole equivalents. The total residue is determined via a common moiety method which converts IFT, IFT-DKN and IFT-BA into the derivative RPA 204497

TVD = top visible dewlap

CH = commercial harvest (normal crop maturity, marketable specimens)

FATE OF RESIDUES IN STORAGE AND PROCESSING

In storage

No data on the fate of isoxaflutole-derived residues during storage under warehouse conditions are available.

In processing

The Meeting received processing studies on soya beans, maize and sugarcane. The effect of processing on the nature of residues was not investigated since isoxaflutole related residues are generally very low.

The processing factors (residue processed commodity divided by residue RAC) were calculated based on the total isoxaflutole-derived residues (sum of IFT and IFT-DKN, expressed as isoxaflutole). For the calculation of the total isoxaflutole-derived residues any residues < LOQ were considered to be equal to the LOQ. When the total isoxaflutole-derived residues in the raw agricultural commodity were < LOQ no processing factor was derived. When the total isoxaflutole-derived residues in the processed commodity were < LOQ the calculated processing factor is reported with a "less than" (<) symbol.

Soya bean processing

A field trial was conducted in the US in 2009 [Fischer, 2010, M-368662-01-1] to measure the magnitude of isoxaflutole residues in soya bean processed commodities. An SC formulation was applied on glyphosate/HPPD resistant soya bean at an exaggerated rate of 0.525 kg ai/ha. Application spray volumes were 122–124 L/ha and Induce (0.5% v/v), AMS (2% w/w), Interlock (6 oz/A = 0.44 L/ha), and Defoamer (4 oz/100 gal = 31 mL/hL) were used as adjuvants in the tank mix. Applications were made using ground-based equipment. A bulk sample of soya bean seed was collected at DAT = 86 at the normal growth stage for commercial harvest (BBCH 89) from 12 different areas of the plot. Soya bean processing was performed using procedures that simulated commercial practices.

Aspirated grain fractions

The bulk soya bean seed sample (1463.2 lbs = 664 kg) was dried at 110–135 °F (i.e. 43–57 °C) in an oven until the moisture was between 10.0 and 13.0%. The moisture adjusted sample (1400 lbs = 635 kg) was split into two batches for dust generation. Each subsample was placed in a dust generation room containing a holding bin, two bucket conveyors, and a screw conveyor. As the sample travelled in the system for 120 minutes, aspiration removed the light impurities in the sample (grain dust, 0.7 lbs = 0.318 kg). Collected grain dust was classified on a sieve shaker equipped with the following sieves: 2360 micron (8 mesh); 2000 micron (10 mesh); 1180 micron (16 mesh); 850 micron (20 mesh); and 425 micron (40 mesh). After classification, the material through the 2360 micron sieve was recombined to produce the aspirated grain fractions (AGF, 0.172 kg).

Cleaned whole soya bean processing

Following generation of aspirated grain fractions, a representative sample of aspirated soya beans (200.0 lbs = 90.7 kg) was removed and cleaned further by aspiration and screening. Light impurities were separated from the sample using an aspirator. After aspiration, the sample was screened using a cleaner to separate large and small foreign particles (screenings) from the whole soya bean sample. Resulting fractions were cleaned whole soya beans (183.6 lbs = 83.3 kg), light impurities (0.7 lbs = 0.318 kg), small screenings (2.9 lbs = 1.32 kg) and large screenings (12.8 lbs = 5.81 kg).

Soya bean oil processing

A portion of the cleaned whole soya beans (70.0 lbs = 31.8 kg) was fed into a roller mill to crack the hull and liberate the kernel. After hulling, the material was passed through an aspirator to separate soya bean hulls and kernels. Resulting fraction were soya bean hulls (5.9 lbs = 2.68 kg) and soya bean kernels (64.1 lbs = 29.1 kg).

A portion of the soya bean kernels (30.0 lbs = 13.6 kg) was taken for further processing. The moisture content of the kernel material was determined and adjusted up to 13.5%. Moisture adjusted kernel was allowed to temper for a minimum of twelve hours prior to further processing. Moisture adjusted kernel material was heated to 160–175 °F (i.e. 71–79 °C) in a mixer and flaked in a flaking roll with a gap setting of 0.008–0.013 " (i.e. 0.20–0.33 mm). Flakes were extruded in a continuous processor, where they were turned into collets by direct steam injection and compression. Collets exited the processor at 200–250 °F (i.e. 93–121 °C). After extrusion, the collets were dried in the oven at 150–180 °F (i.e. 66–82 °C) for 30–40 minutes. Collets were placed in separate stainless steel batch extractors and submerged in 120–140 °F (i.e. 49–60 °C) hexane (solvent). After 30 minutes, the miscella (crude oil and hexane) was drained and fresh hexane was added to repeat the cycle two more times. Final two washes were for 15 minutes each. Extracted collets were desolventized in a paddle mixer by heating to 210–220 °F (i.e. 99–104 °C) and removing from the mixer. Resulting fractions were miscella (2.815 kg) and soya bean meal (21.4 lbs = 9.71 kg).

A portion of the miscella (2.0 kg) was passed through a laboratory vacuum evaporator unit to separate the crude oil and hexane. Crude oil was heated to 195–205 °F (i.e. 91–96 °C) for hexane removal and filtered. Percent free fatty acid (FFA) was determined for the crude oil. Based on the FFA, a weighed amount of crude oil and 14° Baume NaOH was placed in a water bath at 68–75 °F (i.e. 20–24 °C) and mixed for 90 minutes at high RPM, and then for 20 minutes at low RPM and 145–153 °F (i.e. 63–67 °C). Neutralized oil was then centrifuged. Refined oil was decanted and filtered. Resulting fractions were: alkali refined oil (1.85 kg) and soapstock. Soapstock was discarded.

A portion of the alkali refined oil (1.2 kg) was heated to 104–122 °F (i.e. 40–50 °C), activated bleaching earth added (1.0% by weight of oil), and placed under vacuum. Temperature was increased to 185–212 °F (i.e. 85–100 °C), and held for 10 to 15 minutes. After reducing the temperature, the bleached oil was filtered. Resulting fractions were bleached oil (1.149 kg) and spent bleaching earth.

A portion of the bleached oil (1.0 kg) was steam bathed for 28–32 minutes under vacuum and temperature held between 428–446 °F (i.e. 220–230 °C). During the cooling period a 0.5% citric acid

solution was added (1 mL per 100 grams of oil deodorized). Resulting fractions was deodorised oil (RBD oil, 0.986 kg) and deodoriser distillates.

Soymilk processing

A portion of the cleaned whole soya beans (0.70 kg) was washed and soaked in water (3.5 kg) for at least 12 hours. A portion of the soaked beans (1.67 kg) were ground and filtered to remove solids and the soymilk was cooked at 195–205 °F (i.e. 91–96 °C) for 9–11 minutes. Resulting fractions were soymilk (2.873 kg) and okara (soy pulp) (0.703 kg).

Samples of soya bean seed (RAC) were stored frozen (below 0 °C) with a maximum storage period of 153 days (5 months) until analysis. Samples of soya bean seed (RAC) were stored frozen (below 0 °C) for 193 days before being processed. Samples of processed commodities were stored frozen at -15 °C or lower with a maximum storage period of 11 days.

The soya bean seed (RAC) samples and resultant soya bean processed commodities (soya bean meal, soya bean hulls, soya bean oil, soymilk, and soya bean aspirated grain fractions) were analysed in triplicate to determine isoxaflutole and IFT-DKN by modification A of HPLC-MS-MS method IS-004-P10-01. This method is considered valid in the range 0.01–0.1 mg/kg in dry soya bean seed, soya bean meal, soya bean hulls, soya bean oil, soymilk and 0.01–0.5 mg/kg in soya bean aspirated grain fractions. Average concurrent recoveries for mixtures of IFT and IFT-DKN each at 0.01–0.1 mg/kg for soya bean seed, soya bean meal, soya bean hulls, soya bean oil, soymilk or 0.01–0.5 mg/kg for soya bean aspirated grain fractions were within 70–120% for each analyte. Levels in control samples were < 0.003 mg/kg (0.3 LOQ) for each analyte. Average concentrations of IFT, IFT-DKN (n=3 for replicate analytical portions) and corresponding processing factors are indicated in Table 57. The percent dry matter determination on soya bean seed, meal, hulls, and aspirated grain fractions was 89%, 96%, 89%, and 90%, respectively.

Note: Storage stability studies on various commodities showed that total residues (sum of IFT, IFT-DKN and IFT-BA) were stable for at least 11–20 months. Storage stability studies on various commodities showed that isoxaflutole converts to IFT-DKN after 3–6 months of storage and IFT-DKN is stable for at least 16 months in commodities with high oil content and 6 months in all other commodities but converts to IFT-BA within 23 months of storage. Since processed soya bean commodities have been stored for less than 3 months, individual results of IFT and IFT-DKN are considered reliable. Since dry soya beans have been stored for longer than 6 months, part of the IFT may have degraded to IFT-DKN. Since dry soya beans have been stored for less than 16 months, levels of IFT-DKN are not further degraded to IFT-BA and can be considered reliable. If the residue definition includes both IFT and IFT-DKN, processing factors are considered reliable.

Table 57 Processing data on soya beans

Location, Year, (Variety)	Application details	Portion analysed	DAT	IFT mg/kg	IFT-DKN mg/kg	IFT-BA mg/kg	Total mg/kg	PF	Study Trial No
Springfield USA, 2009 (Stine FG72)	1 × 0.525 kg ai/ha at BBCH 60 SC formulation broadcast foliar spray	soya bean seed	86	< 0.01	0.042	NA	0.052	–	RAISP005 IS001-09PA
		soya bean meal	86	< 0.01	0.051	NA	0.061	1.2	
		soya bean hulls	86	< 0.01	0.031	NA	0.041	0.79	
		soya bean RBD oil	86	< 0.01	< 0.01	NA	< 0.02	< 0.4	
		soy milk	86	< 0.01	< 0.01	NA	< 0.02	< 0.4	
		soya bean aspirated grain fractions	86	0.066	0.246	NA	0.312	6.0	

PF is based on total residue (sum of IFT and IFT-DKN and expressed as IFT)

Maize processing

A processing study on maize using wet and dry milling was performed [Mickelson, 1999b, M-240664-01-1]. Since the residues in the raw agricultural commodity (maize grains) and the processed

commodities (grits, flour, meal, starch, refined) were below the LOQ (0.01 mg/kg) in all samples, processing factors could not be derived and therefore the study was not summarized.

Sugarcane processing

Six processing studies on sugarcane were performed to get juice and bagasse [Davis and Keats, 1999a/b/c/d/e/f, M-284383-01-1, M-284347-01-1, M-284356-01-1, M-284369-01-1, M-284408-01-1, M-284324-01-1]. Since the residues in the raw agricultural commodity (raw canes) and the processed commodities (juice, bagasse) were < LOQ (0.01 mg/kg) in all samples, processing factors could not be derived and therefore the study was not summarized.

Residues in the edible portion of food commodities

No data submitted.

RESIDUES IN ANIMAL COMMODITIES

Direct animal treatments

Not relevant for the present use pattern.

Farm animal feeding studies

The Meeting received information on feeding studies in dairy cows and laying hens.

Study 1

A cow feeding study was conducted in the USA in 1995 in order to determine the transfer of isoxaflutole related residues from cattle feed into milk, muscle, fat, liver and kidney [Tew, 1995a, M-192311-01-1]. The study was conducted with 14 Holstein lactating cows of 1058–1709 lbs = 480–775 kg body weight (3 to 6-years old), which were distributed in four groups. Group I was the control group and contained two animals. Groups II, III and IV contained four cows per group. The cows were orally dosed once a day in the morning following milking. Cows in group II, III and IV were dosed for 42 days using gelatine capsules fortified with the appropriate amount of isoxaflutole. Group I animals received a placebo containing cellulose powder. Individual daily doses were calculated and adjusted on a weekly basis, based on the group average feed intake from the previous week (16.1–20.2 kg dry matter per cow). Animals in Group II, III and IV were treated with isoxaflutole at actual dose levels of 4.7, 14.4, and 45.5 mg/kg dw feed, respectively, corresponding to 1×, 3×, and 10× dose groups. Equivalent mg/kg bw concentrations were not stated. Cows were milked twice each day. Pooled milk samples for analysis were collected on days 0 (24 hr before first dosing), 1, 4, 8, 11, 15, 18, 22, 25, 27, 31, 33, 36, 39 and 41. For each of these study days, the PM milk samples were refrigerated overnight and combined with the following morning's AM milk sample to get a pooled (500 g) sample in proportion with AM and PM milk production. Test animals were slaughtered within 7.5 hours after receiving their final dose. Samples of muscle (2 kg composite of thigh and loin), fat (1 kg composite of perirenal and omental), liver (1 kg composite from distal portion of each lobe) and kidney (both) were taken from each animal. The samples were stored at –15 °C or lower for 23–66 days for milk and 83–88 days for tissues.

Single milk samples were analysed for IFT, IFT-DKN, RPA 205834 and IFT-BA using HPLC-UV method RPAC #44882 (= RPA #45532 milk part). The method is considered valid in the range 0.02–2.0 mg/kg IFT, IFT-DKN, RPA 205834 and IFT-BA in milk. Average concurrent recoveries (at 0.02, 0.04 or 0.1 mg/kg) ranged between 70–120% for IFT, IFT-DKN, RPA 205834 and IFT-BA. Residue levels in control samples were either not detected or < LOQ.

Single homogenised tissue samples were analysed for IFT, IFT-DKN, RPA 205834 and RPA 207048 using an HPLC-MS-MS method RPAC #44996, version 1.0. The recovery of residues was only tested at 0.25 mg/kg level. Isoxaflutole is partially degraded during extraction to IFT-DKN and

cannot be determined on its own. Average concurrent recoveries for muscle and fat (at 0.05 mg/kg) ranged between 70–120% for each analyte. Average concurrent recoveries for kidney (at 0.05, 0.45, 0.60 mg/kg) and liver (at 0.05, 0.25, and 2.0 mg/kg) ranged between 70–120% for each analyte. It should be noted that separate recovery samples were prepared and analysed: one for IFT and one for the other compounds. Isoxaflutole is unstable and rapidly metabolizes to IFT-DKN. Therefore, IFT recovery was determined by spiking a control sample with IFT only and the recovery was based on the sum of IFT and IFT-DKN from the analysis. Residue levels in control samples were either not detected or < LOQ.

For Group III, residues in milk of IFT, IFT-DKN, RPA 205834 and IFT-BA were always found to be < 0.02 mg/kg each (Day 0, 4, 8, 22, 36, 39 and 41 analysed). Therefore, milk from Group II was not analysed. For Group IV, residues in milk are summarized in Table 58. In all milk samplings from Group IV (45.5 mg/kg in feed), IFT and IFT-BA were always < 0.02 mg/kg. No plateau was reached and therefore all residues from day 1 and onwards were taken into account for average levels in milk. The levels of isoxaflutole and its metabolites in tissues of cows dosed for 42 consecutive days are summarized in Table 59. None of the results presented in these tables have been corrected for recoveries.

Note: Storage stability studies showed that storage periods of 23–66 days for milk and 83–88 days for tissues will not result in breakdown of IFT, IFT-DKN, or RPA 205834. The results for these compounds are considered reliable. However, stability for RPA 207048 is not guaranteed and this compound may have degraded to about 50% of its original level in tissues. Levels of RPA 207048 in bovine liver at or above the LOQ were therefore multiplied by a factor of 2 to correct for possible degradation.

Note: Milk samples were not analysed for RPA 207048, although this metabolite was found at levels of 0.009 mg/kg eq in a 10 ppm metabolism study in goat (15.0% TRR as RPA 207048 and 75% TRR as IFT-DKN + RPA 205834+RPA 207048). To get total residues B (sum of IFT, IFT-DKN, RPA 205834 and RPA 207048), the sum of IFT, IFT-DKN and RPA 205834 was multiplied by a factor 1.25 to correct for this omission.

Conclusion: The cow feeding study conducted with isoxaflutole shows that residues were mainly transferred to kidney and liver and consisted of metabolites IFT-DKN and RPA 205834. In liver and kidney, there was a linear relationship between the level of isoxaflutole administered to the test animals and the resulting total residue levels.

Table 58 Isoxaflutole related residues in milk for Group IV (45.5 mg/kg in feed)

Total A = sum of IFT and IFT-DKN, expressed as isoxaflutole. Conversion factor of IFT-DKN to isoxaflutole equivalents is 1.00. Residues below LOQ were calculated as being at the LOQ = 0.02 mg/kg.

Total B = sum of IFT, IFT-DKN, RPA 205834 and RPA 207048, expressed as isoxaflutole. Conversion factor of IFT-DKN to isoxaflutole equivalents is 1.00; conversion factor for RPA 205834 to isoxaflutole equivalents is 359.3/361.3 = 0.994. Residues below LOQ were calculated as being at the LOQ = 0.02 mg/kg. Milk was not analysed for RPA 207048, although this metabolite was found at levels of 0.009 mg/kg eq in a 10 ppm metabolism study in goat (15.0% TRR as RPA 207048 and 75% TRR as IFT-DKN + RPA 205834+RPA 207048). The sum of IFT, IFT-DKN and RPA 205834 was therefore multiplied by a factor 1.25 to correct for this omission.

Total A = sum of IFT and IFT-DKN, expressed as isoxaflutole. Conversion factor of IFT-DKN to isoxaflutole equivalents is 1.00. Residues below LOQ were calculated as being at the LOQ = 0.05 mg/kg.

Total B = sum of IFT, IFT-DKN, RPA 205834 and RPA 207048, expressed as isoxaflutole. Conversion factor of IFT-DKN to isoxaflutole equivalents is 1.00; conversion factor for RPA 205834 to isoxaflutole equivalents is 359.3/361.3 = 0.994. Conversion factor of RPA 207048 to isoxaflutole equivalents is 359.3/360.3 = 0.997. Residues below LOQ were calculated as being at the LOQ = 0.05 mg/kg.

^a NA, assumed to be < 0.05 mg/kg for calculation of total residues

^b Original value multiplied by a factor 2 to correct for possible degradation of RPA 207048 during frozen storage.

Study 2

A hen feeding study was conducted in the USA in 1995 in order to determine the transfer of isoxaflutole related residues from poultry feed into eggs, muscle, fat and liver [Tew, 1995b, M-192317-01-1]. The study was conducted with 60 laying hens of 1.1–1.8 kg bodyweight (ca. 76 week old) which were distributed in four groups (15 hens per group). Each group was subdivided into three subgroups (A, B, C) containing five hens each. Hens in Group I served as the control group and received a placebo containing cellulose powder. Hens in Groups II, III and IV were orally dosed once a day for 42 days, after the morning egg collection, using gelatine capsules fortified with the appropriate amount of isoxaflutole. Each group's daily dose was calculated and adjusted weekly based

on the previous week's feed consumption for that group (77.9–103.8 g dry matter per hen). Hens in Group II, III and IV were treated with isoxaflutole at actual dose levels of 0.18, 0.54 and 1.8 mg/kg dw feed, respectively, corresponding to 1×, 3×, and 10× dose groups. Equivalent mg/kg bw concentrations were not stated. Eggs were collected each morning and evening throughout the study and pooled by subgroup. Egg collection for analysis began with the afternoon collection prior to initial dose administration (Study Day 0) and continued until the scheduled animal slaughtering for each animal. Each day's PM egg samples were refrigerated overnight until they were pooled with the AM samples. Test animals were slaughtered within 3 hours after receiving the 42nd (final) dose. Samples of liver (entire), muscle (0.2 kg composite of breast and leg) and skin with adhering fat (0.2 kg) were collected. The samples were stored frozen at -15 °C for a maximum of 83 days for eggs and 64 days for tissues.

Eggs samples were analysed for IFT-DKN only, because preliminary work demonstrated that at high pH (the pH of egg is approx. 9) isoxaflutole degrades rapidly to IFT-DKN. Eggs were analysed using HPLC-UV method #44933. This method is considered valid in the range 0.05–0.25 mg/kg IFT-DKN. Concurrent recoveries for eggs (at 0.05 mg/kg) averaged 92% for IFT-DKN. Residues in control samples were < 0.05 mg/kg.

The tissue samples were analysed for IFT and IFT-DKN using HPLC-MS-MS method RPAC #44996, version 1.0. The recovery of residues was only tested at 0.25 mg/kg level. Concurrent recoveries for tissues (0.05, 0.45, 0.60 or 1.0 mg/kg) ranged between 70–120% for each analyte. It should be noted that separate recovery samples were prepared and analysed: one for IFT and one for IFT-DKN. Isoxaflutole is unstable and rapidly degrades to IFT-DKN. Therefore, IFT recovery was determined by spiking a control sample with IFT only and the recovery was based on the sum of IFT and IFT-DKN from the analysis. Residues in control samples were < 0.05 mg/kg for each analyte.

Egg samples from the Group IV (Days 0, 31, 33, 36, 39 and 41) were analysed for IFT-DKN and no residues (< 0.05 mg/kg) were found. Therefore, no additional egg analyses were performed.

Isoxaflutole related residues in tissues of hens dosed for 42 consecutive days are summarized in Table 60. None of the results presented in these tables have been corrected for recoveries.

Note: Storage stability studies showed that storage periods of 83 days for eggs and 64 days for tissues will not result in breakdown of IFT in tissues or IFT-DKN in eggs or tissues. Results are considered reliable.

Conclusion: The hen feeding study conducted with isoxaflutole shows that residues were mainly transferred to liver. The relationship between IFT-DKN residue levels in liver and the dose level administered is not linear. This may indicate that at the 10× dose level, residue levels have or are beginning to reach saturation.

Total A = sum of IFT and IFT-DKN, expressed as isoxaflutole. Conversion factor of IFT-DKN to isoxaflutole equivalents is 1.00. Residues below LOQ were calculated as being at the LOQ = 0.05 mg/kg.

Total B = sum of IFT, IFT-DKN, RPA 205834 and RPA 207048, expressed as isoxaflutole. Conversion factor of IFT-DKN to isoxaflutole equivalents is 1.00. Residues below LOQ were calculated as being at the LOQ = 0.05 mg/kg. Hen tissues were not analysed for RPA 205038 and RPA 207048, although these metabolites were found in the laying hen metabolism study in hen muscle and hen fat. The sum of IFT and IFT-DKN was therefore multiplied by a factor 1.75 in skin with adhering fat to correct for this omission. Values were then rounded up to 1 figure if below the LOQ. Results in muscle are not corrected because of low expected RPA 207048 levels. Results for liver do not need a correction.

^a NA, assumed to be < 0.05 mg/kg for calculation of total residues

NATIONAL RESIDUE DEFINITIONS

In the past, the isoxaflutole residue data in plant commodities were generated as the sum of IFT and its metabolites IFT-DKN and IFT-BA using a common-moiety method. Thus, the residue definition for monitoring and dietary risk assessment consisted of the sum of the parent IFT and its metabolites IFT-DKN and IFT-BA, expressed as isoxaflutole. Later on, in the late 1990s the residue data were generated using HPLC-MS-MS methods which allow a separate quantification of isoxaflutole, IFT-DKN and IFT-BA. IFT-BA is a common metabolite for both isoxaflutole and pyrasulfotole (another herbicide). Because, IFT-BA is not considered toxicologically relevant in the EU, Australia, USA and Canada, the residue definition for enforcement has been changed and is now described as the sum of the parent IFT and its metabolite IFT-DKN, expressed as isoxaflutole.

EU

The EU the residue definition for MRL setting and dietary risk assessment for plant and animal commodities is identical and is defined as the sum of isoxaflutole and IFT-DKN, expressed as isoxaflutole.

Australia

Since 2013, the residue definition for both plant and animal commodities is: “The sum of isoxaflutole and 2-cyclopropylcarbonyl-3-(2-methylsulfonyl-4-trifluoromethylphenyl)-3-oxopropanenitrile (i.e. IFT-DKN) expressed as isoxaflutole.

Canada

The residue definition for MRL setting is now the sum of isoxaflutole and IFT-DKN, expressed as isoxaflutole equivalents (EMRL2010-21, 24 September 2010)

USA

The residue definition for MRL setting is now the sum of isoxaflutole and IFT-DKN, expressed as isoxaflutole equivalents (Federal Register / Vol.73, No. 240 of 12 December 2008 and Federal Register / Vol.76, No. 235 of 7 December 2011). Residue definitions for dietary risk assessment are summarized in the Memorandum of 10 July 2008.

Matrix	Residues included in Risk Assessment		Residues included in Tolerance Expression
Plants	Maize	Isoxaflutole, RPA 202248	Isoxaflutole, RPA 202248
Rotational Crop	Rotational crops	Isoxaflutole, RPA 202248	Isoxaflutole, RPA 202248
Livestock	Ruminant Poultry	Isoxaflutole, RPA 202248, RPA 205834, RPA 207048	Isoxaflutole, RPA 202248

APPRAISAL

Isoxaflutole was scheduled for the evaluation as a new compound by 2013 JMPR at the Forty-fourth Session of the CCPR (2012). Isoxaflutole is a synthetic compound of the isoxazole group of chemicals used as a herbicide. The mode of action of isoxaflutole is the inhibition of the enzyme 4-hydroxyphenylpyruvate dioxygenase (HPPD), which inhibits pigment formation, causing bleaching of the developing tissues of the target plants. Isoxaflutole controls a wide spectrum of grasses and broadleaf weeds by bleaching emerging or emerged weeds following herbicide uptake via the root system.

The Meeting received information from the manufacturer on identity, metabolism, storage stability, residue analysis, use patterns, residues resulting from supervised trials on sweet corn, chickpeas, glyphosate/HPPD tolerant soya beans, maize, sugar cane and poppy seed, fates of residue during processing, and livestock feeding studies.

Chemical name:

Isoxaflutole

IUPAC: 5-cyclopropyl-4-(2-methylsulfonyl-4-trifluoromethylbenzoyl)-isoxazole

Structural formula:

Metabolites referred to in the appraisal by codes:

IFT-DKN
RPA 202248

Isoxaflutole diketonitrile;
IUPAC: 3-cyclopropyl-2-[2-methyl-4-(trifluoromethyl)benzoyl]-3-oxopropanenitrile;

IFT-BA
RPA 203328

Isoxaflutole benzoic acid
IUPAC: 2-mesyloxy-4-(trifluoromethyl)benzoic acid;

IFT-amide
(no code)

Isoxaflutole benzamide

RPA 205834

IUPAC: 2-mesyloxy-4-(trifluoromethyl) benzamide
2-aminomethylene-1-cyclopropyl-3-(2-mesyloxy-4-(trifluoromethyl)phenyl)-propane-1,3-dione

RPA 207048

1-cyclopropyl-2-hydroxymethylene-3-(2-mesyloxy-4-(trifluoromethyl)phenyl)-propane-1,3-dione

RPA 205568

5-cyclopropyl-1,2-oxazol-4-yl- α,α,α -trifluoro-p-tolyl ketone

No code

4-(trifluoromethyl) benzoic acid
 $\text{CH}_3\text{-C}_6\text{H}_4\text{-COOH}$

Animal metabolism

The Meeting received results of animal metabolism studies in lactating goats and laying hens. Experiments were carried out with [U- ^{14}C -phenyl]-isoxaflutole.

Metabolism in laboratory animals was summarized and evaluated by the WHO panel of the JMPR in 2013. Following oral administration in rats, [U- ^{14}C -phenyl]-isoxaflutole was rapidly and extensively metabolized yielding nine radioactive fractions in the urine and up to eleven in the faeces. There were no indications of any metabolites resulting from phase II (conjugation) reaction. Parent isoxaflutole was only found in the faeces of the single 100 mg/kg bw high dose group and to a lesser extent also in the urine of this group (together 5.7–8.2% of the administered dose). The major radioactive component (70–85% of the administered dose) in both urine and faeces, as well as in solvent fractions of liver was IFT-DKN for all three dose groups (single 1 mg/kg bw low dose, single 100 mg/kg bw high dose, repeated 1 mg/kg bw low dose).

The parent compound metabolized to IFT-DKN (major pathway) or RPA 205834 and subsequently further oxidized, respectively to IFT-BA (most polar, 0.6–3.5% of the administered dose) or RPA 207048. A third minor metabolic pathway includes the cleavage of the sulfonic acid group to metabolite RPA 205568 (only 1.3–2.0% of the administered dose).

Four lactating goats, orally treated twice daily for 7 consecutive days with [U-¹⁴C-phenyl]-isoxaflutole, were sacrificed 23 hours after the last dose. The four goats received low, medium (2) and high actual doses equivalent to 1.1 (goat 1), 10 (goat 2), 13 (goat 3) and 64 (goat 4) ppm dry feed (2.0, 20, 20 and 100 mg ai/kg bw, respectively). Total recovered radioactivity amounted to 97, 88, 78, and 73% of the administered dose in goat 1 to 4, respectively. Radioactivity recovered from urine and faeces ranged from 56% of the administered dose in the high dosed goat (27% in urine, 29% in faeces) to 85% in the low dosed goat (54% in urine, 31% in faeces). Radioactivity in edible tissues and organs ranged from 5.3% of the administered dose in the high dose goat to 11% in the low dose goat. Radioactivity in milk ranged from not detectable in the low dose goat to 0.54–0.60% of the administered dose in the medium to high dosed goats. Radioactivity levels in milk peaked at 0.093–0.095 mg/kg eq in goat 3 at day 4–5, 0.059–0.060 mg/kg eq in goat 2 at day 6–7 and 0.33–0.35 mg/kg eq in goat 4 at day 5–7.

Tissues (goat 3) and milk (goat 2) were subjected to further analysis. The total radioactive residues (TRR) were 2.1 mg/kg eq (liver), 0.90 mg/kg eq (kidney), 0.26 mg/kg eq (muscle), 0.069 mg/kg eq (renal fat), 0.062 mg/kg eq (omental fat) and 0.060 mg/kg eq (milk). Radioactive residues could be extracted with methanol (milk), phosphate buffer pH 7.5 (liver, kidney and fat) or phosphate buffer pH 7.5 in combination with protease treatment (muscle). The extracted radioactive residues in the medium dosed goats amounted to 95% TRR for milk, 98% TRR for liver, 94% TRR for kidney, 76% TRR for muscle, 98% TRR for omental fat and 93% TRR for renal fat.

Parent compound was not found in any of the goat commodities. In goat milk, and all tissues the metabolite IFT-DKN was the most abundant component of the residues in the primary extracts (18–86% TRR or 0.015–1.8 mg/kg eq), followed by the metabolite RPA 207048 (9.1–26% TRR or 0.10–0.016 mg/kg eq, respectively). Muscle contained 18.3% TRR free and 23% conjugated IFT-DKN as well as 9.1% free and 3.4% conjugated RPA 207048; (released as free metabolites by protease treatment). Metabolite RPA 205834 (8.1–18% TRR or 0.005–0.011 mg/kg eq) was only found in milk and fat.

Ten laying hens, orally treated once daily for 14 consecutive days with [U-¹⁴C-phenyl]-isoxaflutole, were sacrificed 23 hours after the last dose. Hens were treated at an actual dose rate of 1.1 (group A) or 11 (group B) ppm dry feed. Total recovered radioactivity amounted to 117% and 92% of the administered dose in group A and B, respectively. Radioactivity from the excreta amounted to 112% and 88% of the administered dose for group A and B, respectively. Low levels of radioactivity were recovered in the eggs (0.12–0.15% of the administered dose) or tissues (1.7% in group A and 0.20% in group B).

In the low dose group (A) the concentrations of radioactivity in egg whites were below 0.002 mg/kg eq at all-time points. The levels of radioactivity in egg yolk reached a steady state within 7 days after the first dose (0.022–0.028 mg/kg eq). In the high dose group (B) the concentration of radioactivity in egg whites reached a steady state (0.010–0.015 mg/kg eq) within 4 days. The levels of radioactivity in egg yolk were up to 16 times higher, with a steady state concentration of 0.14–0.15 mg/kg eq within 7 days of exposure.

The highest radioactivity concentrations in edible tissues were found in the liver (0.84 and 0.95 mg/kg eq for dose group A and B, respectively) and kidney (0.055 and 0.16 mg/kg eq, respectively for A and B). Radioactivity in fat and muscle was only observed in the high (B) dose group, being 0.028 and 0.035 mg/kg eq, respectively. Some radioactivity was found in skin (0.008 and 0.068 mg/kg eq in dose group A and B, respectively).

Radioactivity was characterized in tissues and eggs from the high dose group B. Radioactive residues were extracted sequentially by exhaustive extractions using hexane, methanol, acetonitrile, ethyl acetate, acidified methanol and/or water. The primary extractable residues amounted to 97%

TRR for liver, 74% TRR for kidney, 54% TRR for muscle, 93% TRR for fat, 53% TRR for skin, 66% TRR for egg yolk and 50% TRR for egg white. After treatment with protease, another 16%, 29%, 21%, 46% and 20% TRR could be released from kidney, muscle, skin, egg yolk and egg white, respectively. After extensive acid hydrolysis (6 M HCl at 95 °C for 7 days) another 1.9%, 43%, 7.4% and 20% TRR could be released from kidney, muscle, skin and egg white, respectively.

In egg yolk (0.137 mg/kg eq), the major compounds in the primary extracts represented IFT-DKN (26% TRR) and RPA 205834 (28% TRR). Parent, IFT-BA and RPA 207048 were not found. Exhaustive acid hydrolysis released additional IFT-DKN (17% TRR) from egg yolk. Residues in egg white (0.010 mg/kg eq) and the remaining fractions from egg yolk could not be identified, although two fractions in egg yolk contained considerable radioactivity (10% TRR or 0.014 mg/kg eq in the primary extract and 18% TRR or 0.025 mg/kg eq in the acid hydrolysate).

In hen liver (0.953 mg/kg eq), kidney (0.155 mg/kg eq) and skin (0.068 mg/kg eq), the major compound in the primary extracts represented IFT-DKN (93%, 74% and 37% TRR, respectively). Parent, RPA 207048 and RPA 205834 were not found. IFT-BA was found as minor metabolite in liver and kidney (3.5% TRR and 0.65% TRR, respectively). Protease digestion and exhaustive acid hydrolysis released additional IFT-DKN (18% and 7.4% TRR, respectively) from skin.

In hen muscle (0.035 mg/kg eq) the only compound identified in the primary extracts was RPA 207048 (31%TRR). Parent and RPA 205834 were not found. Exhaustive acid hydrolysis released additional RPA 207048 (17% TRR) as well low levels of IFT-DKN and IFT-BA (5.7% and 5.7% TRR, respectively) from muscle.

In hen fat (0.028 mg/kg eq) the major compounds in the primary extracts were IFT-DKN (29% TRR) and RPA 207048 (21% TRR).

The metabolic pathway of isoxaflutole in livestock involves the opening of the oxazole ring and the formation of the diketo-nitrile derivative (IFT-DKN) or the diketo-amine derivative (RPA 205834). Further degradation occurs through deamination to form the diketo-hydroxy derivative (RPA 207048) or through further cleavage to form the benzoic acid derivative (IFT-BA). Further metabolism involves conjugation of IFT-DKN, RPA 207048 and/or IFT-BA with proteins or acid cleavable compounds.

Parent compound was not found in milk, eggs, goat tissues or hen tissues. This may represent rapid metabolism within the animal or it may represent degradation during frozen storage of the samples or degradation during extraction.

The major compounds identified in goat, hen tissues, milk or eggs are: IFT-DKN, RPA 207048, RPA 205834, conjugated IFT-DKN and conjugated RPA 207048. In goats, metabolites IFT-DKN (18–86% TRR) and RPA 207048 (9.1–26% TRR) were found in all tissues and milk. Metabolite RPA 205834 (8.1–18% TRR) was only found in milk and fat. Conjugated forms of IFT-DKN (23% TRR) and RPA 207048 (3.4% TRR) were only found in goat muscle and free metabolites could be released by protease digestion. In hens, metabolite IFT-DKN (26–93% TRR) was found in eggs and all tissues, except muscle. Metabolite RPA 207048 (21–31% TRR) was only found in muscle and fat. Metabolite RPA 205834 was only found in eggs (28% TRR in egg yolk). Conjugated forms of IFT-DKN (5.7–25% TRR) were found in hen muscle, skin and eggs and free metabolites could be released by protease (skin only) or exhaustive acid hydrolysis. Conjugated forms of RPA 207048 were found in hen muscle only and free metabolites could be released by exhaustive acid hydrolysis. IFT-BA was only found as a minor metabolite in hen liver and kidney (3.5% TRR and 0.65% TRR, respectively) and as conjugate form in hen muscle (5.7% TRR).

The metabolic pathway in ruminants and poultry is identical to the metabolic pathway in rats, although in rats an additional minor pathway to RPA 205568 is found, which is not found in ruminant or poultry. All metabolites identified in livestock are also found in rats.

Plant metabolism

The Meeting received plant metabolism studies for isoxaflutole on cereals (maize and wheat), pulses/oilseeds (soya beans and poppy seeds) and sugar cane after a pre-plant, crop pre-emergence, crop post-emergence or crop foliar application.

The metabolism of [U-¹⁴C-phenyl]-isoxaflutole in outdoor grown maize was studied following pre-plant soil incorporated and pre-emergent applications. Maize forage, grains and fodder were harvested at DAT = 41, 122 and 122/138. Residue levels in maize forage, grains and fodder were 0.20–0.044–0.15 mg/kg eq, respectively, for pre-plant incorporated treatment at 0.21 kg ai/ha and 0.23–0.039–0.12 mg/kg eq, respectively, for pre-emergence treatment after 0.23 kg ai/ha. Residue levels were 0.80–0.15–0.66 mg/kg eq for pre-plant incorporated treatment at 0.66 kg ai/ha and 0.49–0.12–0.53 mg/kg eq for pre-emergence treatment at 1.1 kg ai/ha. Residue levels in maize forage, grains and fodder after pre-plant incorporated treatment were higher than those after pre-emergence treatment at the high dose rate; they were similar at the low dose rates. Exaggerated dose rates exhibited greater phytotoxicity. Radioactivity was characterized in maize from the low dose treatments. The major part of the residues could be extracted with an exhaustive range of solvents: hexane/ethyl acetate, acetonitrile, water pH 5.5, and acidified acetonitrile: 91–99% TRR in forage, 83–87% TRR in grains and 75–79% TRR in fodder. Additional residues could be released by cellulase digestion (3.0–6.5% TRR). Parent isoxaflutole was not found in any of the maize commodities. The major compound identified was free IFT-BA (61–89% TRR) in all maize commodities. Minor metabolites represented conjugated IFT-DKN (0.49–0.53% TRR in forage only) and conjugated IFT-BA (1.1–2.7% TRR in forage and fodder).

In a second study, the metabolism of [U-¹⁴C-phenyl]-isoxaflutole was studied in outdoor grown maize following post-emergent application at 0.21 kg ai/ha in the presence of the safener cyprosulfamide. Maize forage and sweet corn were harvested at DAT 75; maize grains and fodder were harvested at DAT = 106. Residue levels in maize forage, sweet corn, maize grains and fodder were 0.13–0.010–0.015–0.10 mg/kg eq, respectively after pre-plant incorporated treatment. These residue levels were similar to those from the pre-plant incorporated and pre-emergence treatments in the previous study. The major part of the residues could be extracted with acetonitrile and water: 93% TRR in forage, 97% TRR in sweet corn, 77% TRR in grains and 88% TRR in fodder. Aqueous fractions underwent base hydrolysis. Parent isoxaflutole was not found in any of the maize commodities. The major compound identified was free IFT-BA (52–63% TRR) in all maize commodities. Other identified metabolites represented free IFT-DKN (4.0–9.8% TRR in sweet corn, fodder and grain) and conjugated IFT-BA (4.1–15% TRR in forage and fodder).

The metabolism of [U-¹⁴C-phenyl]-isoxaflutole in outdoor grown wheat was studied following a post-emergent application at 0.055 kg ai/ha onto immature plants (Zadoks 30). Residue levels in wheat hay, straw and grains harvested at DAT 41, 93 and 93/99 were 0.172–0.107–0.058 mg/kg eq, respectively. The major part of the residues (86–96% TRR) could be extracted with acetonitrile/water. Parent isoxaflutole was only found in wheat hay (6.5% TRR). Major metabolites identified were free IFT-BA (65–96% TRR) in all wheat commodities and free IFT-DKN (9.9–21% TRR in forage and straw only). A small fraction of the metabolites in straw might be attributed to conjugates because 3% TRR was released through acid reflux.

The metabolism of [U-¹⁴C-phenyl]-isoxaflutole in indoor grown glyphosate/HPPD-tolerant soya was studied following a pre-plant application or a foliar application to plants in full bloom (BBCH 65, 57 days after planting) at 0.331 kg ai/ha. Soya bean forage, hay and seeds were harvested at DAT 74/17, 189/132 and 189/132, respectively, for pre-plant/foliar treatment. Residue levels in soya bean forage, hay and seeds were 0.27–0.49–0.15 mg/kg eq after pre-plant treatment and 13–1.8–0.26 mg/kg eq after foliar treatment. The major part of the residues could be extracted with acetonitrile/water: 91–100% TRR in all soya commodities. The foliar application of isoxaflutole had a significant effect on the metabolic profile. Major compounds identified in the pre-plant application were free IFT-amide (53%, 13% and 8% TRR in forage, hay and seeds, respectively), free IFT-BA (66%, 56% and 27% TRR in seeds, hay and forage, respectively) and free IFT-DKN (13–17% TRR in all soya commodities). Major compounds identified in the foliar application were parent (72% and

25% TRR in forage and hay, respectively), free IFT-BA (62%, 38% and 6% TRR in seeds, hay and forage, respectively) and free IFT-DKN (18–24% TRR in all soya commodities). Minor metabolites identified in the foliar application were free IFT-amide (3–8% TRR in hay and seeds).

FG 72 soya beans express the hppdPfW336 gene from *Pseudomonas fluorescens* and the 2mepsps gene derived from maize. These genes confer tolerance to the herbicide isoxaflutole and glyphosate-containing herbicides, respectively, via a modification of the target enzyme which makes the modified enzymes insensitive against the herbicide. Since in the FG72 soya bean variety the tolerance against glyphosate and isoxaflutole is not based on detoxification of the pesticides, the tolerance to glyphosate is not expected to modify the nature and levels of isoxaflutole-derived residues in treated soya beans. Similarly the tolerance to isoxaflutole is not expected to modify the nature and levels of glyphosate residues.

The metabolism of [U-¹⁴C-phenyl]-isoxaflutole in outdoor grown poppies was studied following a pre-emergent application (3 days after planting) at 0.11 kg ai/ha in the presence of the safener cyprosulfamide. Residue levels in poppy seeds, seed bolls and straw harvested at DAT 110 were 0.056, 0.78 and 0.72 mg/kg eq, respectively. Most of the radioactivity (92–98% TRR) could be extracted with acetonitrile/water. Parent isoxaflutole was not found in any of the samples. The major compound identified was free IFT-BA (66–94% TRR) in all commodities. Free IFT-DKN was found in low levels (2.1–3.5% TRR) in seed bolls and straw, but not in poppy seeds.

The metabolism of [U-¹⁴C-phenyl]-isoxaflutole in outdoor grown sugarcane was studied following a pre-emergent application at 0.210 kg ai/ha or a foliar application (47 days after planting) at 0.133 kg ai/ha. Residue levels in sugarcane plants harvested at DAT 81, 95 and 365 were 0.12–0.15–<0.01 mg/kg eq, respectively, for pre-emergence treatment and 0.18, <0.01 and <0.01 mg/kg eq at DAT 40, 95 and 365, respectively, for foliar treatment. Radioactivity in samples with residues >0.01 mg/kg eq was characterized. Most of the radioactivity could be extracted with acetonitrile: 66%, 79% and 84% TRR in DAT 40, 81 and 95 samples, respectively. Additional residues (9.5–24% TRR) could be released by exhaustive extraction procedures including reflux with acetonitrile, reflux with 0.1 M HCl and reflux with 0.1 M ammonia. The major compound identified in immature sugarcane (DAT 40, 81 and 95) was IFT-BA (66–93% TRR). Parent isoxaflutole (11% TRR) and IFT-DKN (2.2% TRR) were only found in the foliar treated crop harvested at DAT 40. Since initial acetonitrile extracts were combined with more exhaustive extracts, it is not clear whether the identified compounds are free or conjugated.

The effect of the safener cyprosulfamide on the metabolism of isoxaflutole was investigated in 3 day old maize seedlings grown in nutrient solution. Roots were exposed for 24 h to [U-¹⁴C-phenyl]-isoxaflutole alone or in combination with cyprosulfamide. After this period the plants were grown in blank nutrient solution for 3 days. Shoots, seeds and roots were collected and extracted with acetonitrile/water. The effect of the safener cyprosulfamide is a clear reduction of leaf damage (bleaching) and a lower ratio of IFT-DKN to IFT-BA in the shoots.

From these data it is concluded that in cereal grains, seeds of pulses/oilseeds, sugarcanes, forage and fodder of cereals or pulses/oilseeds, metabolite IFT-BA is the only residue identified at significant quantities (52–99% TRR). Parent isoxaflutole (6.5–11% TRR) is only found after post-emergent or foliar treatments in wheat hay or immature sugarcane. Minor metabolites identified were IFT-DKN (2.1–21% TRR in sweet corn, maize grain, immature sugarcane, cereal forage, cereal fodder and poppy straw), conjugated IFT-DKN (0.49–0.53% TRR in maize forage) and conjugated IFT-BA (1.1–15% TRR in maize forage and maize fodder).

Glyphosate/HPPD-tolerant soya has a somewhat different metabolic profile. Major compounds identified in the pre-plant application were free IFT-amide (53%, 13% and 8% TRR in forage, hay and seeds, respectively), free IFT-BA (66%, 56% and 27% TRR in seeds, hay and forage, respectively) and free IFT-DKN (13–17% TRR in all soya commodities). Major compounds identified in the foliar application were parent (72% and 25% TRR in forage and hay, respectively), free IFT-BA (62%, 38% and 6% TRR in seeds, hay and forage, respectively) and free IFT-DKN (18–24% TRR in all soya commodities).

The first hydrolytic step in the degradation in plants is the opening of the isoxazole ring to form IFT-DKN. Further hydrolytical cleavage of the carbonyl bridge and loss of the complete isoxazole moiety leads to the corresponding benzoic acid derivative (IFT-BA). In glyphosate/HPPD tolerant soya beans loss of the complete isoxazole moiety may also lead to the benzamide derivative (IFT-amide).

Metabolites IFT-DKN and IFT-BA are also found in rat. Metabolite IFT-amide (8–53% TRR) seems to be formed in glyphosate/HPPD tolerant soya beans only. This metabolite was not found in rat.

Environmental fate in soil

The Meeting received information on aerobic degradation in soil, soil photolysis and fate in rotational crops.

Aerobic degradation of [U-¹⁴C-phenyl]-isoxaflutole under laboratory conditions was studied at 20 °C in various soil types treated at 0.2 mg ai/kg dry soil (0.20 kg ai/ha). The half-life for isoxaflutole was estimated at 7.6–11 h in clay loam and loamy sand soils, 1.3–2.5 days for sandy loam and clay soils and 4 days for loamy soils. The major metabolites identified were IFT-DKN (max. 52–96% TAR during a period 3–10 days after treatment) and IFT-BA (max. 30–90% TAR during a period of 1–12 months after treatment). IFT-BA levels in clay loam soil were very low (max 7.1% TRR at 7 days). Carbon dioxide was formed from day 1 onwards and these levels increased with time (up to 1.8–37% TRR after 1 year). These study results show that parent isoxaflutole is unlikely to be taken up by crops (and weeds) when applied onto bare soil as pre-plant or pre-emergent application.

Using the data from these soil degradation studies, the half-life for the metabolite IFT-DKN were estimated at 20 days in a sandy loam soil, 25 days in a loam soil, 37 days in a clay soil, 41 days in a clay loam soil and 56 days in a loamy sand soil. The half-life for IFT-BA was estimated at 290 days in clay soil and 980 days in a sandy loam soil. These studies show that metabolites IFT-DKN and IFT-BA are available for take-up by the plants for a considerable period after pre-plant or pre-emergence application depending on the soil type.

Soil photolysis of [U-¹⁴C-phenyl]-isoxaflutole was studied in a sandy loam soil, surface treated at 0.645 kg ai/ha and exposed for 31 days to artificial sunlight. The half-life for isoxaflutole (DT₅₀ 23 hours) was similar to the one for the dark control (DT₅₀ 20 hours). The formation of transformation products specific for photolytic processes was insignificant. The study shows that light has no effect on the degradation of isoxaflutole on soil.

Metabolism of [U-¹⁴C-phenyl]-isoxaflutole was investigated in confined rotational crops following pre-plant incorporated soil treatment or pre-emergence treatment. A sandy loam soil was treated at a rate of 0.213 kg ai/ha under outdoor conditions. Rotational crops (radish, lettuce, mustard greens, sorghum and wheat) were sown 34, 123 and 365–375 days after application, representing first, second and third rotation. Total radioactivity for pre-plant incorporated soil treatment ranged from 0.003–0.24 mg/kg eq after first rotation, 0.001–0.030 mg/kg eq after second rotation and 0.001–0.051 mg/kg eq after third rotation. Total radioactivity for pre-emergence application ranged from 0.010–0.126 mg/kg eq after first rotation, < 0.001–0.042 mg/kg eq after second rotation and 0.001–0.030 mg/kg eq after third rotation. Total radioactivity levels above 0.05 mg/kg eq were only found in immature lettuce and sorghum commodities after the first rotation (0.126–0.24 mg/kg eq in sorghum forage, 0.13 mg/kg eq in sorghum fodder, 0.12 mg/kg in sorghum grain, 0.056 mg/kg eq in immature lettuce) and after the third rotation (0.051 mg/kg eq in sorghum forage). Parent isoxaflutole was not found in any of the rotational crops. IFT-BA represented the major compound and was present in the commodities of the first, second and third rotation at levels between < 0.001–0.11 mg/kg eq (6.9–100% TRR). IFT-DKN was only found in radish leaves and sorghum grain at levels up to 0.005 mg/kg eq (0.8–27.3% TRR) in the first rotation. RPA 205834 was detected by HPLC-MS-MS in trace amounts (< 0.001 mg/kg eq) in mature lettuce of the first rotation. A fourth metabolite (U1) was found in the commodities of the first, second and third rotation at levels between < 0.001–0.022 mg/kg eq (10–100% TRR). The polarity of this compound and the molecular weight of 192, as

determined by HPLC-MS-MS, suggests it is a carboxylic acid degradation product of IFT-BA with the structural formula $\text{CF}_3\text{-C}_6\text{H}_4\text{-COOH}$ (4-trifluoromethyl benzoic acid).

In a field rotational crop study at two different locations in the USA isoxaflutole was applied as pre-plant or pre-emergent application to maize at 0.154–0.161 kg ai/ha. Rotational crops (soya beans, sugar beets, radishes, turnips, mustard greens, wheat and sorghum) were sown 29/30, 104, 119/120, 151, 166, 180, 365 days after application, representing various rotations of maize. No residues (< 0.01 mg/kg) of parent isoxaflutole, metabolites IFT-DKN or metabolite IFT-BA were found in any of the crops at any of the rotations. Metabolite 4-trifluoromethyl benzoic acid was not analysed, but since its levels are expected to be in the same order of magnitude as IFT-BA, based on the confined rotational crop study, it is not expected to be found at levels > 0.01 mg/kg.

From these data it is concluded that the first hydrolytic step in the aerobic degradation in soil is the opening of the isoxazole ring to form IFT-DKN, which is responsible for the mode of action. Further hydrolytical cleavage of the carbonyl bridge and loss of the complete isoxazole moiety leads to the corresponding benzoic acid derivative (IFT-BA). Light has no effect on the degradation of isoxaflutole on soil. Isoxaflutole has a very short half-life of 8 h to 4 days in soil, and consequently is not found in rotational crops after pre-plant or crop pre-emergence applications. Metabolites IFT-DKN and IFT-BA have long half-lives of 20–56 and 290–980 days, respectively, in soil and consequently are the main metabolites found in plants after pre-plant, crop pre-emergence or crop post-emergence applications. Since metabolites IFT-DKN and IFT-BA were also found after foliar treatments of sugarcane and glyphosate/HPPD tolerant soya beans, it is likely that metabolites IFT-DKN and IFT-BA are also formed in plants. In confined rotational crop studies, a third metabolite (4-trifluoromethyl benzoic acid ($\text{CF}_3\text{-C}_6\text{H}_4\text{-COOH}$)) was found (10–100% TRR), formed by the loss of the methylsulfonyl moiety of IFT-BA. It is not clear whether this metabolite is formed exclusively in the plants or is formed in the soil and taken up by the plants. Metabolite 4-trifluoromethyl benzoic acid was not found in rat.

Methods of Analysis

The Meeting received description and validation data for analytical methods of isoxaflutole related residues in plant and animal commodities.

For plants, a HPLC-MS-MS method was submitted as enforcement/monitoring method for the individual determination of parent and its metabolite IFT-DKN. Plant material was extracted with acidified methanol/water followed by filtration. The Meeting considers validation sufficient for commodities with high acid content, high water content, high starch content and high oil content. The LOQ was 0.01 mg/kg for each analyte.

Several other HPLC-MS-MS methods were submitted for the determination of parent and its metabolites IFT-DKN and IFT-BA in plant material. In some trials a GC-MS method was used, where residues were extracted with methanol and converted into a common moiety IFT-methylbenzoate by hydrolysis and methylation. Most analytical methods were considered fit for purpose with LOQs ranging from 0.01 mg/kg eq for total residues or 0.01–0.03 mg/kg for individual analytes.

For animal commodities, the existing multi-residue method QuEChERS was submitted as enforcement/monitoring method. The Meeting considers this method valid for the individual determination of parent and its metabolite IFT-DKN in all animal commodities. The LOQ was 0.01 mg/kg for milk, eggs, meat, fat, liver and kidney for each analyte.

Three other analytical methods were submitted for the determination of isoxaflutole related residues in milk, eggs or animal tissues. HPLC-UV methods were used for milk and eggs. A HPLC-MS-MS method was used for tissues. Conjugates of IFT-DKN and RPA 207048 were not analysed by these methods. The reported LOQ of 0.05 mg/kg for each analyte in meat, fat, liver and kidney needs to be substantiated by additional data, since only 1–2 recoveries per matrix were provided at this level. Parent is degraded during extraction and is measured as increased IFT-DKN in these methods. Based on the validation data available, the methods are considered suitable for determination of

parent, IFT-DKN, RPA 205834 and RPA 207048 in milk at 0.02–2.0 mg/kg and 0.05–0.25 mg/kg in eggs and tissues.

Solvents used in the analytical methods were different from the extraction methods used in the metabolism studies. Extraction efficiency, using radiolabelled samples from the metabolism studies, was not verified for any of the analytical methods.

Stability of pesticide residues in stored analytical samples

The Meeting received information on the stability of isoxaflutole, IFT-DKN and IFT-BA in plant commodities or isoxaflutole, IFT-DKN, IFT-BA, RPA 205834 and RPA 207048 in animal commodities in animal commodities stored frozen.

Storage stability studies at -10 °C and -20 °C showed that total isoxaflutole residues (sum of parent, IFT-DKN and IFT-BA, measured as common moiety) were stable for at least 11 months in commodities with high protein content (chickpea seeds), 15 months in commodities with high starch content (maize grains) and straw (maize fodder) and at least 20 months in commodities with high water content (sugar canes).

Storage stability studies showed that isoxaflutole converts to IFT-DKN after 3–6 months of storage at -10 °C in commodities with high acid content (oranges), high water content (sugar canes), high protein content (dry pinto beans) and high oil content (dry soya beans). The metabolite IFT-DKN remained stable for at least 12 months at -10 °C in commodities with high acid content (oranges), high water content (sugar canes), high protein content (dry pinto beans) and at least 16 months in commodities with high oil content (poppy seeds and dry soya bean seeds). Metabolite IFT-DKN converts to IFT-BA within a period of 23 months at -20 °C in commodities with high water content (sorghum forage, lettuce and radish leaves), high starch content (radish roots), high protein content (sorghum grain) and straw (sorghum fodder).

Based on storage stability studies at -20 °C in fortified samples of animal commodities the Meeting noted that isoxaflutole was not stable. Isoxaflutole degraded rapidly to IFT-DKN in eggs and degraded after a period of 85 days in milk and muscle. Parent isoxaflutole also degrades to IFT-DKN by the extraction method used for tissue analysis in the feeding studies. Metabolite IFT-DKN is stable for a period of at least 113–130 days in liver, kidney, muscle, fat, milk and eggs. If metabolite IFT-DKN is included in the residue definition, any degradation from isoxaflutole to IFT-DKN is covered by the total residues measured.

Metabolite RPA 205834 is stable for a period of 113–131 days in kidney, muscle, fat and milk. Metabolite RPA 205834 is stable for a maximum storage period of 94 days in liver and degrades significantly thereafter (36% remaining after 130 days). Storage stability of RPA 205834 was not investigated in eggs.

Metabolite RPA 207048 is not stable in any animal commodity. RPA 207048 degrades rapidly in kidney to a level of about 45% which is maintained from 13–115 days. RPA 207048 is stable for a maximum storage period of 28 days in muscle, 40 days in liver and 84 days in fat and thereafter remains stable at a level of about 50% of the original residue level for a period up to 85–113 days. Storage stability of RPA 207048 has not been investigated in milk and eggs. Precautions need to be taken when analysing this metabolite. Besides storage conditions, also extraction conditions are critical.

In case quantitative levels of total residues based on parent, IFT-DKN, RPA 205834 and RPA 207048 are needed, samples of animal origin need to be analysed within 30 days. And even then, metabolite RPA 207048 will be underestimated in kidney.

Definition of the residue

Parent compound isoxaflutole was not found in milk, eggs or livestock tissues. Metabolites found at significant levels in livestock commodities were: IFT-DKN, conjugated IFT-DKN, RPA 205834, RPA 207048, and conjugated RPA 207048. Metabolite IFT-DKN (18–93% TRR) was found in milk, eggs, all goat and hen tissues, except hen muscle. Conjugated forms of IFT-DKN (5.7–25% TRR)

were only found in goat muscle, hen muscle, hen skin and eggs and the free metabolite could be released by protease digestion (goat muscle and hen skin) and/or exhaustive acid hydrolysis (hen muscle and eggs). Metabolite RPA 205834 (8.1–28% TRR) was found in milk, eggs (yolk) and goat fat in the metabolism studies on goat and hen, but it was also found in milk, bovine liver and bovine kidney in cow feeding study. Metabolite RPA 207048 (9.1–31% TRR) was found in milk, all goat tissues, hen muscle and hen fat. Conjugated forms of RPA 207048 (3.4% TRR) were only found in goat and hen muscle and could be released by protease digestion (goat muscle) or exhaustive acid hydrolysis (hen muscle). Further there seems to be a metabolic shift between RPA 205834 and RPA 207048 between goat and cow. In goat, RPA 207048 seems to be present in all goat tissues and at higher levels than RPA 205834, while in cow RPA 207048 is not found. This metabolic shift might be related to the shorter period between last application and slaughter time for cows (7.5 h) compared to goats (23 h).

Isoxaflutole is easily converted to IFT-DKN. Since no discrimination can be made whether isoxaflutole is metabolized within the animal, or whether it is degraded because of its sensitivity to physical chemical conditions, isoxaflutole needs to be included in the residue definition for enforcement. Any isoxaflutole degraded because of storage or extraction conditions will be measured as IFT-DKN. The sum of IFT and IFT-DKN can therefore serve as the marker residue for enforcement.

The log K_{ow} for isoxaflutole is 2.34. Isoxaflutole and its metabolite IFT-DKN are extracted with acidified aqueous solvents and highest levels of these metabolites are found in the organs kidney and liver. The sum of parent and IFT-DKN is considered not fat soluble.

Apart from isoxaflutole and IFT-DKN other metabolites found at significant levels in livestock commodities were conjugated IFT-DKN, RPA 205834, RPA 207048, and conjugated RPA 207048.

Toxicity of the free IFT-DKN, RPA 205834 and RPA 207048 is considered to be covered by toxicity studies on isoxaflutole since each of the free metabolites was found in the rat high dose group. Free IFT-DKN is the major compound found in rat urine, faeces and solvent fractions of liver, and its toxicity is considered to be similar to that of the parent compound. Since metabolites RPA 205834 and RPA 207048 have similar structures as IFT-DKN and no data are available to conclude that they are of less toxicological significance, each metabolite is considered relevant for the residue definition for dietary risk assessment. Conjugated forms of IFT-DKN and RPA 207048 are considered relevant for dietary exposure, since the free metabolites can be released during the metabolic process in humans. The Meeting proposed to include parent, IFT-DKN, conjugated IFT-DKN, RPA 205834, RPA 207048, and conjugated RPA 207048 in the residue definition for dietary risk assessment of animal commodities.

The analytical method used in the feeding study cannot determine the conjugated forms of IFT-DKN and RPA 207048. For goat muscle, conjugates represent 26.62% TRR and free compounds (IFT-DKN + RPA 205834 + RPA 207048) represent 27.43% TRR. For hen muscle, conjugates represent 22.81% TRR and free compounds represent 31.4% TRR. For hen eggs, conjugates represent 16.8% TRR and free compounds represent 54% TRR. A multiplication factor 2 for goat and hen muscle and 1.3 for hen eggs could be used on the total residues to compensate for this underestimation of dietary exposure.

In primary crops, metabolite IFT-BA is the only residue identified at significant quantities (52–99% TRR). Parent isoxaflutole is only found after post-emergent or foliar treatments in livestock feed commodities: major amounts in glyphosate/HPPD-tolerant soya bean forage and hay (25–72% TRR) and minor amounts (6.5–11% TRR) in wheat hay or immature sugarcane. Minor metabolites identified were IFT-DKN (2.1–21% TRR), conjugated IFT-DKN (0.49–0.53% TRR) and conjugated IFT-BA (1.1–15% TRR). Metabolite IFT-amide (8–53% TRR) seems only to be formed in glyphosate/HPPD tolerant soya bean (seeds, forage, hay).

Metabolite IFT-BA is the major residue and is relevant for consideration in the residue definition for enforcement. However, IFT-BA can also arise in plant commodities as a result of treatment with pyrasulfotole. For this reason IFT-BA cannot be used as a marker for isoxaflutole.

The only other compounds relevant for the residue definition for enforcement are the parent and IFT-DKN. The sum of IFT and IFT-DKN can therefore serve as the marker residue for enforcement.

Apart from isoxaflutole and IFT-DKN, other metabolites found at significant levels in plant commodities are IFT-BA (feed commodities and tolerant soya beans) and IFT-amide (tolerant soya beans only). Assessment of additional toxicological data on IFT-BA demonstrated that metabolite IFT-BA is considerably less toxic than the parent compound. Thus, from a toxicological point of view it is not necessary to include IFT-BA in the residue definition. Metabolite IFT-amide is not found in rat. But since IFT-amide is present at lower levels than IFT-BA in soya bean seeds and because of its structural similarity with IFT-BA, IFT-amide is considered not relevant for the residue definition.

The Meeting recommended the following residue definition for isoxaflutole:

Definition of the residue for compliance with the MRL and for dietary risk assessment for plant commodities: *sum of isoxaflutole and isoxaflutole diketonitrile, expressed as isoxaflutole.*

Definition of the residue for compliance with the MRL for animal commodities: *sum of isoxaflutole and isoxaflutole diketonitrile, expressed as isoxaflutole.*

The Meeting considers the residue not fat soluble.

Definition of the residue for dietary risk assessment for animal commodities: *sum of isoxaflutole, isoxaflutole diketonitrile, RPA 205834 (2-aminomethylene-1-cyclopropyl-3-(2-mesyl-4-trifluoromethylphenyl)-propane-1,3-dione) and RPA 207048 (1-cyclopropyl-2-hydroxymethylene-3-(2-mesyl-4-trifluoromethylphenyl)-propane-1,3-dione), including their conjugates, expressed as isoxaflutole.*

Results of supervised residue trials on crops

The total residue values selected for maximum residue level recommendations and dietary intake are based on the sum of isoxaflutole and IFT-DKN. In case a common moiety method is used for analysis also the IFT-BA metabolite is included. Since the relative molecular weight of IFT-DKN is identical to that of isoxaflutole, no molecular weight conversion is needed. Soil type and the addition of the safener cyprosulfamide affect the residue levels in plant commodities. Residue trials were conducted in a range of soil types, which included those with the longest half-lives.

Since IFT-DKN is included in the residue definition, any degradation from isoxaflutole to IFT-DKN is covered by the total residues measured. Since IFT-BA is not part of the residue definition, any degradation from IFT-DKN to IFT-BA means an underestimation of the original residue present in the sample. Therefore, the Meeting takes only those trials into account, where samples have been stored for a maximum of 16 months (commodities with high oil content) or 12 months (all other commodities). Also trials where IFT-BA is below LOQ can be taken into account, because it indicates that no degradation of IFT or IFT-DKN to IFT-BA occurred.

Sweet corn (corn-on-the-cob)

Field trials involving sweet corn were performed in Spain, Italy, Greece, Portugal, Germany, France, Netherlands and the United Kingdom.

Critical GAP for sweet corn in France is for a single post sowing pre-emergence treatment (BBCH 00–08) at 0.099 kg ai/ha, where the safener cyprosulfamide is added. Trials from Spain, Italy, Germany, France, Netherlands and the UK (0.099–0.10 kg ai/ha, growth stage BBCH 0–06, cyprosulfamide added) matched this GAP. For sweet corn harvested at BBCH 79, total residues were: < 0.02 (10) mg/kg (n=10).

Several trials, where isoxaflutole was applied at the same dose rate at a later growth stage (BBCH 13–14), as well as a metabolism study in sweet corn following a post-emergence treatment at 0.21 kg ai/ha, confirmed the non-residue situation.

The Meeting estimated a maximum residue level of 0.02* mg/kg on sweet corn (corn-on-the-cob). The Meeting estimated an STMR of 0 mg/kg.

Pulses

Field trials involving chick-peas (dry) were performed in Australia.

Critical GAP for chick-peas in Australia is a single post plant crop, pre-emergence application at 0.075 kg ai/ha. In trials from Australia (1×0.075 kg ai/ha post planting pre-emergent) matching this GAP, total residues were: < 0.01 (3) and $< 0.01^a$ mg/kg ($n=4$) with a common moiety method (including IFT-BA). The superscript (a) indicates the addition of an adjuvant. The addition of which did not result in a difference in total residue levels.

An additional four trials at the same locations using a single post-plant crop emergence application at a higher application rate of 0.15 kg ai/ha, as well as a metabolism study in poppy seeds after post-plant crop pre-emergence treatment at 0.11 kg ai/ha, confirmed the no residue situation.

The Meeting estimated a maximum residue level of 0.01* mg/kg on chickpea, dry and an STMR of 0 mg/kg.

Field trials involving glyphosate/HPPD tolerant soya beans (FG72) (dry) were performed in the USA and Canada.

No authorised uses were available for glyphosate/HPPD tolerant soya beans (FG72). The Meeting agreed that no recommendations could be set for soya beans.

Maize

Field trials involving maize were performed in Spain, Italy, Greece, Portugal, Germany, France, Netherlands, the United Kingdom, the USA and Canada.

Critical GAP for maize in France is a single early post emergence treatment up to 3 leaf stage of the crop (BBCH 13) at 0.099 kg ai/ha with the addition of the safener cyprosulfamide. In field trials from Spain, Italy, Greece, Portugal, Germany, France, the Netherlands and the United Kingdom (1×0.10 kg ai/ha, BBCH 13, with cyprosulfamide) matching this GAP, total residues for maize grain harvested at BBCH 89 were: < 0.02 (14) mg/kg.

The GAP for maize in the USA is a single pre-emergence treatment at 0.16 kg ai/ha without the addition of the safener cyprosulfamide or a single early post-emergence treatment at 0.105 kg ai/ha up to 2 leaf-collar growth stage of the crop (GS 12) with the addition of the safener cyprosulfamide. In field trials from the USA (1×0.15 – 0.17 kg ai/ha, pre-emergent, no adjuvants) matching the first GAP, total residues for maize grains harvested at maturity were < 0.02 (17) mg/kg. In field trials from the USA (1×0.13 kg ai/ha, post-emergent GS 12, with safener cyprosulfamide, no adjuvants) matching the second GAP, total residues for maize grains harvested at maturity were < 0.03 (17) mg/kg.

A metabolism study with mature maize grains at 0.21 kg ai/ha after pre plant or post-emergence application did not confirm the non-residue situation.

The Meeting estimated a maximum residue level of 0.02* mg/kg and an STMR of 0.02 mg/kg.

Sugar cane

Supervised residue trials on sugar cane were conducted in Australia, Mexico and Brazil.

There were no authorised uses available for Mexico and Brazil.

Critical GAP for sugar cane in Australia is a single soil directed application at 0.15 kg ai/ha when the sugar cane was at least 0.75 m high and with a PHI of 19 weeks without adjuvant. In field trials from Australia (1× 0.150 kg ai/ha, PHI 133–166 days) matching this GAP, total residues were < 0.01 (2) mg/kg with a common moiety method (including IFT-BA).

Two additional trials, at the same locations, at 1× 0.225 kg ai/ha and a PHI of 133–166 days, two trials in Brazil using two applications at 0.150 kg ai/ha and a PHI of 92–95 days and a metabolism study in mature sugar cane after soil directed application to emerged plants at 0.133 kg ai/ha, confirmed the no residue situation.

The Meeting estimated a maximum residue level of 0.01* mg/kg on sugar cane and an STMR of 0 mg/kg.

Poppy seed

Field trials involving poppy seed were performed in France, Spain, Germany, Netherlands and Hungary.

Critical GAP for poppy seed in Spain is for a single pre-emergence application at 0.060 kg ai/ha without the safener cyprosulfamide. There were no trials matching this GAP.

Critical GAP for poppy seed in Hungary is for a single pre-emergence application at 0.11 kg ai/ha with the safener cyprosulfamide. In field trials from Germany, the Netherlands and Northern France (1× 0.10 kg ai/ha, pre-emergence, with cyprosulfamide) matching this GAP, total residues poppy seeds were < 0.02 (3) mg/kg.

A metabolism study in poppy following post-plant crop pre-emergence treatment at 0.11 kg ai/ha confirmed the no residue situation.

The Meeting estimated a maximum residue level of 0.02* mg/kg in poppy seeds and an STMR of 0 mg/kg.

Legume animal feeds

Field trials involving chick-pea forage were performed in Australia.

Critical GAP for chickpeas in Australia is a single post plant crop pre-emergence application at 0.075 kg ai/ha with a PHI of 6 weeks for use as forage. There were no trials matching this GAP.

Field trials involving chick-pea fodder were performed in Australia.

Critical GAP for chick-peas in Australia is a single post plant crop pre-emergence application at 0.075 kg ai/ha. In trials from Australia (1× 0.075 kg ai/ha, post planting pre-emergent) matching this GAP, total residues were: < 0.01 (3) and < 0.01^a mg/kg (n=4) with a common moiety method (including IFT-BA). The superscript (a) indicates the addition of adjuvant. The addition of which did not result in a difference in total residue levels.

An additional trial at the same location using a single post-plant pre-emergence application at a higher application rate of 0.20 kg ai/ha did not confirm the non-residue situation.

The Meeting estimated a maximum residue level of 0.01* mg/kg on chickpea fodder, a median residue of 0.01 mg/kg and a highest residue of 0.01 mg/kg for livestock dietary burden calculations.

Forage and fodder of cereal grains and grasses

Field trials involving maize forage were performed in Spain, Italy, Greece, Portugal, Germany, France, the Netherlands, the United Kingdom, the USA and Canada.

Critical GAP for maize in France is a single early post-emergence treatment up to 3 leaf stage of the crop (BBCH 13) at 0.099 kg ai/ha with the addition of the safener cyprosulfamide. No PHI is mentioned. High total residues ranging from 1.3–16 mg/kg eq were found immediately after treatment (DAT=0). However, the Meeting considers DAT=0 irrelevant for maize forage harvest and considers

growth stage BBCH 16 or 33 (3 nodes with 6 leaves) the earliest grazing time for maize forage. In field trials from Spain, Italy, Greece, Portugal, Germany, France, Netherlands and the United Kingdom ($1 \times 0.099\text{--}0.10\text{ kg ai/ha}$, BBCH 13, with cyprosulfamide) matching the French GAP, total residues for maize forage harvested at BBCH 19 or 33–35 (DAT 40–41) were < 0.02 (11) and 0.34 mg/kg ($n=12$).

Critical GAP for maize in the USA is a single early post-emergence treatment at 0.105 kg ai/ha up to 2 leaf-collar growth stage of the crop (BBCH 14 or 32) with the addition of the safener cyprosulfamide, with or without the addition of an adjuvant. The pre-harvest interval is 45 days. In field trials from the USA ($1 \times 0.13\text{ kg ai/ha}$, PHI 43–45 days, with safener cyprosulfamide, no adjuvants) matching this GAP, total residues for early maize forage were < 0.03 (15) mg/kg .

The Meeting agreed that the dataset matching French GAP could be used to estimate a median residue of 0.02 mg/kg and a highest residue of 0.34 mg/kg for livestock dietary burden calculations.

Field trials involving maize fodder were performed in Spain, Italy, Greece, Portugal, Germany, France, Netherlands, the United Kingdom, the USA and Canada.

Critical GAP for maize in France is a single early post emergence treatment up to 3 leaf stage of the crop (BBCH 13) at 0.099 kg ai/ha with the addition of the safener cyprosulfamide. In field trials from Spain, Italy, Greece, Portugal, Germany, France, Netherlands and the United Kingdom ($1 \times 0.099\text{--}0.10\text{ kg ai/ha}$, BBCH 13, with cyprosulfamide) matching this GAP total residues for maize fodder harvested at BBCH 79 (sweet corn fodder) were < 0.02 (13) mg/kg .

Critical GAP for maize in the USA is a single pre-emergence treatment at 0.16 kg ai/ha without the addition of the safener cyprosulfamide or a single early post-emergence treatment at 0.105 kg ai/ha up to 2 leaf-collar growth stage of the crop (i.e. GS 12) with the addition of the safener cyprosulfamide, each with or without the addition of an adjuvant. In field trials from the USA ($1 \times 0.15\text{--}0.17\text{ kg ai/ha}$, pre-emergent, no adjuvants) matching the first GAP, total residues for maize fodder harvested at dent stage to maturity were < 0.02 (17) mg/kg . In field trials from the USA ($1 \times 0.13\text{ kg ai/ha}$, post-emergent GS 12, with safener cyprosulfamide, no adjuvants) matching the second GAP, total residues for maize fodder harvested at maturity were < 0.03 (14) mg/kg .

A metabolism study with mature maize fodder at 0.21 kg ai/ha after post-emergence application did not confirm the non-residue situation.

The Meeting estimated a maximum residue level of 0.02^* mg/kg , a median residue of 0.02 mg/kg and a highest residue of 0.02 mg/kg for livestock dietary burden calculations.

Miscellaneous forage and fodder crops

Supervised residue trials on sugar cane tops/fodder were conducted in Australia.

The Meeting estimated a maximum residue level of 0.01^* mg/kg on sugar cane fodder, a median residue of 0 mg/kg and a highest residue of 0.01 mg/kg for livestock dietary burden calculations.

Residues from rotational crops

Total residues above 0.01 mg/kg eq are not expected in rotational crops.

Fate of residues during processing

Processing studies with isoxaflutole were undertaken for soya beans. However, since no MRLs could be set for soya beans, no processing factors are needed.

Residues in animal commodities

The Meeting estimated the dietary burden of isoxaflutole residues on the basis of the livestock diets listed in the FAO manual appendix IX (OECD feedstuff table). Calculation from highest residue and

STMR (some bulk commodities) provides the levels in feed suitable for estimating maximum residue levels, while calculation from STMR values from feed is suitable for estimating STMR values for animal commodities. Commodities used in the dietary burden calculation are maize grains, maize forage, chickpea fodder, maize forage, maize fodder and sugar cane tops.

Dietary burden calculations for beef cattle, dairy cattle, broilers and laying poultry are provided in Annex 6. A mean and maximum dietary burden for livestock, based on isoxaflutole use, is shown in the table below.

Animal dietary burden for isoxaflutole total residues, expressed as ppm of dry matter diet

	US	EU	AU	JP	overall
	max	max	max	max	max
beef cattle	0.146	0.685	0.688	0.017	0.688
dairy cattle	0.394	0.518	0.688	0.436	0.688 ^{a, b}
poultry broiler	0.017	0.016	—	0.016	0.017
poultry layer	0.017	0.102	—	0.018	0.102 ^{c, d}
	mean	mean	mean	mean	mean
beef cattle	0.026	0.045	0.048	0.017	0.048
dairy cattle	0.034	0.038	0.048	0.036	0.048 ^{a, b}
poultry broiler	0.017	0.016	—	0.016	0.017
poultry layer	0.017	0.022	—	0.018	0.022 ^{c, d}

^a Highest mean and maximum dietary burden suitable for maximum residue level and STMR estimates for mammalian meat

^b Highest mean and maximum dietary burden suitable for maximum residue level and STMR estimates for milk

^c Highest mean and maximum dietary burden suitable for maximum residue level and STMR estimates for poultry meat

^d Highest mean and maximum dietary burden suitable for maximum residue level and STMR estimates for eggs

Livestock feeding studies

The Meeting received a feeding study on lactating cows and laying hens. Total residues in animal commodities for enforcement are defined as the sum of isoxaflutole and IFT-DKN, expressed as isoxaflutole equivalents. Total residues for dietary risk assessment are defined as the sum of isoxaflutole, IFT-DKN, RPA 205834 and RPA 207048, and their conjugates, expressed as isoxaflutole equivalents.

Four groups of four lactating Holstein cows were dosed once daily via capsules at levels of 0.0, 4.7, 14.4 and 45.5 ppm parent compound in dry weight feed for 42 consecutive days. Milk was collected throughout the study and tissues were collected on day 42 within 7.5 h after the last dose. Milk was not analysed for RPA 207048, but the level of RPA 207048 has been estimated based on relative levels to the other metabolites in the metabolism study. Residues found at the 4.7 ppm dose level are summarized in the residues section below.

Four groups of 15 laying hens were dosed once daily via capsules at levels of 0.0, 0.18, 0.54 and 1.8 ppm parent compound in dry weight feed for 42 consecutive days. Eggs were collected throughout the study and tissues were collected on day 42 within 3 h after the last dose. Eggs and hen tissues were not analysed for RPA 205834 and RPA 207048, but the level of these metabolites has been estimated based on relative levels to the other metabolites in the metabolism study. Residues found at the 0.18 ppm dose level are summarized in the residue section below.

Residues in animal commodities*Cattle*

For maximum residue level estimation, the highest residue in the tissues and milk were calculated by interpolating the maximum dietary burden (0.688 ppm) between the relevant feeding levels (0–4.7 ppm) from the dairy cow feeding study and using the highest tissue concentrations based on the residue definition for enforcement from individual animals within those feeding groups and using the mean milk concentration from those feeding groups (see table below).

The STMR values for the tissues and milk were calculated by interpolating the mean dietary burden (0.048 ppm) between the relevant feeding levels (0–4.7 ppm) from the dairy cow feeding study and using the mean tissue and milk concentrations based on the residue definition for dietary risk assessment from those feeding groups (see table below).

				Total residues (mg/kg eq) in			
	Feed level (ppm) for milk residues	Total residues (mg/kg eq) in milk	Feed level (ppm) for tissue residues	Muscle	Liver	Kidney	Fat
Maximum residue level—beef or dairy cattle (residue definition for enforcement)							
Feeding study ^a	4.7	NA	4.7	NA	0.82	0.22	NA
Dietary burden and residue estimate	0.688	0	0.688	0	< 0.1	< 0.1	0
STMR—beef or dairy cattle (residue definition for dietary risk assessment)							
Feeding study ^b	4.7	NA	4.7	NA	0.81	0.29	NA
Dietary burden and residue estimate	0.048	0	0.048	0	< 0.2	< 0.2	0

NA not analysed, because highest dose level of 45.5 ppm showed residues below or just above the LOQ

^a highest residues for tissues and mean residues for milk

^b mean residues for tissues and mean residues for milk

The Meeting estimated a maximum residue level for total isoxaflutole residues of 0.01* mg/kg in meat (from mammals other than marine mammals), mammalian fats (except milk fats), milks, and 0.1 mg/kg in mammalian edible offal. The residue in animal commodities is considered not fat soluble.

The Meeting estimated an STMR for total isoxaflutole residues of 0 mg/kg in meat (from mammals other than marine mammals), mammalian fats (except milk fats) and milks, and 0.2 mg/kg in mammalian edible offal.

Poultry

For maximum residue level estimation, the high residue in the tissues and eggs were calculated by interpolating the maximum dietary burden (0.102 ppm) between the relevant feeding levels (0–0.18 ppm) from the laying hen feeding study and using the highest tissue and egg concentrations based on the residue definition for enforcement from individual animals within those feeding groups (see table below).

The STMR values for the tissues and eggs were calculated by interpolating the mean dietary burden (0.022 ppm) between the relevant feeding levels (0–0.18 ppm) from the laying hen feeding study and using the mean tissue and egg concentrations based on the residue definition for dietary risk assessment from those feeding groups (see table below).

				Total residues (mg/kg eq) in			
	Feed level (ppm) for egg residues	Total residues (mg/kg eq) in egg	Feed level (ppm) for tissue residues	Muscle	Liver	Kidney	Fat
Maximum residue level—poultry broilers or layers (residue definition for enforcement)							
Feeding study ^a	0.18	NA	0.18	NA	0.21	–	NA
Dietary burden and residue estimate	0.102	0	0.102	0	0.12	–	0
STMR—poultry broilers or layers (residue definition for dietary risk assessment)							
Feeding study ^b	0.18	NA	0.18	NA	0.19	–	NA
Dietary burden and residue estimate	0.022	0	0.022	0	< 0.1	–	0

NA not analysed, because highest (1.8 ppm) and medium (0.54 ppm) dose level did not show residues

^a highest residues for tissues and eggs

^b mean residues for tissues and eggs

The Meeting estimated a maximum residue level for isoxaflutole total residues of 0.2 mg/kg in poultry edible offal, 0.01* mg/kg in poultry meat, poultry fats and poultry eggs. The residue in animal commodities is considered not fat soluble.

The Meeting estimated an STMR for isoxaflutole total residues of 0.1 mg/kg in poultry edible offal, 0 mg/kg in poultry meat and poultry fats, and eggs.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits.

Definition of the residue for compliance with the MRL and for dietary risk assessment for plant commodities: *sum of isoxaflutole and isoxaflutole diketonitrile, expressed as isoxaflutole.*

Definition of the residue for compliance with the MRL for animal commodities: *sum of isoxaflutole and isoxaflutole diketonitrile, expressed as isoxaflutole.*

The Meeting considers the residue not fat soluble.

Definition of the residue for dietary risk assessment for animal commodities: *sum of isoxaflutole, isoxaflutole diketonitrile, RPA 205834 (2-aminomethylene-1-cyclopropyl-3-(2-mesyl-4-trifluoromethylphenyl)-propane-1,3-dione) and RPA 207048 (1-cyclopropyl-2-hydroxymethylene-3-(2-mesyl-4-trifluoromethylphenyl)-propane-1,3-dione), including their conjugates, expressed as isoxaflutole.*

Summary of recommendations

CCN	Commodity name	MRL mg/kg	STMR mg/kg	HR mg/kg
VO 0447	Sweet corn (corn-on-the-cob)	0.02*	0	—

Sugar cane	Tops/forage	0.01	0

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Daily Intakes (IEDI) of for isoxaflutole was calculated from recommendations for STMRs for raw and processed commodities in combination with consumption data for corresponding food commodities. The results are shown in Annex 3 of the 2013 JMPR Report.

The IEDI of in the 13 GEMS/Food cluster diets, based on the estimated STMRs were in the range 0–1% of the maximum ADI of 0.02 mg/kg bw. The Meeting concluded that the long-term intake of residues of isoxaflutole from uses considered by the Meeting is unlikely to present a public health concern.

Short-term intake

Since no ARfD is considered necessary, no short-term intake assessment is considered necessary. The Meeting concluded that the short-term intake of residues of isoxaflutole from uses considered by the Meeting is unlikely to present a public health concern.

MALATHION (049)

The first draft was prepared by Professor Árpád Ambrus, Hungarian Food Chain Safety Office

EXPLANATION

Residues of malathion was evaluated by the JMPR first time in 1966 and re-evaluated several times. As part of the periodic review programme, the 1999 JMPR Meeting concluded that the residue definition for plant commodities for compliance with MRL and for consumer risk assessment was malathion. The Meeting recommended maximum residue limits for a wide range of commodities, but concluded that the supporting data was not sufficient for recommending maximum residue levels and withdrew the previous recommendation for cherries.

The manufacturer provided current US labels for ground and aerial application of malathion on sweet and tart cherries, and resubmitted the reports of supervised trials conducted in 1993 in the USA at partly higher rates than permitted by the present GAP assuming that the proportionality concept adopted by the 36th Session of CAC would be applied.

No new or additional information was provided.

RESIDUE ANALYSIS*Analytical methods*

The analytical methods used for the trials were evaluated by the 1999 JMPR Meeting. No new information was provided.

USE PATTERN

Malathion is an insecticide and acaricide used for controlling black cherry aphid, fruit tree leaf-roller, Japanese beetle, cherry fruit fly, and eye-spotted bud moth. The GAPs in the USA for cherries are summarized in Table 1.

Table 1 Registered uses of malathion on cherries (sweet and tart) in the USA

Product	Formulation Ai content %	Application				PHI (Days)
		kg ai/ha	Water L/ha	Intervals (days)	Max.No	
FYFANON® 57% EC	EC (57.0%)	1.96	Min 3740	3	4	3
FYFANON® ULV AG	ULV (96.5%)	1.37	—	7	4 (sweet cherries) 6 (tart cherries)	1
MALATHION 8 AQUAMUL (81.8% EC)	EC (81.8%)	1.96	Min 94	3	4	3

*Residues resulting from supervised trials on Cherries**Cherries*

A total of six supervised trials, three on sweet cherries and three on sour cherries were conducted in 1993 in various locations in the United States (FYF83 and FYF85). Each trial consisted of three plots, one untreated control plot, one plot treated 6–7 times 7 days apart with an EC formulation at 4.2 kg ai/ha rate by foliar airblast (ground) application, and one plot treated six times with an ULV formulation at a rate of 1.37 kg ai/ha by aerial application without carrier. In two trials, the first three or four early ground applications were made at the rate of 8.96 kg ai/ha.

In the EC formulation trials, samples of cherries were collected at 3, 7 and 14 days after the last application. In the ULV formulation trials, samples of cherries were collected at 1, 4, 7 and 14 days after the last application. Control samples were collected 1 day after the last application. Cherries were sampled to give a minimum sample weight of 0.9–2.7 kg (2–6 lb.).

RESIDUES IN ANIMAL COMMODITIES

Cherries are not animal feed items, and therefore there is no change to the dietary burden calculations evaluated at the 2005 JMPR Meeting.

APPRAISAL

The JMPR evaluated malathion residues for the first time in 1966, and several times thereafter. The compound was evaluated within the periodic review programme in 1999, and the residue was defined as malathion for compliance with MRL values as well as for consumer dietary intake assessment. An ADI of 0–0.03 mg/kg bw and an ARfD of 2 mg/kg bw were established by the 1999 and 2005 JMPRs, respectively.

The manufacturer provided current US labels for ground and aerial application of malathion on sweet and tart cherries, and resubmitted the reports of supervised trials conducted in 1993 in the USA at higher rates than permitted by the present US GAP, to be evaluated applying the proportionality concept adopted by the Thirty-sixth Session of CAC. No new information was provided.

Results of supervised trials on crops

The present US GAP specifies a maximum 4 ground treatments of cherries at 3 day intervals, a maximum dose rate of 1.96 kg/ha with a PHI of 3 days. The compound may be used for aerial application four times at seven days intervals on sweet cherries and six times on tart cherries at a maximum dose rate of 1.37 kg ai/ha with a PHI of 1 day.

Supervised trials were conducted in USA in 1993. The sweet and tart cherry plots were treated 6 or 7 times with an EC formulation at 4.2 kg ai/ha rate by foliar ground application 7 days apart. Samples were collected at 3, 7 and 14 days after the last application.

The residues in whole sweet cherries at a 3-day PHI were: 0.26, 0.45 and 1.2 mg/kg.

The residues in whole tart cherries at a 3-day PHI were: 1.1, 1.6 and 2.6 mg/kg

At the same geographical locations the cherry trees were aerially treated 6 times with an ULV formulation at a rate of 1.37 kg ai/ha 7 days apart. Samples were collected at 1, 4, 7 and 14 days after the final application.

The residues in whole sweet cherries at a 1-day PHI were: 0.02, 0.17 and 0.19mg/kg.

The residues in whole tart cherries at a 1-day PHI were: 0.03, 0.34, 0.47 mg/kg.

The Meeting noted that the last 3 ground treatments were carried out at 4.2 kg/ha rate in all trials and the early applications with 8.96 kg ai/ha did not affect the residues in harvested fruits, as the residues derived from these trials were within the residue ranges observed in other trials. As a result the Meeting agreed to apply the proportionality approach to the data set.

The residues following ground treatments were adjusted with the proportionality factor of $1.96/4.2=0.467$. This resulted in residues in sweet cherries of 0.12, 0.21 and 0.56 mg/kg, and in tart cherries of 0.51, 0.75 and 1.21mg/kg.

The Meeting noted that the aerial treatment resulted in lower residues in both commodities than the ground application, and that tart cherries contained higher residues than the sweet cherries. Since the highest and lowest residue values in the datasets overlapped the Meeting decided to use the residue data derived from ground application to estimate maximum, median and high residues.

The combined residue data in cherries in rank order were: 0.12, 0.21, 0.51, 0.56, 0.75 and 1.21 mg/kg.

The Meeting considered that residues in sweet and tart cherries properly represent various cherry fruits and estimated a median residue of 0.535 mg/kg, a HR of 1.21 mg/kg and a maximum residue level of 3 mg/kg for cherries.

RECOMMENDATIONS

On the basis of the data from supervised trials, the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI assessment.

Definition of the residue (for compliance with the MRL and for estimation of dietary intake) for plant and animal commodities: malathion

The residue is fat soluble.

Commodity		Recommended MRL, mg/kg		STMR or STMR-P (mg/kg)	HR or HR-P (mg/kg)
CCN	Name	New	Previous		
FS 0013	Cherries	3	-	0.535	1.21

DIETARY RISK ASSESSMENT

Long-term intake

The evaluation of malathion resulted in recommendations for MRL and STMR values for cherries. The results are shown in Annex 3. The International Estimated Daily Intake for the 13 GEMS/Food diet based on estimated STMR value was up to 0% of the maximum ADI of 0.03 mg/kg bw. The Meeting concluded that the long-term intake of residues of malathion from cherries is unlikely to present a public health concern.

Short-term intake

The International Estimated Short-term Intake (IESTI) for malathion was calculated for cherries for which maximum residue levels and STMR values were estimated. The results are shown in Annex 4. The IESTI was 0% of the ARfD (2 mg/kg bw).

Meeting concluded that the short-term intake of residues of malathion resulting from its use on cherries is unlikely to present a public health concern.

MANDIPROPAMID (231)*First draft prepared by Dr. Yibing He,**Department of Science and Education, Ministry of Agriculture, China***EXPLANATION**

Mandipropamid was first evaluated by JMPR in 2008 when an ADI of 0–0.2 mg/kg bw was established and an ARfD was considered unnecessary. At the 44th Session of the CCPR, mandipropamid was scheduled for the evaluation of 2013 JMPR for additional uses on hops.

RESIDUE ANALYSIS*Analytical methods*

The Meeting received descriptions and validation data for analytical methods for residues of mandipropamid in hops and processed commodities. Methods rely on HPLC-MS/MS for analysis of mandipropamid in hops and wort.

Data collection method

Validation of Residue Analytical Method RAM 415/01 for the Determination of Residues in Crops. (Gill JP and Mound EL, 2004, NOA446510/0159)

Analyte: Mandipropamid, LC-MS/MS, Method RAM 415/01

LOQ: 0.01 mg/kg in crops

Description: Residues of mandipropamid were extracted from crop samples by homogenisation with acetonitrile:water (80:20 v/v). Extracts were centrifuged and aliquots diluted with water prior to being cleaned-up using polymeric solid-phase extraction cartridges. Residues of mandipropamid were quantified using high performance liquid chromatography with triple quadrupole mass spectrometric detection (LC-MS/MS). The transition monitored for mandipropamid was 412.1 to 327.9.

Enforcement methods

RAM 415/02 is the up-dated version of RAM 415/01 that includes the relevant modifications for the analysis of hops and has two LC-MS/MS transitions. Two MRM transitions were monitored for quantification (m/z 412.0→328.0) and confirmation (m/z 412.0→125.0). The analytical procedures were similar. The validation data on hops and hop processed fractions using method RAM 415/01 are valid for RAM 415/02.

Table 1 Recovery results obtained during validation of method RAM 415/01 for mandipropamid in hops, green and dried cones (Transition m/z = 412.0→328.0)

Matrix	Fortification (mg/kg)	Number of Analyses	Mean Recovery (%)	RSD (%)	Recovery Range (%)

	Overall	10	93	22.9	64–123

Method RAM 415/02 was successfully and independently validated for the analysis of mandipropamid residues in hops. Method RAM 415/02 is suitable to be used in support of pre-registration data requirements and post-registration monitoring of hops.

Stability of residues in stored analytical samples

The Meeting received information on the stability of residues of mandipropamid in tomatoes, grapes, potatoes, lettuce, cucumbers, wheat and soya beans.

A study on the stability of mandipropamid residues in crop commodities was conducted during 2004 to 2006 (Hamilton LS, Joseph T, 2006, NOA446510/0921). Stability of mandipropamid residues was tested in both raw agricultural commodities and in processed commodities. Commodities used were tomatoes (fruit and paste), grapes (fruit and juice), potatoes (tubers and granules/flakes), lettuce, cucumbers, wheat (forage, grain and straw) and soya beans (beans, hulls, meal and oil). These include representatives of the four crop types specified in the EU guidance, i.e., predominantly water, oil, protein and starch containing materials.

Crop samples (10 g) were fortified with mandipropamid at 0.5 mg/kg. Immediately after fortification, sample sets were stored in a freezer at approximately -20 °C until analysed. At the desired storage intervals of approximately zero, three, six, twelve and twenty-four months a sample set of each substrate, consisting of a control sample, two freshly fortified samples and two freezer stored fortified samples, were analysed for residues of mandipropamid using method RAM 415/01. Analysis of the soya bean oil samples required a modification of this method, using hexane in the homogenization process instead of acetonitrile/water and replacing the solid phase extraction clean-up with a liquid-liquid partition.

USE PATTERN

Mandipropamid is registered in the EU and the USA for the control of downy mildew on hops. The most critical Good Agricultural Practices (GAP) for the foliar application of mandipropamid on hops from Germany and USA are summarised in Table 9.

Table 9 Registered field uses of mandipropamid in Germany and USA. Labels for the following use on hops were available to the Meeting

Crop	Country or Region	Enduse product	F/G/I ^a	Method	No. per crop season min. max.	Application Min. Interval (days)	Max. Rate (g ai/ha per application)	Max. Water Volume (L/ha)	PHI [days]
Hops	Germany	SC, 250 g/L	F	spraying	2	10	400 ^b	– ^b	14
Hops	USA	SC, 250 g/L	F	spraying ^c	3	7–10	100–145	– ^d	7

^a F = field use, G = glasshouse application, I = indoor application.

^b A maximum of two applications of mandipropamid are made to hops. The rates and volumes of application are dependent upon the growth stage of the crop at the time of application. For hops, proven water application rates are 1300 to 2800 L water/ha.

^c Applied by ground, chemication or aerial application.

^d For best results, use sufficient water volume to provide thorough coverage.

RESIDUES RESULTING FROM SUPERVISED TRIALS

The Meeting received information on supervised field trials for mandipropamid uses on the following crops.

Crop	Country	
Hops:	France, Germany, UK	Table 10
Hops:	USA	Table 11

Where residues were not detected, they are reported as below the LOQ. Residue data, application rates and spray concentrations have generally been rounded to two significant figures or, for residues near the LOQ, to one significant figure. Residue data are recorded unadjusted for % recovery. Multiple results are recorded in the data tables where the trial design included replicate plots and where separate samples have been identified as being from these replicate plots. Results used to estimate STMRs are double underlined.

A total of 10 residue trials were carried out according to GAP ($\pm 30\%$) in France, Germany and UK in 2005, 2006 and 2009 (Elliott, A, 2007, NOA 446510/1151; Gizler, A, Lakaschus, S, 2008, NOA 446510/1342; Lakaschus, S, Gizler, A, 2009, A12946B_10718). In all trials, mandipropamid was applied two times as an SC formulation containing 250 g ai/L at about 10 days intervals at a nominal rate of 300 g ai/ha as a foliar application to hops. The water rate was between 1500–2000 L/ha. The PHI was 14 days. The residue data from the supervised trials is summarised in Table 10.

Three independent supervised trials were conducted on hops according to the US GAP in Washington state (two) and Idaho (one) during 2005 (Joseph T 2007, NOA446510/1076). The trials account for 94% of total US hops production based on acreage. In each trial, mandipropamid formulated as a suspension concentrate (SC) containing 250 g mandipropamid per litre, was applied three times at rates of 151 to 166 g ai/ha (nominally 0.135 lb ai/acre), i.e. within 25% of the nominal maximum rate of 145 g ai/ha. The application intervals were 7 days. The water volumes during applications were in the range from 235 to 433 L/ha in the trials conducted in Washington state, and about 20 L/ha in the trial conducted in Idaho to simulate an aerial application rate. Duplicate samples of fresh hop cones were collected with PHIs of 7 and 14 days from all trials. The green hops samples were kiln dried using simulated commercial technique to produce dried hops of commercial quality. Dried hops samples were analysed for residues of mandipropamid using analytical method RAM 415/01 with minor modifications. The residue data from the supervised trials is summarised in Table 11.

FATE OF RESIDUES IN STORAGE AND PROCESSING

In processing

The Meeting received information on the fate of mandipropamid residues during processing into beer.

Six residue trials were performed in Germany and northern France (Gizler, A, Lakaschus, S, 2008, NOA 446510/1342). Samples from one of the trials in Germany were taken for processing into beer. In this trial, mandipropamid formulated as a suspension concentrate (SC) containing 250 g mandipropamid per litre, was applied to hops. Two applications, at growth stages BBCH 75–82 and BBCH 79–85 and separated by an interval of 7 days, were made at 415 and 406 g ai/ha (nominal 400 g/ha for each application). Seven days after the final application, samples (approximately 2.5 kg) of treated and untreated dry hop cones were collected and transported frozen to the processing facility. The mandipropamid residues in hop cones prior to processing and in beer is presented in Table 10. The summary of processing factors was listed in Table 12.

Table 12 Summary of processing factors for mandipropamid residues

Raw agricultural commodity (RAC)	Processed commodity	Calculated processing factors	Median or best estimate
	Beer	0.002, 0.002, 0.002, 0.002	0.002

APPRAISAL

Mandipropamid was first evaluated by JMPR in 2008 when an ADI of 0–0.2 mg/kg bw was established and decided that an ARfD was unnecessary. At the Forty-fourth Session of the CCPR, mandipropamid was scheduled for the evaluation of 2013 JMPR for additional uses on hops.

Methods of analysis

The Meeting received descriptions and validation data for analytical methods for residues of mandipropamid in hops and processed hop samples.

Hop samples were extracted with acetonitrile:water (80:20 v/v). Extracts are centrifuged and aliquots diluted with water prior to being cleaned-up using polymeric solid-phase extraction cartridges. Residues of mandipropamid were quantified with HPLC-MS/MS. Validated LOQs was 0.01 mg/kg.

Stability of residues in stored analytical samples

The Meeting received information on the stability of residues in crop commodities in tomatoes, grapes, potatoes, lettuce, cucumbers, wheat and soya beans for two years.

The commodities in which stability was tested were both raw agricultural commodities and processed, such as tomatoes (fruit and paste), grapes (fruit and juice), potatoes (tubers and granules/flakes), lettuce, cucumbers, wheat (forage, grain and straw), and soya beans (beans, hulls, meal and oil). There was no significant change in the mandipropamid residue levels in any commodity during the 24 months of storage at -20 °C with any apparent losses being < 30%. These commodities contained representatives of the four crop types, i.e., predominantly water, oil, protein, and starch containing materials. Therefore, residues of mandipropamid are expected to be stable in all crop commodities including hops stored under these conditions for at least two years.

Supervised residue trials on crops

The Meeting received supervised trials data for mandipropamid uses on hops.

Hops

Ten trials were conducted on hops in Europe (maximum German GAP: 0.40 kg ai/ha, two applications, 14-day PHI) in 2005 and 2006 and in the USA (maximum USA GAP: 0.145 kg ai/ha, three applications, 7-day PHI). In eight trials conducted at the maximum German GAP, the ranked order of concentrations in dry cone, median underlined, were: 14, 20, 26(2), 31, 32 and 34(2) mg/kg. In three trials conducted at the maximum US GAP, the ranked order of concentration in the dry cones was: 4.3, 5.4 and 10.6 mg/kg.

Noting that European trials resulted in higher residues in dry cones, the Meeting estimated a maximum residue level and an STMR value for mandipropamid in hops, dry of 90 and 28.5 mg/kg on the basis of European dataset.

Fate of residues during processing

The Meeting received information on the fate of mandipropamid residues during the food processing of hops.

The processing factor for beer (0.002) was applied to the estimated STMR for dry cone (28.5 mg/kg) to produce an STMR-P value for beer (0.057 mg/kg).

RECOMMENDATIONS

On the basis of the data from supervised trials, the Meeting concluded that the residue concentrations listed below are suitable for establishing MRLs and for assessing IEDIs.

Definition of the residue (for compliance with the MRL and for estimation of dietary intake for plant and animal commodities): *mandipropamid*.

CCN	Commodity	MRL, mg/kg	STMR or STMR-P, mg/kg
DH 1100	Hops, dry	90	28.5
-	Beer	-	0.057

DIETARY RISK ASSESSMENT

Long-term intake

The Meeting noted that the new estimation of dry hops did not result in a significant change of the long term dietary intake and concluded that the long-term intake of residues of mandipropamid resulting from its uses that have been considered by JMPR is unlikely to present a public health concern.

Short-term intake

The 2008 JMPR decided that an ARfD was unnecessary. The Meeting therefore concluded that the short-term intake of mandipropamid residues is unlikely to present a public health concern.

PENTHIOPYRAD (253)

First draft was prepared by Mr Chritian Sieke, BfR, Germany

EXPLANATION

Penthiopyrad is a carboxamide fungicide used to control a broad spectrum of diseases on large variety of crops. Penthiopyrad inhibits fungal respiration by binding to mitochondrial respiratory complex II. It was considered for the first time by the 2011 JMPR for toxicology, establishing an acceptable daily intake (ADI) of 0–0.1 mg/kg bw and an acute reference dose (ARfD) of 1 mg/kg bw. In 2012, the Meeting evaluated uses from the USA for residues, resulting in the recommendation of various maximum residue levels for plant commodities and poultry matrices.

The present Meeting received new GAP information for penthiopyrad from Australia, Ireland, Italy, New Zealand, United Kingdom and the USA. No new data were submitted.

USE PATTERN

Penthiopyrad is a non-systemic protectant fungicide. The Meeting received information on additional uses involving foliar spray applications mainly before harvest.

Table 1 List of additional registered uses submitted to the 2013 JMPR

Crop	Country	Application detail					
		Form	Type	kg ai/ha	L/ha	No.	Pre harvest interval (PHI) in days
Alfalfa	USA	SC	foliar spray (F)	0.36	min. 140	2 (max. 0.72 kg ai/ha and year)	14
Almond	Australia		Foliar	0.3 kg ai/hL		3	14
Aubergine (field and protected)	Italy	SC	Foliar	0.04 kg ai/hL		1	3
Barley, oats	Ireland	SC	Foliar	0.25	200-300	2	Up to beginning of flowering (BBCH 61), PHI covered by growth stage
Barley, oats	UK	SC	Foliar	0.3	200-300	2	Up to end of heading (BBCH 59), PHI covered by growth stage
Berries (strawberry, blueberry)	USA	SC	foliar spray (F)	0.36	min. 140	3 (max. 1.1 kg ai/ha and year)	0
Brassica vegetables including leafy brassica	Australia		Foliar	0.3		2	0
Brassica, leafy vegetables (cabbge, broccoli, cauliflower, mustard greens)	USA	SC	foliar spray (F)	0.45	min. 140	3 (max. 1.1 kg ai/ha and year)	0
Bulb vegetables (green and dry)	USA	SC	foliar spray (F)	0.36	min. 140	3 (max. 1.1 kg ai/ha and year)	3
Chestnut	Australia		Foliar	0.3 kg ai/hL		3	14
Courgette/Zucchini (field and protected)	Italy	SC	Foliar	0.04 kg ai/hL		1	3
Cucumber (field and protected)	Italy	SC	Foliar	0.04 kg ai/hL		1	3
Cucurbits (cucumbers, melons, watermelon, squashes)	USA	SC	foliar spray (F)	0.24	min. 140	4 (max. 1 kg ai/ha and year)	1
Cucurbits (field and protected)	Australia		Foliar	0.3		2	1

Crop	Country	Application detail					
		Form	Type	kg ai/ha	L/ha	No.	Pre harvest interval (PHI) in days
Fruiting vegetables	USA	SC	foliar spray (F+G)	0.36	min. 140	3 (max. 1.1 kg ai/ha and year)	0
Fruiting vegetables (tomatoes, eggplant, peppers, field and protected)	Australia		Foliar	0.3		2	0
Hazelnut	Australia		Foliar	0.3 kg ai/hL		3	14
Leafy vegetables	Australia		Foliar	0.3		2	3
Leafy vegetables (lettuce, celery, spinach)	USA	SC	foliar spray (F)	0.36	min. 140	3 (max. 1.1 kg ai/ha and year)	3
Legume vegetables (succulent shelled or podded)	USA	SC	foliar spray (F)	0.45	min. 140	3 (max. 1.1 kg ai/ha and year)	0
Onions	Australia		Foliar	0.3		2	3
Peanut	USA	SC	foliar spray (F)	0.36	min. 140	3 (max. 1.1 kg ai/ha and year)	14
Pome fruit	Australia		Foliar	0.25 kg ai/hL		3	28
Pome fruit	New Zealand	SC	Foliar	0.25 kg ai/hL		3	Apply before 50% petal fall and/or before fruitlet formation , PHI covered by growth stage
Pome fruits	USA	SC	foliar spray (F)	0.3	min. 140	4 (max. 0.91 kg ai/ha and year)	28
Root and tuber vegetable	Australia		Foliar	0.3		2	7
Root vegetables (except sugar beets)	USA	SC	foliar spray (F)	0.45	min. 140	3 (max. 0.91 kg ai/ha and year)	0
Spring onions	Australia		Foliar	0.3		2	3
Stone fruit	Australia		Foliar	0.3 kg ai/hL		3	0
Stone fruits	USA	SC	foliar spray (F)	0.3	min. 140	4 (max. 0.91 kg ai/ha and year)	0
Strawberry	Australia		Foliar	0.35		2	0
Tomato (field and protected)	Italy	SC	Foliar	0.04 kg ai/hL		1	3
Tree nuts (incl. Pistachios)	USA	SC	foliar spray (F)	0.3	min. 140	4 (max. 0.91 kg ai/ha and year)	14
Wheat, rye, triticale	Ireland	SC	Foliar	0.25	200-300	2	Up to watery ripe stage (BBCH 71), PHI covered by growth stage
Wheat, rye, triticale	UK	SC	Foliar	0.3	200-300	2	Up to end of flowering (BBCH 69), PHI covered by growth stage

For the USA general label restrictions on rotational crops were implemented not allowing the planting of crops without authorised uses with penthiopyrad within 120 days after treatment.

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

For penthiopyrad no additional residue data were submitted to the 2013 JMPR. However, for the selection of residue data for estimating maximum residue levels, STMR and HR values, supervised field trials approximating the new European labels are presented below. For a complete overview of the available data, including supervised field trials not taken into account, please refer to the 2012 JMPR Evaluation.

APPRAISAL

Penthiopyrad (ISO common name) is a carboxamide fungicide used to control a broad spectrum of diseases on a large variety of crops. Penthiopyrad inhibits fungal respiration by binding to mitochondrial respiratory complex II. It was considered for the first time by the 2011 JMPR for toxicology, establishing an acceptable daily intake (ADI) of 0–0.1 mg/kg bw and an acute reference dose (ARfD) of 1 mg/kg bw. In 2012, the Meeting evaluated uses from the USA for residues, resulting in the recommendation of various maximum residue levels for plant and poultry commodities.

However, the Meeting estimated a maximum and mean dietary burden for beef and dairy cattle above the highest dose level administered in livestock animal feeding studies on cows and concluded, that no recommendations on mammalian animal products and milk could be made based on the available data. The maximum and mean dietary burden was calculated based on the Australian diet for beef and dairy cattle (main contributor: soya bean hay).

The Forty-fifth Session of the CCPR scheduled penthiopyrad for the evaluation of additional labels from Australia, Ireland, Italy, New Zealand, United Kingdom and the USA. In addition, following official communication from Australia that no fodder crops are imported, a re-evaluation of the dietary burden for livestock animals was requested. No additional residue data were provided to the 2013 Meeting.

Results of supervised residue trials on crops

As indicated the present Meeting did not receive additional supervised trial data for penthiopyrad. New European GAPs residue data was previously presented in the 2012 Evaluation for penthiopyrad, which at the time could not be taken into account as label authorisations had not been finalised.

For the new labels registered for penthiopyrad in Australia, New Zealand and the USA the Meeting noted that none of the GAPs involves higher application rates or shorter PHIs than evaluated in 2012. Since no additional supervised field trial data were submitted, no re-evaluation of these uses was conducted by the 2013 JMPR.

For dietary intake assessment the residue is defined as the sum of penthiopyrad and PAM, expressed as penthiopyrad (referred to as “total”). Since residue data were expressed in mg of the specific analyte per kg sample, PAM needs to be converted into penthiopyrad equivalents. The corresponding factor is: PAM → penthiopyrad = 359.42 g/mol ÷ 193.13 g/mol = 1.86. In supervised field trials PAM residues were normally found at much lower levels than parent penthiopyrad. As a result, no adjustment of PAM or addition of LOQs was conducted, if both analytes were below the LOQ. For all other purposes of calculation < LOQ values were handled as their numeric value (e.g., < 0.01 mg/kg as 0.01 mg/kg).

This is illustrated below:

Penthiopyrad [mg/kg]	PAM [mg/kg]	Total [mg/kg]* (Sum of penthiopyrad and PAM, expressed as penthiopyrad equivalents)
< 0.01	< 0.01	< 0.01
0.1	< 0.01	0.12 (0.1 + 1.86 × 0.01)
< 0.01	0.1	0.2 (0.01 + 1.86 × 0.1)
0.1	0.1	0.29 (0.1 + 1.86 × 0.1)

* rounded to two significant figures above the LOQ

Cucurbits with edible peel

In Italy penthiopyrad is registered for the use on cucumber and summer squash (zucchini) with one foliar application of 0.04 kg ai/hL with a 3 day PHI. Supervised field trial data on courgettes (zucchini) and cucumbers involving two treatments at the registered spray concentration were available for glasshouse use (Belgium, France, Greece, Italy and Spain) and field application (France, Greece, Italy and Spain). The analysis of samples collected directly before the second treatment indicates a contribution by the previous application of < 25% to the final residue, making these trials acceptable for evaluation.

For the purposes of MRL estimation penthiopyrad residues in protected summer squash were (n=2): 0.13 and 0.23 mg/kg.

For the dietary intake purposes the total residues in protected summer squash were (n=2): 0.15 and 0.25 mg/kg.

For the purposes of MRL estimations penthiopyrad residues in field summer squash were (n=2): 0.075, 0.12 mg/kg.

For the dietary intake purposes the total residues in field summer squash were (n=2): 0.095 and 0.14 mg/kg.

For the purposes of MRL estimations penthiopyrad residues in protected cucumber were (n=4): 0.031, 0.041, 0.053, 0.058 mg/kg.

For the dietary intake purposes the total residues in protected cucumber were (n=4): 0.051, 0.061, 0.073, 0.078 mg/kg.

For the purposes of MRL estimations penthiopyrad residues in field cucumber were (n=5): 0.013, 0.019, 0.082, 0.13, 0.3 mg/kg.

For the dietary intake purposes the total residues in field cucumber were (n=5): 0.033, 0.039, 0.1, 0.15, 0.32 mg/kg.

The Meeting decided that the previous recommendation for a maximum residue level of 0.5 mg/kg for penthiopyrad in fruiting vegetables, cucurbits also covered residues in cucumber and summer squash resulting from the new uses considered.

Tomato and eggplants

In Italy penthiopyrad is registered for the use on tomato and eggplants with one foliar application of 0.04 kg ai/hL with a 3 day PHI. Supervised field trial data on tomato involving two treatments at the registered spray concentration were available for glasshouse (Belgium, France, Greece, Italy, Spain) and field application (France, Greece, Italy, Spain). The analysis of samples collected directly before the second treatment indicates a contribution by the previous application of < 25% to the final residue, making these trials acceptable for evaluation.

For the purposes of MRL estimations penthiopyrad residues in protected tomato were (n=7): 0.15, 0.24, 0.31, 0.38, 0.55, 0.76, 0.76 mg/kg.

For the dietary intake purposes the total residues in protected tomato were (n=7): 0.17, 0.26, 0.33, 0.4, 0.57, 0.78, 0.78 mg/kg.

For the purposes of MRL estimations penthiopyrad residues in field tomato were (n=5): 0.11, 0.18, 0.22, 0.29, 0.32 mg/kg.

For the dietary intake purposes the total residues in field tomato were (n=5): 0.13, 0.2, 0.24, 0.31, 0.34 mg/kg.

The Meeting recognized that residue data on tomato can also be extrapolated to eggplants.

The Meeting decided that the previous recommendation for a maximum residue level of 2 mg/kg for penthiopyrad in fruiting vegetables, other than cucurbits, except sweet corn and mushrooms also covers residues in tomatoes and eggplants resulting from the new uses considered.

Barley and oats

In Ireland and the UK penthiopyrad is registered for the use on barley and oats with two foliar application up to 0.3 kg ai/ha each. The PHI is covered by a specified growth stage (BBCH 61). Supervised residue trials approximating this GAP were submitted to the 2012 Meeting from France, Germany, Hungary and the UK.

For the purposes of MRL estimations penthiopyrad residues in barley grain were (n=14): < 0.01(3), 0.01, 0.01, 0.039, 0.057, 0.063, 0.069, 0.071, 0.076, 0.1, 0.12 mg/kg.

For the dietary intake purposes the total residues in barley grain were (n=14): < 0.01(3), 0.03, 0.03, 0.059, 0.083, 0.089, 0.091, 0.096, 0.1, 0.12, 0.14 mg/kg.

The Meeting recognized that barley and oats share an identical GAP and decided to extrapolate residue data from barley to oats.

The Meeting estimated a maximum residue level and an STMR of 0.2 mg/kg and 0.086 mg/kg for penthiopyrad in barley and oats, respectively, replacing its previous recommendation of a maximum residue level of 0.15 mg/kg for barley and oats.

Wheat, rye and triticale

In Ireland and the UK penthiopyrad is registered for the use on rye, triticale and wheat with two foliar application up to 0.3 kg ai/ha each. The PHI is covered by a specified growth stage (BBCH 71). Supervised residue trials approximating this GAP were submitted to the 2012 Meeting from France, Germany, Hungary and the UK.

For the purposes of MRL estimations penthiopyrad residues in wheat grain were (n=13): < 0.01(9), 0.013, 0.015, 0.015, 0.081 mg/kg.

For the dietary intake purposes the total residues in wheat grain were (n=13): < 0.01(9), 0.033, 0.035, 0.035, 0.1 mg/kg.

The Meeting recognized that wheat, rye and triticale share an identical GAP and decided to extrapolate residue data from wheat to rye and triticale.

The Meeting estimated a maximum residue level of 0.1 mg/kg and confirmed its previous estimate of an STMR of 0.01 mg/kg for penthiopyrad in wheat, rye and triticale, respectively, replacing its previous recommendation of a maximum residue level of 0.04 mg/kg for wheat, rye and triticale.

Animal feeds

Barley, oats, rye, triticale and wheat forage

In Ireland and the UK penthiopyrad is registered for the use on barley, oats, rye, triticale and wheat with two foliar application up to 0.3 kg ai/ha each. The PHI is covered by specified growth stages (BBCH 61 & 71). Supervised residue trials approximating this GAP were submitted to the 2012 Meeting from France, Germany, Hungary and the UK.

For the calculation of the livestock animal dietary burden total residues in barley forage (fresh) were (n=6): 2.0, 3.5, 3.9, 3.9, 4.0 and 4.5 mg/kg.

For the calculation of the livestock animal dietary burden total residues in wheat forage (fresh) were (n=6): 2.2, 3.0, 3.8, 4.3, 5.3 and 5.7 mg/kg.

The Meeting decided that the previously estimated median and highest residues in barley, oats, rye, triticale and wheat forage (fresh) of 10 mg/kg and 17 mg/kg, respectively, covered residues resulting from the new uses considered by the present Meeting.

Barley, oats, rye, triticale and wheat straw and fodder of cereals

In Ireland and the UK penthiopyrad is registered for the use on barley, oats, rye, triticale and wheat with two foliar application up 0.3 kg ai/ha each. The PHI is covered by specified growth stages (BBCH 61 & 71). Supervised residue trials approximating this GAP were submitted to the 2012 Meeting from France, Germany, Hungary and the UK.

For the purposes of MRL estimations penthiopyrad residues in barley straw (fresh) were (n=12): < 0.05, 0.051, 0.11, 0.13, 0.15, 0.2, 0.25, 0.28, 0.28, 0.36, 0.57 and 0.68 mg/kg.

For the calculation of the livestock animal dietary burden total residues in barley straw (fresh) were (n=12): < 0.05, 0.15, 0.21, 0.23, 0.25, 0.3, 0.35, 0.38, 0.38, 0.46, 0.67, 0.78 and 1.0 mg/kg.

For the purposes of MRL estimations penthiopyrad residues in wheat straw (fresh) were (n=13): 0.05, 0.052, 0.059, 0.067, 0.077, 0.12, 0.13, 0.16, 0.21, 0.26, 0.75, 1.1 and 2.3 mg/kg.

For the calculation of the livestock animal dietary burden total residues in wheat straw (fresh) were (n=13): 0.15, 0.16, 0.16, 0.17, 0.18, 0.22, 0.23, 0.26, 0.31, 0.36, 0.85, 1.2 and 2.6 mg/kg.

The Meeting decided that the previously estimated maximum residue level, median and highest residue in barley, oats, rye, triticale and wheat straw of 80 mg/kg (DM based), 21 mg/kg and 54 mg/kg, respectively, covered residues resulting from the new uses considered by the present Meeting.

Fate of residues during processing

The Meeting estimated new maximum residue levels for barley, oats, rye, triticale and wheat and a new STMR for barley and oats.

The estimation of maximum residue levels is based on the parent substance only, whereas for the dietary intake assessment the total residue needs to be taken into account. Based on the processing factors derived by the 2012 Meeting the following residues in processed products were estimated:

Commodity	Processing factor	Processing factor (median or best estimate)	MRL / STMR (mg/kg)	MRL, STMR-P (mg/kg)
Barley beer	Total: < 0.11, < 0.36	Total: < 0.24	STMR: 0.086	STMR-P: 0.021
Pot barley	Total: 0.67, 0.68	Total: 0.68	STMR: 0.086	STMR-P: 0.058
Wheat bran	Penthiopyrad: 1.8	Penthiopyrad: 1.8	MRL: 0.1	MRL: 0.2
Wheat germ	Penthiopyrad: 2.1	Penthiopyrad: 2.1	MRL: 0.1	MRL: 0.2

For wheat processed into wheat bran and wheat germ the Meeting estimated maximum residue levels of 0.2 mg/kg, respectively, and agreed to withdraw its previous recommendations of 0.1 mg/kg.

Residues in animal commodities

Livestock dietary burden

Livestock feeding studies involving administration of penthiopyrad to lactating cows and laying hens were reported in the 2012 JMPR Report.

Estimated maximum and mean dietary burdens of livestock

Dietary burden calculations for beef cattle, dairy cattle, broilers and laying poultry are presented in Annex 6.

The Meeting received official communication from Australia that no fodder crops are imported. The Meeting therefore decided to make a refined calculation of the livestock dietary burden based using the following parameters:

For the Australian diet only feed commodities corresponding to Australian authorisations plus globally traded non-fodder commodities are taken into account (e.g., grains and seeds).

For US-Canada, EU and Japan the calculation was conducted according to the usual procedure described in FAO Manual and amended by the new estimated median residue of 0.086 mg/kg for barley and oats. However, in contrast to 2012, forage crops were only included in the dietary burden for regions with corresponding labels (e.g. barley, oats, rye, triticale and wheat forage for Europe).

The dietary burdens were estimated using the OECD diets listed in Appendix IX of the 2009 edition of the FAO Manual.

	Livestock dietary burden, total residue*, ppm of dry matter diet							
	US-Canada		EU		Australia		Japan	
	max.	mean	max.	mean	max.	mean	max.	mean
Beef cattle	12	4.5	23	12	1.3	1.3	1.9	0.46
Dairy cattle	55 ^{a c}	26 ^{b d}	30	13	1.1	1.1	4.6	0.9
Poultry - broiler	0.2	0.2	0.19	0.19	0.19	0.19	0.17	0.17
Poultry - layer	0.2	0.2	22 ^e	11 ^f	0.19	0.19	0.14	0.14

^a Highest maximum beef or dairy cattle burden suitable for MRL estimates for mammalian meat

^b Highest mean beef or dairy cattle burden suitable for STMR estimates for mammalian meat

^c Highest maximum dairy cattle burden suitable for MRL estimates for milk

^d Highest mean dairy cattle burden suitable for STMR estimates for milk

^e Highest maximum broiler or laying hen burden suitable for MRL estimates for poultry products and eggs

^f Highest mean broiler or laying hen burden suitable for STMR estimates for poultry products and eggs

* total residue: sum of penthiopyrad and PAM, expressed as penthiopyrad

Animal commodities, MRL estimation

For beef and dairy cattle maximum and mean dietary burdens of 55 ppm and 26 ppm were estimated, respectively. The calculation to estimate highest total residues for use in estimating maximum residue levels, STMR and HR values were shown below.

Penthiopyrad feeding study	Feed level	Total residue				
	(ppm)	(mg/kg) in milk	(mg/kg) in muscle	(mg/kg) in kidney	(mg/kg) in liver	(mg/kg) in fat
Maximum residue level: dairy cattle						
Feeding study	21.4	< 0.01	< 0.01	0.03	0.04	0.03
	74.6	0.042	0.036	0.07	0.08	0.04
Dietary burden and residue estimate	55	0.03	0.026	0.055	0.065	0.036
STMR dairy cattle						
Feeding study	21.4	< 0.01	< 0.01	0.03	0.04	0.03
	74.6	0.042	0.036	0.07	0.08	0.04
Dietary burden and residue estimate	26	0.013	0.012	0.033	0.043	0.031

For beef and dairy cattle the Meeting estimated HR values for penthiopyrad (total residue) of 0.026 mg/kg in muscle, of 0.065 mg/kg in edible offal (based on liver) and of 0.036 mg/kg in fat. STMR values were estimated at levels of 0.013 mg/kg for milk, 0.012 mg/kg for meat, 0.043 mg/kg for edible offal (based on liver) and 0.031 mg/kg for fat.

The Meeting also estimated the following maximum residue levels: milk 0.04 mg/kg, meat (mammalian except marine mammals) 0.04 mg/kg, mammalian fat 0.05 mg/kg and edible offal 0.08 mg/kg.

For poultry the mean and maximum dietary burden differed insignificantly compared to the calculation by the 2012 Meeting (Max/Mean; 2012: 22 ppm/10ppm; 2013: 22 ppm/11ppm). The previous recommendations for penthiopyrad in poultry tissues and eggs are confirmed.

RECOMMENDATIONS

The Meeting estimated the STMR, HR and MRL values shown below.

Definition of the residue for compliance with MRL for plant commodities: *penthiopyrad*

Definition of the residue for compliance with MRL for animal commodities and for the estimation of dietary intake for plant and animal commodities: *sum of penthiopyrad and 1-methyl-3-trifluoromethyl-1H-pyrazole-4-carboxamide (PAM), expressed as penthiopyrad*

The residue is not fat-soluble.

Maximum residue levels and dietary intake

Commodity		MRL, mg/kg		STMR or STMR-P, mg/kg	HR, mg/kg
CCN	Name	New	Previous

	Barley, pearl			0.058	

DIETARY RISK ASSESSMENT***Long-term intake***

The WHO Panel of the 2011 JMPR established an Acceptable Daily Intake (ADI) of 0-0.1 mg/kg bw/day for penthiopyrad.

The 2013 evaluation of penthiopyrad resulted in new recommendations for MRLs and STMR values for barley, oats, rye, triticale, wheat and mammalian animal products. Where data on consumption were available for the listed food commodities evaluated in 2012 or 2013, dietary intakes were calculated for the 13 GEMS/Food Consumption Cluster Diets. The results are shown in Annex 3 of the 2013 JMPR Report.

The IEDIs in the thirteen Cluster Diets, based on the estimated STMRs were 0-6% of the maximum ADI (0.1 mg/kg bw). The Meeting concluded that the long-term intake of residues of penthiopyrad from uses that have been considered by the JMPR is unlikely to present a public health concern.

Short-term intake

The WHO Panel of the 2011 JMPR established an Acute Reference Dose (ARfD) of 1 mg/kg bw for penthiopyrad.

The International Estimated Short-Term Intake (IESTI) for penthiopyrad was calculated for the food commodities for which STMRs or HRs were estimated by the present Meeting and for which consumption data were available. The results are shown in Annex 4 of the 2013 JMPR Report. The IESTI for children and for the general population was 0% of the ARfD.

The Meeting concluded that the short-term intake of residues of penthiopyrad resulting from uses that have been considered by the 2013 JMPR is unlikely to present a public health concern.

PROPICONAZOLE (160)

The first draft was prepared by Professor Eloisa Dutra Caldas

University of Brasilia, Brasilia/DF, Brazil

EXPLANATION

The triazole fungicide propiconazole was first evaluated by the JMPR in 1987 and has been reviewed for residues in 1991, 1994, and within the periodic review programme in 2007, when a number of maximum residue levels being recommended. Propiconazole has an ADI of 0–0.07 mg/kg bw and an ARfD of 0.3 mg/kg bw. The compound was scheduled at the Fort-fourth Session of the CCPR (2012) for the evaluation of residues in additional crops by the 2013 JMPR. Information and data on citrus, stone fruits and tomato following post-harvest applications of propiconazole were submitted.

Residue definition for plant and animal commodities is *propiconazole* for compliance with the MRL, and *propiconazole plus all metabolites convertible to 2,4-dichlorobenzoic acid, expressed as propiconazole* for the estimation of the dietary intakes.

METHODS OF RESIDUE ANALYSIS***Stability of pesticide residues in stored analytical samples***

A storage stability study was conducted with citrus (IR-4 PR 09715), with samples fortified with 5 mg/kg propiconazole and stored at -20 °C. The results are shown in Table 1.

Table 1 Stability of propiconazole residues in citrus fruit and processed fractions, and cherries and of total residues in tomato stored under frozen conditions (-20 °C)

Matrix	Fortification (mg/kg)	Storage interval (days)	% remaining
Citrus fruit	5	207	87, 91, 90
Orange juice	5	155	96, 95, 95
Dried orange pulp	5	154	104, 102, 105
Orange oil	5	224	102, 97, 108
Cherries without pits and stems	0.5	189	108, 89, 93
Tomato ^a	0.5	160	84, 86, 81

^a measured by the common moiety method.

USE PATTERN

The post-harvest trials on citrus fruits, stone fruits, and tomato submitted in this dossier were conducted in the United States. The recommended use patterns in the US for post-harvest applications of propiconazole on the commodities relevant for this submission are summarized in Table 2.

Table 2 Registered post-harvest use of propiconazole (WP, 45%) in the USA

Commodity	Application			PHI (days)
	Method	No.	Rate	
Citrus ^b	In-Line Dip/Drench ^a	2	0.027-0.054 kg a.i./ 100 L	NA
	In-line aqueous or fruit coating spray	2	0.90-1.8 g ai/1000 kg fruits	NA
Stone fruit	In-Line Dip/Drench ^a	1	0.067-0.0135 kg ai/100 L	NA
	In-line aqueous or fruit coating spray	1	0.28-0.56 g ai/1000 kg fruits	NA
Tomato	In-Line Dip/Drench ^a	1	0.014-0.27 g ai/100 L	NA
	High volume (dilute spray) application	1	2.2-4.5 g ai/1000 kg fruit	NA

^a dip fruits for a minimum of 30 seconds and allow to drain;

^b treat fruit once before storage and once after storage, just prior to marketing

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

Supervised residue trials conducted with propiconazole in Canada and USA were submitted to the Meeting. Studies were conducted according to GLP, and concurrent determination of residues in untreated crops gave residues < LOQ, unless specified otherwise. Residues of propiconazole arising from use patterns with the rate or PHI within $\pm 25\%$ of the GAP are underlined and were considered for estimation of maximum residue levels and STMRs. All the trials were conducted using a WP formulation.

Residues of propiconazole were analysed by LC-MS/MS. Samples were analysed within a storage period that was shown not to impact the residue levels, according to storage stability studies evaluated previously by the JMPR.

Citrus fruits

A total of twelve post-harvest trials on citrus were conducted in 2006 in the United States. Fruits were treated with the first application, allowed to dry, then the second application was made. Except for trials CA131, CA134, CA135, CA136, the samples were washed before the second application. Table 3 summarizes the results.

Table 3 Propiconazole residues in citrus fruit from post-harvest treatments from trials conducted in USA in 2006 using (IR-4 PR 09715)

State	Crop (variety)	Treatment	Rate, kg ai/hL	no.	Propiconazole [mean]	Trial
Florida,	Orange (Orlando Tangelo)	Dip for 30 sec.	0.048	2	0.96, 0.77 [0.87]	09715.06-FL42
California	Orange (Washington Navel)	Dip for 30 sec	0.048	2	2.16, 2.33 [2.2]	09175.06-CA131
California	Orange (Valencia)	Dip for 30 sec	0.048	2	5.66, 4.15 [4.9]	09175.06-CA 132

Texas,	Grapefruit (Red Rio)	Dip for 30 sec	0.048	2	0.93, 0.90 [0.9]	09175.06-TX41
California	Grapefruit (Marsh)	Dip for 30 sec	0.048	2	1.17, 1.44 [1.3]	09175.06-CA137
California	Lemon (Eureka)	Dip for 30 sec	0.048	2	3.19, 2.79 [3.0]	09175.06-CA138
California	Lemon (Eureka)	Dip for 30 sec	0.048	2	1.92, 2.29 [2.1]	09175.06-CA 140
California,	Orange (W. Murcott mandarin)	In-line fruit coating spray	1.7 + 1.6 g ai/ 1000 kg fruit	2	2.32, 2.24 [2.3]	09175.06-CA135
California	Orange (Dancy mandarin)	In-line fruit coating spray	1.7 + 1.6 g ai/ 1000 kg fruit	2	1.18, 1.51 [1.3]	09175.06-CA136
California	Grapefruit (Marsh)	In-line fruit coating spray	1.6 + 1.7 g ai/ 1000 kg fruit	2	1.41, 1.19 [1.3]	09175.06-CA137
California	Lemon (Eureka)	In-line fruit coating spray	1.7 + 1.6 g ai/ 1000 kg fruit	2	1.10, 1.14 [1.1]	09175.06-CA138
California	Lemon (Eureka)	In-line fruit coating spray	1.6 + 1.6 g ai/ 1000 kg fruit	2	0.92, 0.94 [0.9]	09175.06-CA 140

Note: For risk assessment purposes, following the residue definition, total residues were calculated by applying a factor of 1.1 to convert propiconazole only residues to total residues of propiconazole and metabolites convertible to 2,4-DCBA.

Stone fruits

A total of nine post-harvest trials on stone fruits were conducted in 2007 in the United States. Propiconazole was applied to harvested mature fruits either as a high-volume spray, low-volume spray or dipped for 30 seconds. Fruit wax was included in each of the tank mixes, except in the dip in the GA*17 peach trial. Fruits were allowed to air dry following treatment. The results are shown in Table 4.

Table 4 Propiconazole residues in stone fruits without stone from post-harvest treatments from trials conducted in USA using WP formulation in 2007/2008 (IR-4 PR 09787)

State	Crop (variety)	Treatment Method	Rate	no.	Propiconazole only	Total residues	Trial

c= residues in control samples

Tomato

A total of six post-harvest trials on tomato were conducted in the United States in 2009. Mature tomatoes were collected from the field, rinsed with water, allowed to dry, and treated with propiconazole and fludioxonil in a tank mix, except in two trials. In the NC19 and NC32 trials, the tomatoes were collected and placed in storage at 14 to 20 °C until treatment within 1 to 3 days; the tomatoes were not rinsed prior

to treatment. For the dip application, the fruit was dipped in the test solution for approximately 30 seconds and drained. For the drench application, the test solution was applied with either a watering can or a drench plate. For the spray application, the test solution was applied as the fruit passed under the nozzle on brush rollers. The fruit was allowed to air dry following treatment. The results are shown in Table 5.

FATE OF RESIDUES IN STORAGE AND PROCESSING

Effect of processing on the nature of the residues

The hydrolytic stability of [triazolyl-¹⁴C]-propiconazole was investigated in aqueous buffer solutions at three pH values and temperatures to simulate processing practices (Adam D., 2008; Report No. T005078). The study was performed at pH 4 and 90 °C to simulate pasteurisation, pH 5 and 100 °C to simulate baking/brewing/boiling and at pH 6 and 120 °C to simulate sterilisation.

Buffer solutions containing [triazolyl-¹⁴C]-propiconazole at an initial concentration of 1.7 mg/L (significantly less than its water solubility of 100 mg/L at 20 °C) were incubated in closed high-pressure glass vessels in oil baths. The temperatures were maintained constant throughout incubation time (max ± 0.2 °C) and no significant variation of the pH values were observed in the buffered solutions. At time 0 and after 20 or 60 minutes incubation, duplicate samples per pH value (except at time 0) were taken, measured for total radioactivity by liquid scintillation counting (LSC), and analysed to determine the nature of degradates by high-performance liquid chromatography (HPLC). Selected samples were additionally analysed by two-dimensional thin layer chromatography (2D-TLC) to confirm the HPLC results. Mean recoveries of applied radioactivity were 99.0±1.3% (pH 4), 99.9% (pH 5) and 99.8±0.5% (pH 6). The results from analysis of the buffer solutions following incubation are summarised in Table 6.

Table 6 Analysis of ^{14}C -propiconazole in buffer solutions before and after incubation

Duplicate	Percentage of initial radioactivity (mg parent equivalents/litre solution)					
	pH 4 (90°C)		pH 5 (100°C)		pH 6 (120°C)	
	0 min	20 min	0 min	60 min	0 min	20 min
A	100 (1.696)	98.8 (1.675)	100 (1.676)	99.4 (1.666)	100 (1.673)	100.2 (1.675)
B	100 (1.696)	97.2 (1.647)	100 (1.676)	100.3 (1.682)	100 (1.673)	99.0 (1.656)
Mean	100 (1.696)	98.0 (1.661)	100 (1.676)	99.9 (1.674)	100 (1.673)	99.6 (1.666)

RESIDUES IN PROCESSED COMMODITIES

Orange samples collected in trial 06-CA133 (Table 3) were processed to oil, juice and dried pomace using procedures simulating commercial practice.

Oranges were washed, peeled by abrasion and a cold water mist was sprayed into the peeler to trap the highly volatile oil. The resulting emulsion of water and oil was treated with 0.2% of a pectinase enzyme preparation and allowed to react overnight at approximately 20 °C. The oil emulsion was passed through a screen separator, the peels were resuspended to extract any clinging oil and then passed through a centrifuge to separate solids, water, and the oil stream. The oil stream was centrifuged, kept frozen for at least 16 hours, filtered, anhydrous sodium sulfate added, and filtered again to obtain the oil.

Oranges were processed through a juice extractor, the juice processed through a finisher equipped with a 0.051-cm screen to remove coarse pulp and peel pieces, and then heated in a small steam jacketed kettle to 90 °C.

The peel from the juice extraction process was shredded and ground, combined with the other peel solid fractions (from oil separation) and blended with lime slurried water. The neutralized peel/pulp fraction was passed through a continuous screw press, resulting in fractions of expressed liquid and wet pulp. The wet pulp was spread on stainless steel trays and dried at 65 to 75 °C until reaching approximately 92% dry matter (dried orange pomace).

All processed samples were shipped frozen to the analytical laboratory within 85 days of processing for analysis of propiconazole. The results are shown in Table 7.

Table 7 Residues of propiconazole in orange processed fractions

Matrix	Residues of propiconazole (mg/kg)	Processing factor
Orange (RAC)	0.94	-
Juice	<0.01	<0.011
Dried Pulp	1.29	1.4
Oil	174	185

APPRAISAL

Propiconazole was evaluated by the JMPR for residues in 1987, 1991, 1994, and within the periodic review program in 2007, when a number of maximum residue levels were recommended. Propiconazole has an ADI of 0–0.07 mg/kg bw and an ARfD of 0.3 mg/kg bw. Information and residue trial data on citrus, stone fruits and tomato following post-harvest applications of propiconazole were submitted to current Meeting.

The residue definition for plant and animal commodities is *propiconazole* for compliance with the MRL and *propiconazole plus all metabolites convertible to 2,4-dichlorobenzoic acid, expressed as propiconazole* for the estimation of the dietary intakes.

Methods of analysis

Methods of analysis evaluated by the 2007 JMPR are divided into two groups. Methods where only propiconazole is analysed involves mostly LC-MS/MS detection, with LOQ of 0.01 mg/kg for citrus and tomato and of 0.05 mg/kg for stone fruits. The common moiety method measure all residues convertible to 2,4-dichlorobenzoic (2,4-DCBA) and are performed using mostly GC-MSD (after derivatisation of 2,4-DCBA to its methyl ester) with an LOQ of 0.05 mg/kg.

Stability of residues in stored analytical samples

A study to investigate the stability of residues in analytical samples in peach submitted to the 2007 JMPR showed that residues of propiconazole in peach samples are stable up to 36 months after frozen storage. New studies evaluated by the present Meeting have shown that propiconazole residues were stable for up to 207 days in orange, 154 days in juice and dried pulp, and 224 days in orange oil and 189 days in cherries. Propiconazole residues measured using the common moiety method in tomato (fortified with propiconazole at 0.5 mg/kg level) were stable up to 160 days, and the samples in the residue trials were analysed within this period. No storage stability study for total residues was performed in stone fruits (samples were stored for at least 560 days).

Results from supervised residue trials on crops

The 2007 JMPR agreed that, based on metabolism study, a factor of 3 needs to be applied to convert parent residues to total residues (all residues convertible to 2,4-DCBA and expressed as propiconazole). Data evaluated by the present Meeting are from post harvested uses, and it is unlikely that propiconazole metabolites are formed between treatment and sample preparation for analysis. Furthermore, residues of propiconazole will be used for dietary exposure assessment, without using the factor of 3.

Citrus fruits

In USA, propiconazole can be applied twice as post-harvest treatment as in line dip/drench twice at up to 0.054 kg ai/hL or in-line aqueous or fruit coating spray at up to 1.8 g ai/1000 kg fruit. Seventeen post-harvest trials on citrus were conducted in 2006 in USA according to GAP rate, but in eight trials the samples were washed before the second application.

In four trials conducted in orange using dip application conducted according to GAP, residues of propiconazole were 2.2, 2.5, 3.4 and 3.7 mg/kg (highest level of duplicate sample was 4.9 mg/kg).

The Meeting estimates a maximum residue level of 9 mg/kg, a STMR of 2.95 mg/kg and a HR of 4.9 mg/kg for propiconazole in oranges.

Stone fruits

In USA, propiconazole can be applied once as post-harvest treatment in stone fruits using in line dip/drench twice at up to 0.014 kg ai/hL or in-line aqueous or fruit coating spray at up to 0.56 g ai/1000 kg fruit. Nine post-harvest trials on stone fruits were conducted in 2007 in USA according to GAP. In all trials, fruits without stone was analysed, but the Meeting agreed that the residues found in whole fruit is within 10% (higher) of that found in the fruits without the stones and consider the data appropriate.

Residues of propiconazole from trials conducted using dip application were 1.2, 1.4, 1.7 and 2.1 mg/kg in peaches (highest value of duplicate samples of 2.2 mg/kg), 0.18 and 0.20 mg/kg in plums (highest value of duplicate samples of 0.22 mg/kg) and 0.67 and 0.85 mg/kg in cherry.

Residue of propiconazole in fruits without stone from trials conducted using in-line aqueous application were 0.14, 0.20, 0.49 and 0.50 mg/kg in peaches, 0.16 and 0.19 mg/kg in plum and 0.17 mg/kg in cherry.

The Meeting agreed that trials conducted using dip application in peach gave the highest residues and recommends a maximum residue level of 5 mg/kg (Po), a STMR of 1.55 mg/kg and a HR of 2.2 mg/kg for propiconazole in peaches.

Residues in plums from dip and spray application are similar and can be grouped as 0.16, 0.18, 0.19 and 0.20 mg/kg. The Meeting recommends a maximum residue level of 0.6 mg/kg, a STMR of 0.185 mg/kg and a HR of 0.22 mg/kg for propiconazole in plums.

The Meeting agreed that there is not enough trials to estimate a maximum residue level for cherry.

Tomato

In USA, propiconazole can be used in tomato as a post-harvest treatment in line dip or drench at up to 0.27 kg ai/hL or high volume spray application at 4.5 g ai/1000 kg fruit. Nine post-harvest trials on tomato were conducted in 2009 in USA according to GAP.

In six trials using dip or drench application, residues of propiconazole in tomatoes were 0.47 (2), 0.80 (2), 0.87 and 1.4 mg/kg. In three trials using in-line spray, residues were 0.37, 0.74 and 1.5 mg/kg.

The Meeting agreed that the dip/drench and the in-line spray trials gave similar results that can be grouped as (n=9) 0.37, 0.47 (2), 0.74, 0.80 (2), 0.87 and 1.4 and 1.5 mg/kg (highest level among the samples was 1.5 mg/kg)

The Meeting estimates a maximum residue level of 3 mg/kg, a STMR of 0.80 mg/kg and a HR of 1.5 mg/kg for propiconazole in tomato.

Fate of residues in storage and processing

Effect on the nature of the residues during processing

The hydrolytic stability of [triazolyl-U-¹⁴C]-propiconazole was investigated in aqueous buffer solutions at three pH values and temperatures to simulate processing practices. The study was performed at pH 4 and 90 °C for 20 minutes to simulate pasteurisation, pH 5 and 100 °C for 60 min to simulate baking/brewing/boiling, and at pH 6 and 120 °C for 20 min to simulate sterilisation. Only the parent compound was detected in the buffer solutions throughout the study, indicating that propiconazole is hydrolytically stable under the conditions of the tests.

Residues in processed commodities

In one study, orange were processed to oil, juice and dried pomace using procedures simulating commercial practice. Residues of propiconazole in oranges were 0.94 mg/kg, not detected in juice (< 0.01 mg/kg), 1.29 mg/kg in dried pulp and 174 mg/kg in oil, giving processing factors of < 0.011 for orange juice and of 184 for orange oil.

Based on a STMR of 1.95 mg/kg in oranges, the Meeting estimated a STMR-P of 0.02 mg/kg in orange juice.

Residues in animal commodities

Dried orange fruit can contribute to animal diets and is listed on the OECD animal diet. However, in commercial practice, post-harvest treatment is normally reserved for high value commodities and is unlikely that dried fruit from treated fruits would be fed to livestock. The Meeting considered that the estimations for propiconazole in orange will not change the dietary burden calculated by the 2007 JMPR meeting, and confirms its previous recommendations for animal commodities

RECOMMENDATIONS

Residues: For plant and animal commodities is *propiconazole* for compliance with the MRL and *propiconazole plus all metabolites convertible to 2,4-dichlorobenzoic acid, expressed as propiconazole* for the estimation of the dietary intakes.

CCN	Commodity name	Recommended maximum residue level (mg/kg)		STMR (P) mg/kg	HR (P) mg/kg
		New	Previous		
FS 0247	Peach	5 (Po)		1.55	2.2
FS 0014	Plums (including prunes)	0.6 (Po)		0.185	0.22
FC 0004	Oranges, Sweet, Sour (including Ordange-like hybrids): several cultivars	9 (Po)		2.95	4.9
JF 0004	Orange juice			0.02	
VO 0448	Tomato	3 (Po)		0.80	1.5

DIETARY RISK ASSESSMENT

Long-term intake

The IEDI of propiconazole based on the STMRs estimated by this and previous Meetings for the 13 GEMS/Food regional diets were 1–20% of the maximum ADI of 0–0.07 mg/kg bw (see Annex 3 of the 2013 Report). The Meeting concluded that the long-term dietary intake of residues of propiconazole is unlikely to present a public health concern.

Short-term intake

The ARfD for propiconazole is 0.3 mg/kg bw. The International Estimated Short-Term Intake (IESTI) for propiconazole was calculated for the plant commodities for which STMRs, HRs and maximum residue levels were estimated by the current Meeting and for which consumption data were available. The results are shown in Annex 4 of the 2013 Report. The IESTI represented a maximum of 100% of the ARfD for oranges (children 2–6 years). The Meeting concluded that the short-term intake of propiconazole residues from uses considered by the current Meeting were unlikely to present a public health concern.

PYRIMETHANIL (226)

The first draft was prepared by Dr Michael Doherty, Office of Pesticide Programs, United States Environmental Protection Agency

EXPLANATION

Pyrimethanil is an anilinopyrimidine fungicide that was first reviewed by the JMPR in 2007. During this review, maximum residue levels for commodities from field and post-harvest uses were recommended and subsequently adopted by the Codex Alimentarius Commission as Codex MRLs. Among these were maximum residue levels for pre-harvest uses on apricot, plums and peach and on post-harvest uses on pome fruit and cherries.

The sponsors (Janssen and IR-4) have since provided additional studies on the properties of pyrimethanil in a motion to re-evaluate the maximum residue levels of pyrimethanil on pome and stone fruits. Further, preharvest residue data on lemon and ginseng have also been submitted.

Structural Formulae**RESIDUE ANALYSIS***Description of analytical methods*

A number of analytical methods developed to determine pyrimethanil residues in plant matrices, including those used in pre- and post-harvest trials on pome fruit and stone fruit, were submitted and reviewed by JMPR in 2007. For plant commodities, methods consisted of organic solvent extraction (acetone or methanol), clean-up, and analysis by either gas chromatography with mass spectrometric detection (GC/MS), or by high performance liquid chromatography with ultraviolet detection (HPLC/UV). The HPLC/UV method was validated for apples with an LOQ of 0.05 mg/kg. The GC/MS method was validated for apples, peaches, and plums with an LOQ of 0.05 mg/kg. Multiresidue methods (US FDA and DFG S 19) were also reported for pyrimethanil and validated with an LOQ of 0.05 mg/kg. The JMPR concluded that adequate analytical methods exist for both data collection and enforcement purposes for pyrimethanil residues in plant commodities.

The new field trial studies used analytical methods similar to those reviewed by the 2007 JMPR. Among the new field trial data submitted to the 2013 JMPR, ginseng is the only new crop for which no data were submitted to the 2007 JMPR. Ginseng samples were analysed for pyrimethanil residues via GC/MS after an acetone homogenization/extraction step, an acid/base partitioning procedure, and additional clean up by silica SPE column. The method LOQ was 0.05 mg/kg; at this spiking level, method validation recoveries were $101 \pm 8\%$ (n=6).

Method validation and procedural recoveries

A summary of the method validation and procedural recoveries for the new pome and stone fruit studies for 2013 JMPR review are provided in Table 1. Average method and concurrent recoveries were all within the acceptable range of 70–120%, with relative standard deviations (RSD) below 20%.

Table 1 Summary of Method Validation and Procedural Recoveries

Storage Stability Studies

The 2007 JMPR received data for pyrimethanil demonstrating adequate residue stability for at least one year in the following crop matrices held in frozen storage: apple, grape, tomato, lettuce, carrot, pea, peach, and plum. Ginseng samples were stored frozen for a maximum of 259 days in the field trials. The supporting storage stability study showed recoveries of 80, 89, and 90% (86% average) after 259 days of storage at < -20 °C, for control samples spiked at 0.50 mg/kg.

USE PATTERN

Pyrimethanil may be applied both pre-harvest and post-harvest for disease control in a range of crops. The various national GAPs relevant to the pre-harvest treatment and post-harvest treatment studies reported herein are summarized in Table 2 and in Table 3, respectively. For pome fruit, a combination of pre-harvest and post-harvest applications can be followed by a thermofog treatment except in the situation where a dip/drench treatment has already been made. For stone fruit, combinations of pre-harvest and post-harvest treatments are permitted, but no thermofog treatments have been registered.

Table 2 Summary of Pre-harvest GAP Uses of Pyrimethanil in/on Pome and Stone Fruit, Ginseng and Lemon^a

Pome fruit	USA	160 g/L NH	Thermofogging		9.6 g ai/1000 kg of fruit	1 Do not apply to fruit already treated via drench or dip/wash applications

^a Submitted to 2007 JMPR, but additional trials and complete GAPs submitted for 2013 JMPR consideration [In 2007, the only thermofog GAP was from Chile as a proposed use on pome fruit].

RESIDUES FROM SUPERVISED TRIALS ON CROPS

Pre-harvest Lemon Trials

The 2013 Meeting received data reflecting residues of pyrimethanil on lemons following foliar spray according to the USA GAP (600 g/L SC, single foliar application at 0.78 kg ai/ha).

Table 4 Pyrimethanil Residues in Lemon following Pre-Harvest Treatment (Reference PR 09085)

Lemon Year Variety	Application Rate (kg ai/ ha)	Number of Applications	DAT	Pyrimethanil Residue (mg/kg) Whole Fruit [Average]

New Post-Harvest Trials on Pome Fruits

The 2013 Meeting received new and updated labels for post-harvest uses of pyrimethanil. In addition, 15 post-harvest dipping/drenching trials on apples and 10 on pears conducted from 2001-2005 in Australia, Italy, France, Spain and Belgium, as well as 7 thermofogging trials from the USA (2007)

and Belgium (2001) were submitted. All dip/drench trials followed the GAP in Belgium (200 g ai/L SC, dip/drench at the rate of 0.03 kg ai/hL). Note: Netherlands and Italy have similar GAPs. Table 6 summarizes the post-harvest trials on pome fruit, with residues according to GAP underlined.

One thermofogging trial was conducted in the US in 2007, following the GAP there (160 g/ai/L HN, one application at 9.6 kg ai/1000 kg fruits) (Report 06001). Three of the five thermofogging trials were carried out in Belgium in 2001 following the GAP ($\pm 25\%$) in the country (160 g ai/L HN, one application at the rate of 5.6 to 8 kg ai/1000 kg fruits). The trials are summarized in Table 7, with residues according to GAP underlined.

Stone fruits

A number of pre- and post-harvest supervised trials on stone fruit were submitted and reviewed by the JMPR in 2007. Those data are included in the table below.

Table 8 Summary of pyrimethanil/stone fruit residue data reviewed by 2007 JMPR

Application	Crop	GAP	Residues (mg/kg)

Post-harvest, dip	Cherry	Chile	0.82, 1.0, 1.1, 1.2, 1.4, 1.4, 1.4, 1.5

New post-harvest trials on cherry

Five post-harvest trials on sweet cherry were conducted in the USA during 2006, in support of the GAP in the US (400 g ai/L SC, 0.05 kg ai/hL for dip and high volume line application and 0.2 kg ai/hL for low volume line application (Report PR 080701). At each trial, fruit samples were dipped for approximately 30 seconds in a pyrimethanil solution containing 400 g ai/378 litres (0.11 kg ai/hL). Two other treatments were examined at a high-volume application of 1000 kg fruits, applied at a spray concentration of 0.1 kg ai/hL. Fruit wax was added to the mixtures in all treatments. The trials are summarized below.

Table 9 Pyrimethanil residues in cherries resulting from post-harvest treatments

Pre-harvest Ginseng trials

The 2013 Meeting received data reflecting residues of pyrimethanil on ginseng following foliar spray according to the USA GAP (600 g/L SC, foliar application at 0.78 kg ai/ha on a 7 to 14-day interval, seasonal maximum of 2.35 kg ai/ha). Three-year old ginseng plants were treated and the roots were harvested 29 days after the last application. The roots were dried in a commercial drying facility. Untreated and treated roots were placed on separate racks at opposite ends of a grower's commercial drying room. The roots were dried at approx. 18–27 °C from 10/3 to 10/06 and at approx. 90–115 °F from 10/6 to 10/17/2007 when they were sampled.

Table 10 Pyrimethanil Residues in Dried Ginseng following Pre-Harvest Treatment (Reference PR 09707)

Ginseng Year Variety	Application Rate (kg ai/ ha)	Number of Applications	Total Rate (kg ai/ ha)	RTI (days)	DAT	Pyrimethanil Residue (mg/kg) Whole, Dried Root [Average]
2007 MI11: Edgar, WI (American Ginseng)	0.78	3	2.372	6	29	0.35 0.47 [0.41]
2007 MI12: Nutterville, WI (American Ginseng)	0.78	3	2.391	6	29	0.11 0.088 [0.099]
2007 MI13: Mosinee, WI (American Ginseng)	0.78	3	2.377	6	29	0.48 0.69 [0.585]

APPRAISAL

Pyrimethanil was most recently evaluated for toxicology and residues by the JMPR in 2007. The Meeting derived an ADI of 0.2 mg/kg bw per day and decided that an ARfD is unnecessary.

In 2007 the Meeting agreed that the residue definition for both enforcement and dietary intake for plant commodities is parent pyrimethanil. The Meeting further concluded that the residue definition for both enforcement and dietary exposure considerations for milk is the sum of pyrimethanil and 2-anilino-4,6-dimethylpyrimidin-5-ol, expressed as pyrimethanil; and for livestock tissues (excluding poultry) is the sum of pyrimethanil and 2-(4-hydroxyanilino)-4,6-dimethylpyrimidine, expressed as pyrimethanil.

The compound was listed by the Forty-fourth Session of the CCPR for the evaluation of additional MRLs. The 2013 JMPR received residue data for pome fruit, stone fruit, lemons and ginseng.

Methods of analysis

The Meeting received information on the analytical methods used for determination of pyrimethanil residues in samples obtained from supervised trials on pome fruit, stone fruit, lemon, and ginseng. The residues were measured using GC/MS or HPLC/UV with LOQs of 0.05 mg/kg. The methods were reviewed by the JMPR in 2007, which concluded that adequate analytical methods for pyrimethanil exist for both data collection and enforcement purposes. The methods used in the trials submitted to the 2013 Meeting are essentially identical to those accepted at the 2007 Meeting.

Stability of residues in stored analytical samples

Detailed information from the 2007 JMPR showed that pyrimethanil residues are stable (> 70% remaining) in frozen storage for at least 12 months in the tested commodities, i.e., apple, grape, tomato, lettuce, carrot, pea, peach, and plum. Concurrent storage stability studies were submitted with the ginseng trials and demonstrated residue stability for at least 259 days.

The periods of demonstrated stability cover the frozen storage intervals in the residue studies.

Results of supervised residue trials on crops

The 2007 JMPR received supervised trials for many crops, including pre- and post-harvest uses of pome and stone fruit. However, due to incomplete GAP information, pome fruit thermofog data were not included in the pome fruit MRL recommendation. The 2013 JMPR received complete GAP information for pome and stone fruits, as well as expanded post-harvest residue data. For completeness, all relevant pome and stone fruit supervised trial data for pyrimethanil are considered in the following sections. The USA GAP allows for pre- and post-harvest applications of pyrimethanil to pome and stone fruit; however, few trials reflect residues from the combined pre- and post-harvest applications.

Lemon

In the USA, pyrimethanil is registered for use on lemons for up to 4 treatments at a rate of 1.7 kg ai/ha, with a PHI and a retreatment interval of 7 days. Five supervised field trials are available at this GAP from the USA.

Rank-order pyrimethanil residues in lemon were (n=5): 0.18, 0.21, 0.27 (2), and 0.82 mg/kg.

The Meeting noted that there is a current MRL for citrus fruit at 7 mg/kg based on post-harvest uses and concluded that the current MRL for citrus is adequate to cover the submitted pre-harvest-use lemon data. Therefore, the Meeting confirms its previous recommendation.

Pome fruits

In 2007, the Meeting reviewed residue values on pome fruits from pre-harvest and post-harvest trials according to Belgium, France, Germany, Greece, Italy, Netherlands, United Kingdom, and USA GAPs. Residues from post-harvest GAPs were higher and served as the basis for the previous recommendations for maximum residue level, STMR, and HR estimates of 7(Po), 0.7, and 3.8 mg/kg, respectively.

The 2013 Meeting has evaluated data from the USA and Europe matching a new GAP for uses of pyrimethanil as a post-harvest thermofog treatment. Although the GAP for thermofog uses in the US has a higher application rate than the GAPs in European countries (one application at 9.6 kg ai/1000 kg fruits vs. one application at the rate of 5.6 to 8 kg ai/1000 kg fruits), the residues resulting from the trials conducted according to the GAP in Europe were approximately 10-fold higher than the trial conducted according to the US GAP; therefore, the meeting selected data according to GAP in Europe.

Residues from post-harvest trials in apples (n=8, new data in bold) were: 1.1, 1.4 (2), 1.5, 1.6, 4.9, 6.4, and 7.1 mg/kg.

Residues from post-harvest trials in pears (n=4) were: 1.0, 1.6, 1.8, and 3.5 mg/kg.

As the residue data from apples and pears are from the same population, they were combined to give the following residues (n=12, median underlined): 1.0, 1.1, 1.4 (2), 1.5, 1.6 (2), 1.8, 3.5, 4.9, 6.4, and 7.1 mg/kg. The Meeting agreed to replace its previous maximum residue level recommendation of 7 mg/kg with a new estimated STMR of 1.6 mg/kg and a maximum residue level of 15 (Po) mg/kg for pome fruit.

Stone fruits

In 2007, the Meeting recommended an STMR of 1.3 mg/kg and a maximum residue level of 4 (Po) for cherries based on the post-harvest GAP for Chile. The 2013 Meeting received new information on the post-harvest GAP in the USA. Post-harvest trials were conducted at 2× the USA GAP. Since post-harvest data may not be adjusted via proportionality, there are no new data for the Meeting to use for a recommendation. Therefore, the Meeting confirmed its prior recommendations.

Berries and other small fruits

From the 2007 JMPR:

“Eight trial were conducted on the foliar application of pyrimethanil to strawberries in the USA, where the GAP is 600 g/L SC, 0.8 kg ai/ha, 2.4 kg ai/ha/season, 1 day PHI. All trials were at maximum GAP, and the residues in ranked order (median underlined) were: 0.79, 0.93, 0.99, 1.1, 1.2, 1.3(2), and 2.3 mg/kg. The Meeting estimated an STMR of 1.2 mg/kg and a maximum residue level of 3 mg/kg for strawberries.”

The current Meeting was asked to extrapolate the strawberry field trial data to Berries and Other Small Fruits [Subgroup 004E, Low Growing Berries (including Bakeapple; Cranberry (FB 0265); Cloudberry (FB 0277); Muntries (FB 0283); Partridge berry; Squaw vine; Strawberry (FB 0275); Strawberries, wild (FB 0276); Strawberry, Musky)], reflecting the USA label allowing use on the Low Growing Berry Crop Subgroup 13-07G.

Taking into account the available historic data showing that pesticide residues in strawberry are generally comparable to or higher than residues in other low-growing berries, the Meeting agreed to extrapolate the residue estimates for strawberry to commodities comprising the low-growing berries subgroup. Therefore, for the low-growing berries subgroup (Subgroup 004E, FB 2009) the Meeting recommended a maximum residue level of 3 mg/kg and estimated an STMR of 1.2 mg/kg. The Meeting agreed to withdraw its previous recommendation of 3 mg/kg for strawberry.

Ginseng

In the USA, pyrimethanil is registered for use on ginseng for up to 3 treatments at a rate of 0.78 kg ai/ha, with a PHI of 30 days and a retreatment interval of 7 days. Three supervised field trials were available at this GAP from the USA.

Rank-order pyrimethanil residues in dried ginseng were (n=3): 0.099, 0.41, and 0.59 mg/kg.

The Meeting estimated an STMR value of 0.41 mg/kg and a maximum residue level value of 1.5 mg/kg for ginseng, dried.

Fate of residue during processing

In 2007, the Meeting estimated the following STMR-Ps for citrus juice, citrus pulp (dried) and citrus oil, respectively: 0.028 mg/kg; 1.3 mg/kg; 56 mg/kg. As these estimates adequately cover residues in lemon, the Meeting confirmed its prior recommendations for citrus.

The 2007 Meeting estimated a processing factor of 0.45 for apple juice, 0.37 for apple puree, and 4.1 for wet apple pomace. Applying these processing factors to the estimated STMR for pome fruit (1.6 mg/kg) resulted in STMR-P estimates of 0.72 mg/kg for apple juice, 0.59 mg/kg for apple puree, and 6.6 mg/kg for wet apple pomace. The Meeting agreed these values should replace the estimates made in 2007.

Residues in animal commodities

Dietary burden calculations for beef cattle and dairy cattle are provided below. The dietary burdens were estimated using the OECD diets listed in Appendix IX of the 2009 edition of the FAO Manual.

Potential cattle feed items include: apple pomace, almond hulls, carrot culls, citrus pulp, grape pomace, pea seed and pea straw. Pyrimethanil residues in all these feed items were as estimated by the 2007 JMPR except for apple pomace, which has a revised STMR-P of 6.6 mg/kg (the previous estimate was 2.9 mg/kg).

Summary of livestock dietary burdens (ppm of dry matter diet)

	US-Canada		EU		Australia		Japan	
	max	mean	max	mean	max	mean	max	mean
Beef cattle	0.14	0.14	4.3	3.6	4.6 ^a	3.9 ^c	0.0	0.0
Dairy cattle	2.5	2.1	2.8	2.1	4.1 ^b	3.4 ^d	0.0	0.0

^a Highest maximum beef or dairy cattle dietary burden suitable for MRL estimates for mammalian meat

^b Highest maximum dairy cattle dietary burden suitable for MRL estimates for mammalian milk

^c Highest mean beef or dairy cattle dietary burden suitable for STMR estimates for mammalian meat.

^d Highest mean dairy cattle dietary burden suitable for STMR estimates for milk.

Animal commodity maximum residue levels

The calculations used to estimate residues in animal commodities based on comparisons of the dietary burden to results of the bovine feeding study, for use in estimating maximum residue levels, STMR and HR values, are shown below.

Pyrimethanil feeding study	Feed level	Residues	Feed level	Residues (mg/kg) in			
	(ppm) for milk residues	(mg/kg) in milk	(ppm) for tissue residues	Muscle	Liver	Kidney	Fat
MRL beef or dairy cattle							
Feeding study ^a	3	< 0.01	3	< 0.05	< 0.05	0.08	< 0.05
	10	0.017	10	< 0.05	< 0.05	0.13	< 0.05
Dietary burden and high residue	4.1	< 0.01	4.6	< 0.05	< 0.05	0.09	< 0.05
STMR beef or dairy cattle							
Feeding study ^b	3	< 0.01	3	< 0.05	< 0.05	0.066	< 0.05
	10	0.017	10	< 0.05	< 0.05	0.12	< 0.05
Dietary burden and residue estimate	3.4	< 0.01	3.9	< 0.05	< 0.05	0.07	< 0.05

^a highest residues for tissues and mean residues for milk

^b mean residues for tissues and mean residues for milk

Residue estimates in animal commodities are unchanged relative to those recommended in 2007; therefore, the Meeting confirmed its prior recommendations: an STMR of 0.01 mg/kg for milk and estimated a maximum residue level of 0.01 mg/kg for milk. The Meeting estimated STMRs of 0.0 mg/kg for each of meat and fat and maximum residue levels of 0.05 (*) mg/kg for meat. The Meeting estimated an STMR of 0.07 mg/kg for edible offal based on the STMR value for beef cattle kidney.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI assessment.

Definition of the residue (for compliance with MRL and dietary intake) for plant commodities: *pyrimethanil*.

The residue is not fat-soluble.

Commodity		MRL, mg/kg		STMR, mg/kg	HR, mg/kg
CCN	Name	New	Previous		
FP 0009	Pome fruits	15 Po	7	1.6	
FB 2009	Low Growing Berries	3		1.2	
FB 0275	Strawberry	W	3		
DV 0604	Ginseng	1.5		0.41	
JF 0226	Apple, Juice			0.72	

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Daily Intakes (IEDIs) of pyrimethanil were calculated for the 13 GEMS/Food cluster diets using STMRs/STMR-Ps estimated by the current Meeting. The ADI is 0–0.2 mg/kg bw and the calculated IEDIs were 0–5% of the maximum ADI (0.2 mg/kg bw). The Meeting concluded that the long-term intakes of residues of pyrimethanil, resulting from the uses considered by the current Meeting, are unlikely to present a public health concern.

Short-term intake

The 2007 JMPR decided that an ARfD was unnecessary and concluded that the short-term intake of pyrimethanil residues is unlikely to present a public health concern.

SPIROTETRAMAT (234)

The first draft was prepared by Professor Mi-Gyung Lee, Andong National University Republic of Korea

EXPLANATION

Spirotetramat was evaluated by the JMPR in 2008 for the first time for toxicology and residues. The Meeting derived an ADI of 0–0.05 mg/kg bw and an ARfD of 1.0 mg/kg bw and recommended maximum residue levels for a range of crops. In 2011 and 2012, the JMPR recommended additional MRLs. The compound was again listed by the Forty-fourth Session of CCPR for the evaluation of 2013 JMPR for additional MRLs.

Residue definitions established by the 2008 JMPR are:

- For compliance with the MRL for plant commodities: *spirotetramat plus spirotetramat enol, expressed as spirotetramat.*
- For dietary intake estimation for plant commodities: *spirotetramat plus the metabolites enol, ketohydroxy, enol glucoside, and monohydroxy, expressed as spirotetramat.*
- For compliance with the MRL and for dietary intake estimation for animal commodities: *spirotetramat enol, expressed as spirotetramat.*

The residue is not fat soluble.

The present Meeting received supervised field trial data for berries and other small fruits (blueberries and cranberries), assorted tropical and sub-tropical fruits (bananas, pineapples and pomegranates), bulb vegetables (bulb onions and spring onions), watercress, globe artichokes and coffee beans. Information on analytical methods, storage stability testing results (bananas and coffee) and residue levels in processed products (pineapple juice and process residue, roasted bean coffee and freeze-dried coffee) was also received.

METHODS OF RESIDUE ANALYSIS***Analytical methods***

The Meeting received information on analytical methods used for the determination of spirotetramat and its major metabolites in the submitted residues trials. In all trials, method 00857 (Shōning *et al.*, 2005) or modified 00857 (Coopersmith, 2009) was used as a reference method. These methods are based on LC-MS/MS using isotopically labelled internal standards. Method 00857 was previously reported and evaluated by the 2008 and 2011 JMPR.

Further modifications of the reference method were made and applied to determine spirotetramat, the metabolites spirotetramat-enol, spirotetramat-ketohydroxy, spirotetramat-monohydroxy and spirotetramat-enol-glucoside (enol-Glc) in blueberries, cranberries, bananas, pineapples (including juice and processing residues), pomegranates, bulb onions, spring onions, watercress, globe artichokes and coffee beans (including roasted beans and freeze-dried coffee). Residues in samples were extracted with 0.22 mL of formic acid (88%) or 0.20 mL formic acid (98%) in 4:1 acetonitrile:water. The extract was filtered (using Celite or polyethylene frit) or non-filtered (pineapple juice) and cleaned up with C18 SPE cartridge or in tandem with an Envi-Carb SPE (or HLB SPE). Quantitation was made by LC-MS/MS. Conversion factors to parent equivalents were used as follows: enol, $\times 1.239$; ketohydroxy, $\times 1.177$; monohydroxy, $\times 1.231$; and enol-glucoside, $\times 0.806$.

Except in some cases (enol-Glc in roasted coffee beans and all analytes in freeze-dried coffee), recovery tests for all analytes in all matrices were conducted at the fortification levels of ≥ 0.01 mg/kg (as parent equivalents). With the exception of enol-Glc in pineapple juice and the process residues, the recoveries were within 70–120% (RSD below 20%) and the limits of

quantitation were 0.01 mg/kg (as parent equivalents) for each analyte and 0.05 mg/kg for total spirotetramat equivalents. The average recoveries of enol-Glc in pineapple juice and process residues were 134% (range, 98–161%) and 137% (range, 102–159%), respectively, at the fortification levels of 0.01 mg/kg, therefore the method was not considered suitable for the pineapple products.

For enol-Glc in roasted coffee beans, recovery tests were conducted at the fortification levels of ≥ 0.05 mg/kg (as parent equivalents). The average recovery was 98% (range, 82–121%) and the limit of quantification was 0.05 mg/kg.

In recovery tests for each analyte (parent and four metabolites) in freeze-dried coffee, the lowest spiking level was 0.1 mg/kg (as parent equivalents). Some recoveries of parent and enol-Glc were 50, 59 and 67%, and 130, 133 and 139%, respectively, at the fortification level. Overall, the method performance was not considered acceptable.

Results of the method validation and procedural recoveries for commodities for which residues trials are reported are summarized in Table 1.

Table 1 Recovery percentage of spirotetramat and its metabolites obtained with method 00857

Sample	Analyte	Fortification, mg/kg	No.	Range of recoveries, %	Mean recovery, %	Recovery, SD

Method 00857 (Shöning *et al.*, 2005; Coopersmith, 2009) was further modified for matrices.

For bananas, pineapples, pomegranates, watercress and coffee beans, concurrent recoveries were included.

^a Recoveries at fortification levels of 0.1 mg/kg.

Stability of residues in stored analytical samples

Storage stability studies were performed on bananas with peel, peeled bananas, green bean coffee, roasted coffee bean and freeze-dried coffee for days 771, 770, 418, 438 and 448, respectively. Actual storage periods of the samples are shown in Table 2. For others, storage periods were as follows: blueberries - 587 days, cranberries - 483 days, pineapples without crown/juice/process residues - 179/119/114 days, pomegranates - 412 days, bulb onions - 434 days, spring onions - 550 days, watercress - 472 days and globe artichokes - 500 days.

As shown in Table 2, the results demonstrated that the residues in the samples are stable for the testing period. In addition, the 2008 JMPR reported frozen storage (-18 °C) stabilities of spirotetramat and its metabolites up to 2 years on various plant commodities. These cover storage stability for the samples in this evaluation.

Table 2 Storage stability of spirotetramat and its metabolites in banana and coffee

Crop	Analyte	Fortification level, mg/kg	Days of storage testing	Actual storage days	Remaining, %	Average spirotetramat equivalents ^a mg/kg

^a Spirotetramat converted to its metabolites after fortification.

USE PATTERN

Spirotetramat is a systemic insecticide used for the control of a broad spectrum of sucking insects. The authorized uses of spirotetramat on crops, submitted for evaluation by the present JMPR, are summarized in Table 3.

Table 3 Registered use of spirotetramat 240 SC formulation on some crops

Crop	Country	Application ^a			PHI, days
		Rate, kg ai/ha	Interval, days	Total/season, kg ai/ha	
Bush berry (blueberries) and low growing berry (cranberry) ^b	Canada	0.053–0.20	7	0.44	7
Banana and plantain	USA	0.18–0.28	14	1.4	1
Pineapple	USA	0.18	14	0.36	1
Pomegranate	USA	0.15–0.18	14	0.36 per 12-month period	1
Bulb vegetables (bulb onion)	USA	0.090	7	0.18	3
Bulb vegetables (spring onion)	USA	0.090	7	0.18	7
Watercress	USA	0.067–0.22	7	0.45	3
Artichoke, globe	USA	0.090–0.15	7	0.56	3
Coffee	USA	0.15–0.18	21	0.53	14

^a The spirotetramat 240 SC, w/w, 22.4% (240 g/L) formulation must be tank-mixed with a spray adjuvant /additive.

In trees, tropical and vine crops, minimum application volumes of water are 470 L/ha for conventional ground airblast sprayer, 280 L/ha for high air velocity, low volume or air curtain sprayers and 94 L/ha for aerial application.

In vegetable and potato crops, minimum application volumes of water are 140 L/ha by ground and 47 L/ha by aerial application. The formulation may also be applied through overhead irrigation systems. If needed, repeat application at a 7- to 10 day interval.

^b Usage is registered as 220–585 mL/ha/application and 1.833 L/ha/crop season.

Apply 200–3000 L total volume/ha by ground. For chemigation (cranberry only), the higher rate of the 240 SC formulation and a maximum spray volume of 3000 L total volume are recommend.

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

Supervised residue trials were conducted in the USA and Canada according to GLP principles under IR-4 programmes of the USA. The results of the supervised trials are shown in the following tables:

Crop group	Commodity	Table No.
Berries and other small fruits	Blueberries	4
	Cranberry	5
Assorted tropical and sub-tropical fruits—inedible peel	Banana	6
	Pineapple	7

Crop group	Commodity	Table No.
	Pomegranate	8
Bulb vegetables	Onion, bulb	9
	Spring onion	10
Leafy vegetables (including Brassica leafy vegetables)	Watercress	11
Stalk and stem vegetables	Artichoke, globe	12
Seed for beverages and sweets	Coffee beans	13

Where two replicate field samples were taken and residues were determined in each, a mean value was calculated for estimating a maximum residue level. From trials carried out side-by-side, the higher residue was chosen.

Total spirotetramat equivalents are the sum of all components converted to spirotetramat equivalents by multiplying by the following conversion factors: enol $\times 1.239$, ketohydroxy $\times 1.177$, monohydroxy $\times 1.231$ and enol-glucoside $\times 0.806$. Where a component is reported as '<value', the '<value' is added into the calculation of the total equivalents. The following example illustrates this.

Residues as spirotetramat equivalents (mg/kg)

Spirotetramat	enol	keto-hydroxy	mono-hydroxy	enol-glucoside	total residue	Spirotetramat + enol
0.15	0.30	< 0.012	< 0.012	< 0.008	0.48	0.45
0.55	0.68	0.012	0.022	0.010	1.3	1.2
< 0.01	< 0.012	< 0.012	< 0.012	< 0.008	< 0.055	< 0.022

Berries and other small fruits

Blueberries

Eleven residue trials were conducted in the USA (seven trials) and Canada (four trials) during the 2009 growing season. Four trials were conducted on low-bush blueberries and seven trials were conducted on high-bush blueberries. Spirotetramat 240 SC (240 g/L) was applied to blueberry as three foliar applications ranging from 0.17–0.19 kg ai/ha, with re-treatment intervals of 5 to 8 days. The total seasonal application rate ranged from 0.52 to 0.56 kg ai/ha. A non-ionic surfactant was included in the spray mixtures at 0.25% with the exception of Trial ID#132 (non-ionic surfactant of 1%) and the spray volume of 115–573 L/ha was used. The blueberry samples were harvested 6 to 8 days after the final application. One decline trial was conducted, with blueberry samples harvested at 1, 3, 7, and 10 days after the last application, to assess the decline in potential residues over time.

^a Mean value of residues is expressed in bold

^b The two trials were conducted at the same site with the same variety, on 1st application 8 days apart, thus they were not independent.

Cranberry

Six trials were conducted in the USA (five trials) and Canada (one trial) during the 2009 growing season. Five trials were conducted in the US and one trial in Canada. Spirotetramat 240 SC formulation was applied to cranberries as three foliar applications ranging from 0.17 to 0.19 kg ai/ha, with re-treatment intervals of 6 to 8 days. The total seasonal application rate ranged from 0.52 to 0.55 kg ai/ha. A non-ionic surfactant was included in all spray mixtures at a rate of 0.25% and the spray volume of 240–555 L/ha was used. One decline trial was conducted, with cranberry samples harvested at 1, 4, 7 and 11 days after the last application, to assess the decline in potential residues over time.

^a Mean value of residues expressed in bold

*Assorted tropical and sub-tropical fruits - Inedible peel**Banana*

Spirotetramat is used to control banana aphids (*Pentalonia nigronervosa*) in banana production. In Hawaii, USA, five trials (HI05, HI06, HI09, HI10 and HI14) were conducted during the 2008 and 2009 growing seasons. In each trial, the test substance (spirotetramat 240 SC) was applied in five foliar directed applications of approximately 0.28–0.30 kg ai/ha each, for a total of approximately 1.4–1.5 kg ai/ha. An organosilicone surfactant was included in each tank mix and the spray volume of approximately 500 L/ha was used.

The test substance was applied to bagged bunches in the HI05 trial. The bunches were not bagged in the other trials. All applications were made approximately 14 days apart and timed so that marketable-sized bananas could be collected 1 day after the final application. For decline determination, banana samples were collected additionally from HI14 trial at 3, 7, and 14 days after last application. In HI06 and HI10 trials, the bananas were cut in half lengthwise, retaining one half as samples for the banana fruit with peel samples. From the HI06 trial, the samples were additionally collected at 1-day PHI to determine residues in peeled fruits where a whole fruit was peeled and retained as a sample.

^a Mean value of residues was expressed as a bold letter. Portion analysed was a whole banana with peel.

^b Test substance was applied to bagged bunches. In the other trials, the bunches were not bagged.

Pineapple

Spirotetramat is needed to control grey mealybugs and pink mealybugs (vectors of pineapple mealybug wilt virus) in pineapple production. Five field trials (HI01-HI05) were conducted in Hawaii, USA during 2011. At each trial, two foliar broadcast applications of the test substance (spirotetramat 240 SC) 13–14 days apart were made. The application rates were in the range 0.17–0.18 kg ai/ha per application for a total rate range of 0.35–0.36 kg ai/ha per season. All applications were made using appropriate spray equipment with an adjuvant in the tank mix, and the spray volumes of 830–1900 L/ha were sufficient to provide adequate dispersal of the test substance.

At the HI02 trial, duplicate samples were collected 0, 3, 7, and 14 days after the last application. Additional samples taken from the HI01 trial were subjected to processing into pineapple juice and process residue.

HI01, HI02 and HI05 trials were conducted on different plantations at the same site with the same variety, the 1st application 36–106 days apart. HI03 and HI04 were also conducted on different plantations at the same site with the same variety, the 1st application 40 days apart. These five trials were considered as independent.

At all trials, samples were harvested one day after the last application. Crowns were removed from the sampled fruit and were cut into quarters longitudinally, retaining one quarter of each for the sample. In field site, sample size reduction should be avoided. These trials are not appropriate for evaluation.

^a Mean value of residues was expressed in bold. Portion analysed was fruit crown removed.

Pomegranate

Spirotetramat is used to control aphids, whiteflies, and grape mealybug in pomegranate production. In California, USA, four field trials were conducted during the 2009 growing season. In each trial, the test substance (spirotetramat 240 SC) was applied in two foliar directed applications of approximately 0.35–0.36 kg ai/ha each, for a total of approximately 0.17–0.18 kg ai/ha. An adjuvant was included in each tank mix and the spray volume of 550–1060 L/ha was applied. The applications were made 14 days apart and timed so that marketable-sized pomegranates could be collected 1 day after the final application. Additional samples for decline determination were collected from one trial, CA69 at 3, 7, and 14 days. Each fruit was cut into quarters, retaining opposite quarters as samples. Cutting of samples in field site was not appropriate.

^a Mean value of residues was expressed in bold

^b The two trials were conducted at the same site with the same variety, on the same dates of application. Thus they were not independent.

^c The two trials were conducted at the same site with the same soil type and maintenance, with the same variety, on 1st application 21 days apart. They were not considered as independent.

Bulb vegetables

Onion, bulb

Twelve field trials were conducted in Canada (four trials) and in the USA (eight trials) during 2008 and 2009 growing season. Two foliar broadcast applications of spirotetramat 240 SC formulation were made at a rate of application ranged from 0.084 to 0.094 kg ai/ha. The spray volumes ranged from approximately 205 to 533 L/ha and the PHI was 2 to 4 days, with a 6 to 8 day retreatment interval between applications. A non-ionic surfactant (Agral 90 or Dyne-Amic), at the target rate of 0.25% v/v in the spray mixture was included with each application. Two residue decline trials were conducted with samples collected at 1, 6–7, and 9–10 days after the last application, in addition to the samples collected at the target PHI of 3 to 4 days.

^b The trials were conducted at the same site with the same variety, on the same dates of application.

Spring onion

Two field trials were conducted during the 2009 growing season in Ontario and Quebec of Canada. Spirotetramat 240 SC formulation was applied to green onions as two foliar applications ranging from 0.090 to 0.092 kg ai/ha each, with re-treatment intervals of six to seven days, for maximum seasonal rates of 0.18 kg ai/ha. A non-ionic surfactant was included at 0.25% in the spray mixtures and the spray volume of approximately 300 L/ha was applied. Samples were harvested 6 to 7 days after the final application. One decline trial was conducted with additional samples harvested at 1, 4, and 11

days following the last application to assess the decline pattern of spirotetramat and its metabolites residues.

Leafy vegetables (including Brassica leafy vegetables)

Watercress

Three field trials were conducted in the USA (Florida and Maryland) during 2008 (Trial FL38, FL39, MD27). In the FL39 and MD27 trials, the plots received two applications of spirotetramat 240 SC formulation using conventional broadcast sprayers at the rate of 0.21–0.22 kg ai/ha. In the FL38 trial, additionally, two chemigation applications were made in the different plot using overhead mini-sprinklers at the rate of 0.22 kg ai/ha. The organo-silicone surfactant Dyne-Amic was used with all applications (except application 1 at the FL39 trial) at all the field trials. Applications of the test substance were made at 7–8 day intervals when the watercress was in the vegetative stage with the last application 3 days before the harvest. The foliage (leaves and stems) was cut with a knife/pruners and placed directly into sample bags. Samples were taken from at least 12 separate areas within each plot. For chemigation application of FL38 trial, half of each sample was taken from the plot area where the sprinkler spray overlapped and the other half was taken from areas where the spray did not overlap.

^a Mean value of residues was expressed in bold. Italic values mean residues from chemigation application using overhead mini-sprinklers.

^b FL 38 trials using backpack sprayer and mini-sprinkler were conducted at the same site with the same variety on the same dates of application. FL38 and FL 39 trials were conducted at the same site and soil type with the same variety, on 1st application 13 days apart. These trials were not considered as independent.

Stalk and stem vegetables

Artichoke, globe

Five trials were conducted in the USA (three trials) and Canada (two trials) during the 2009 and 2010 growing season. Spirotetramat 240 SC formulation was applied to artichoke as four foliar applications ranging from 0.13 to 0.15 kg ai/ha, with re-treatment intervals of 5 to 9 days, and the last application timed for a 3 ± 1 day PHI. The total seasonal application rate ranged from 0.56 kg ai/ha. A non-ionic surfactant was included at 0.25% in the spray mixtures and the spray volumes ranged from 92 to 708 L/ha. The artichoke samples were harvested 2 to 3 days after the final application. One decline trial was conducted, with artichoke samples harvested at 1, 3, 7 and 10 days after the last application, to assess the potential decline in residues over time.

Seed for beverages and sweets

Coffee beans

Spirotetramat is used to control green scale (*Coccus viridis*) in coffee production. Five field trials were conducted in Hawaii, USA during the 2009 growing season. In each trial, the test substance (spirotetramat 240 SC) was applied in three foliar directed applications of approximately 0.18–0.19 kg ai/ha each, for a total of approximately 0.54–0.57 kg ai/ha. An organosilicone surfactant was included in each tank mix and the spray volumes ranged from 240 to 470 L/ha.

The applications were made 20 to 22 days apart in HI09, HI10, and HI13 trials. The interval between the second and third application was shortened to 13 days and 7 days, respectively, in HI11 and HI12 because the beans were ripening earlier than expected. Ripe coffee bean “cherries” were collected 13 to 14 days after the final application in all but HI11, where samples were collected at 7 days HI11 because the crop was maturing faster than expected. Additional samples for decline determination were collected from HI13 at 1, 7, and 21 days.

At the field facility, the coffee bean cherries were run through a mechanical pulper and demulsilager to remove the flesh from the bean. The beans were then dried in an oven at 50 °C for up to 2 days, hulled, and winnowed. The green bean coffee samples from HI12 were further processed into roasted coffee beans and freeze-dried coffee at a processing facility.

^a Mean value of residues was expressed in bold. Analysed sample is green bean coffee.

^b Trials were conducted at the sites within 3 km with the same variety, 1st application 22 days apart. They were not considered as independent.

^c Interval between the second and third application was shortened due to an earlier ripening of coffee beans.

^d Harvested earlier due to the faster maturing of coffee beans.

FATE OF RESIDUES IN STORAGE AND PROCESSING+-

Magnitude of residue in processing

The Meeting received information on the residue levels on the processed products of pineapple and green bean coffee. They are summarized in Table 14.

Pineapple (juice and process residue)

One processing study for pineapple was carried out in Hawaii, USA (HI01, IR-4 PR No. 10635). The trial plot received two foliar broadcast applications with the test substance (spirotetramat 240 SC) 14 days apart. The application rates were in the range 0.17–0.18 kg ai/ha per application for a total rate range of 0.36 kg ai/ha per season. The spray solutions included adjuvant in the tank mix. The fruit samples were harvested one day after the last application.

Crowns were removed from the sampled fruit and the fruits without crown were processed into juice and process residue as follows. Both ends of the fruits were cut and peeled. The peeled fruit, scraped flesh from peels and end cuts were juiced using a commercial juicer. Juice and pulp were collected separately. Antifoam agent was added into the separated juice, mixed and heated in a water bath to 88 °C. The juice was cooled to 8 °C. For preparing process residue, the retained pineapple peels were chopped in a food cutter. Pulp left over from juicing was added and stirred to mix thoroughly. Juice and process residue samples were placed in the freezer until shipment to the residue laboratory.

From the results, processing factors for juice and process residue, based on total spirotetramat residues, could not be calculated as valid LOQ values at or below 0.01 mg/kg for enol glucoside were not provided.

Coffee beans (roasted coffee bean and freeze-dried coffee)

One processing study was conducted in Hawaii, USA (09-HI12, IR-4 PR No. 10041). Spirotetramat 240 SC formulation was applied in three foliar directed applications of approximately 0.18 kg ai/ha

each, for a total of approximately 0.54 kg ai/ha. An organosilicone surfactant was included in each tank mix. The applications were made 7 to 21 days apart and ripe coffee bean “cherries” were collected 14 days after the final application.

At the field facility, the coffee bean cherries were run through a mechanical pulper and demusilager to remove the flesh from the bean. The beans were then dried in an oven at 50 °C for up to 2 days, hulled, and winnowed. The green bean coffee (RAC) samples were further processed into roasted coffee beans and freeze-dried coffee at a processing facility.

The green beans were roasted to light to medium roast in the coffee roaster set at 208 °C. The roasted beans were thoroughly mixed and a portion was moved to freezer storage. The remaining roasted beans were ground fine in a small burr grinder, added to boiling water, steeped at least 10 minutes brewing (1600 g ground coffee per 10 litre water), and filtered. The filtered coffee extract was cooled in an ice water bath and then placed on a tray in a freezer set at approximately -50 °C and frozen overnight. The following day, the frozen coffee grounds were placed in a prepared freeze-dryer for 3 days (shelf temperature, 35 °C; vacuum chamber pressure, approximately 100 m Torr). Freeze-dried coffee samples were placed in frozen storage until shipment to the analytical laboratory.

No spirotetramat or spirotetramat equivalent residues were observed in coffee green bean (RAC), except spirotetramat enol, 0.011 mg/kg. However, this value is very close to the LOQ (< 0.01 mg/kg). Further, the high LOQ values for enol-Glc in roasted coffee bean and all analytes in freeze-dried coffee made an estimation of processing factors for total spirotetramat residues impossible.

Table 14 Residues on pineapple and coffee processed fractions from the foliar application of spirotetramat (IR-4 PR No. 10635, IR-4 PR No. 10041)

^a The analytical method performance was not acceptable due to high recoveries.

APPRAISAL

Spirotetramat was evaluated for the first time by the JMPR in 2008 for toxicology and residues. The Meeting derived an ADI of 0–0.05 mg/kg bw and an ARfD of 1.0 mg/kg bw and recommended

maximum residue levels for a range of crops. In 2011 and 2012, the JMPR recommended additional maximum residue levels. The residue is defined as follows.

For compliance with the MRL for plant commodities: *spirotetramat plus spirotetramat enol, expressed as spirotetramat*.

For dietary intake estimation for plant commodities: *spirotetramat plus the metabolites enol, ketohydroxy, enol glucoside, and monohydroxy, expressed as spirotetramat*.

For compliance with the MRL and for dietary intake estimation for animal commodities: *spirotetramat enol, expressed as spirotetramat*.

The residue is not fat soluble.

The present Meeting evaluated supervised field trial data for various crops including their analytical methods, stability of frozen sample and stability tests, and processing studies.

Methods of analysis

Analytical methods used in raw agricultural commodities from field trials were suitable for quantifying spirotetramat residues including the metabolites spirotetramat enol, spirotetramat ketohydroxy, spirotetramat monohydroxy and spirotetramat enol glucoside in the various plant commodities. The methods were based on LC-MS/MS and the reference method used was evaluated by the Meeting in 2008 and 2011. The limits of quantitation for the raw commodities are 0.01 mg/kg (parent equivalents) for each analyte and 0.05 mg/kg for total spirotetramat equivalents.

For the processed products of pineapple and coffee bean, overall, the method performance was not acceptable. In pineapple juice and processing by-products, average recoveries of enol glucoside (0.01 mg/kg as parent equivalents) were not in the allowable range.

In roasted coffee bean, a limit of quantitation for enol glucoside was as high as 0.05 mg/kg. For freeze-dried coffee, the LOQ levels for spirotetramat enol, -ketohydroxy and - monohydroxy were 0.1 mg/kg, i.e., the fortification levels were not sufficiently low enough, further, some recoveries of parent and enol glucoside at the indicated LOQ level were outside the acceptable range, as a result the method performance was not considered satisfactory.

Stability of residues in stored analytical samples

Storage stability studies were performed with banana with peel, peeled banana, green coffee bean, roasted coffee bean and freeze-dried coffee. They indicated that the residues were stable during the frozen storage intervals of field trial samples. Stabilities of residues in commodities not assessed by the present Meeting are covered by the storage stability data evaluated by the 2008 JMPR, which demonstrated stability of all analytes for up to 2 years for a diverse range of commodities.

Results of supervised residue trials on crops

The Meeting received supervised residue trial data for the foliar application of spirotetramat as a suspension concentrate formulation (SC) to a variety of crops, i.e., blueberries, cranberry, banana, pineapple, pomegranate, blub onion, spring onion, watercress, globe artichoke and coffee.

In the discussions below, spirotetramat plus enol residues considered first for the estimation of maximum residue levels followed by total residues (spirotetramat plus the metabolites enol, ketohydroxy, monohydroxy, and enol glucoside, expressed as spirotetramat) for estimation of STMR and HR values for the dietary risk assessments.

Berries and other small fruits

Blueberries

In Canada, spirotetramat is registered at a rate of 0.20 kg ai/ha, a 7-day retreatment interval, a total seasonal rate of 0.44 kg, and a 7-day PHI. Eleven residue trials were conducted in the USA (7) and

Canada (4) with three applications at a rate of 0.17–0.19 kg ai/ha, total seasonal rate of 0.52–0.56 kg ai/ha, 5–8 days retreatment intervals and 6–8 days PHIs. Of the trials, two were not considered independent as they were conducted at the same site, with the same variety at very close dates of application.

Residues of spirotetramat plus enol from the trials were (n=10): 0.14, 0.17, 0.21, 0.31, 0.37, 0.39, 0.53, 0.53, 0.68 and 0.69 mg/kg.

Total residues of spirotetramat from the trials were (n=10): 0.38, 0.44, 0.45, 0.49, 0.60, 0.66, 0.69, 1.1, 1.2 and 1.6 mg/kg.

The Meeting estimated a maximum residue level of 1.5 mg/kg and an STMR of 0.63 mg/kg and an HR of 1.6 mg/kg for bush berries as blueberry is a representative crop of the subgroup.

Cranberry

In Canada, spirotetramat is registered for the use on cranberry at a rate of 0.20 kg ai/ha, a 7-day retreatment interval, a total seasonal rate of 0.44 kg, and a 7-day PHI. Six residue trials were conducted in the USA and Canada with three applications at a rate of 0.17–0.19 kg ai/ha, total seasonal rate of 0.52–0.55 kg ai/ha, 6–8 days retreatment intervals and 7–8 days PHIs, approximating the Canadian GAP.

Residues of spirotetramat plus enol from the trials were (n=6): < 0.02, 0.023, 0.025, 0.046, 0.058 and 0.12 mg/kg.

Total residues of spirotetramat from the trials were (n=6): < 0.05, 0.054, 0.055, 0.076, 0.088 and 0.15 mg/kg.

The Meeting estimated a maximum residue level of 0.2 mg/kg and an STMR of 0.066 mg/kg and an HR of 0.15 mg/kg for cranberry.

Assorted tropical and sub-tropical fruits-inedible peel

Banana

Five residue trials were conducted using five applications in Hawaii, USA, according to the USA GAP (rate of 0.28 kg ai/ha, 14-day retreatment interval, total seasonal rate of 1.4 kg ai/ha, and 1-day PHI). In one trial, application was made on bagged banana. For the other four trials, banana bunches were not bagged, however, residues in pulp were not analysed, except one trial.

From the trials, residues of spirotetramat plus enol in unbagged whole banana were (n=4): 0.16 0.55, 1.0, 1.4 and 1.7 mg/kg.

From the trials, total residues of spirotetramat in unbagged whole banana were (n=4): 0.2, 0.62, 1.2, 1.4 and 1.8 mg/kg.

In the one trial, residues in pulp were 0.14 mg/kg (0.55 mg/kg for whole) for spirotetramat plus enol and 0.19 mg/kg (0.62 mg/kg for whole) for total spirotetramat.

The Meeting could not estimate a maximum residue level for banana as the number of trials was considered insufficient.

Pineapple

Five trials were conducted in Hawaii, USA with two applications, according to the USA GAP (rate of 0.18 kg ai/ha, 14-day retreatment interval, total seasonal rate of 0.36 kg ai/ha, and 1-day PHI). In these trials the preparation of samples did not comply with the relevant FAO guidelines, i.e., samples underwent cutting/quarterming at the field site.

As the handling of samples did not comply with the relevant FAO guidelines on sample preparation, the Meeting decided that residue data could not be used for the estimation of a maximum residue level.

Pomegranate

Four trials were conducted in the USA with two applications, complying with the GAP of the USA (rate of 0.18 kg ai/ha, 14-day retreatment interval, 0.36 kg ai/ha/12-month, and a 1-day PHI). In these trials the preparation of samples did not comply with the relevant FAO guidelines, i.e., samples underwent cutting/quartering at the field site. As a result the residue data could not be used in estimating a maximum residue level.

*Bulb vegetables,**Onion, bulb*

Twelve trials were performed in Canada and USA with two applications, according to the USA GAP (rate of 0.09 kg ai/ha, 7-day retreatment interval, total seasonal rate of 0.18 kg ai/ha, and 3-day PHI). Two trials were not independent as they were conducted at the same site with the same variety with the same dates of application.

Residues of spirotetramat plus enol from the trials were (n=11): < 0.02, < 0.02, < 0.02, 0.026, 0.046, 0.051, 0.057, 0.058, 0.075, 0.095 and 0.28 mg/kg.

Total residues of spirotetramat from the trials were (n=11): < 0.05, < 0.05, < 0.05, 0.056, 0.076, 0.081, 0.087, 0.088, 0.11, 0.13 and 0.32 mg/kg.

Based on the residue values, the Meeting estimated a maximum residue level of 0.4 mg/kg.

The 2011 JMPR recommended a maximum residue level of 0.4 mg/kg, an STMR of 0.11 mg/kg and an HR of 0.27 mg/kg, based on the residues from trials in Australia matching GAP (2 applications at 0.048 kg ai/ha with a PHI of 7 days).

The Meeting therefore confirmed its previous maximum residue level recommendation of 0.4 mg/kg for onion, bulb.

Spring onion

Two trials were performed in Canada with two applications, matching the USA GAP (rate of 0.09 kg ai/ha, 7-day retreatment interval, total seasonal rate of 0.18 kg ai/ha, and 7-day PHI). The residues were 0.093 and 0.24 mg/kg as spirotetramat plus enol, 0.16 and 0.32 mg/kg as total residues.

The Meeting considered the number of trials insufficient to estimate a maximum residue level.

Watercress

Three trials were performed in the USA with two applications, according to GAP of the country (rate of 0.22 kg ai/ha, 7-day retreatment interval, total seasonal rate of 0.45 kg ai/ha, and 3-day PHI).

Two trials were not independent as they were conducted at the same site with the same variety, with dates of application 13 days apart. In addition, in one trial, two methods of application were utilized, i.e., using a backpack sprayer and overhead mini-sprinkler in a separate plot. These treatments were considered replicates of the trial. As a result one residue value was selected from each of the trials.

Residues from the trials were 0.26 and 0.32 mg/kg for spirotetramat plus enol, 0.51 and 0.56 mg/kg for total residues. The Meeting could not estimate a maximum residue level due to insufficient residue data.

The Meeting noted that the residues from the trials were covered by the previously recommended maximum residue level for leafy vegetables.

Artichoke, globe

Five trials were conducted in Canada and the USA with four applications, according to the USA GAP (rate of 0.15 kg ai/ha, 7-day retreatment interval, total seasonal rate of 0.56 kg ai/ha, and 3-day PHI).

Residues of spirotetramat plus enol from the trials were (n=5): 0.13, 0.20, 0.27, 0.47 and 0.49 mg/kg.

Total residues of spirotetramat from the trials were (n=5): 0.23, 0.34, 0.41, 0.60 and 0.70 mg/kg.

The Meeting estimated a maximum residue level of 1 mg/kg and an STMR of 0.41 mg/kg and an HR of 0.70 mg/kg for artichoke, globe.

Coffee beans

Five trials were conducted in Hawaii, USA with three applications, according to the GAP of that country (rate of 0.18 kg ai/ha, 21-day retreatment interval, total seasonal rate of 0.53 kg ai/ha, and 14-day PHI). Exceptionally, in one trial, a retreatment interval between the second and third application was 7 days due to an earlier ripening of coffee beans. The Meeting considered such a divergence from GAP would have little impact on the final residue level. Two trials were not considered independent as they were carried out at geographically close sites on the same variety within the same growing season.

Residues of spirotetramat plus enol from the four trials available were: 0.020, 0.028, 0.031 and 0.038 mg/kg; and 0.050, 0.059, 0.062 and 0.072 mg/kg for total residues of spirotetramat.

The Meeting considered the number of trials insufficient to estimate a maximum residue level.

Animal feeds

Residue information on animal feeds was not available for this Meeting.

Fate of residues during processing

One processing study for pineapple juice and pineapples processing by-products, roasted coffee bean and freeze-dried coffee were made available. However, the estimation of processing factors was not required as maximum residue levels could not be recommended for pineapple and coffee beans.

Residues in animal commodities

From the evaluations by the present Meeting, no feed items were added to the feed list evaluated by the 2011 JMPR. The Meeting retained the residue levels for animal commodities estimated by the 2011 and 2012 JMPR.

RECOMMENDATIONS

On the basis of the data from supervised trials, the Meeting concluded that the residue concentrations listed below are suitable for establishing MRLs and for assessing IEDIs and IESTIs.

Definition of the residue (for compliance with MRL for plant commodities: Spirotetramat and its enol metabolite, 3-(2,5-dimethylphenyl)-4-hydroxy-8-methoxy-1-azaspiro[4.5]dec-3-en-2-one, expressed as spirotetramat.

Definition of the residue (for estimation of dietary intake)for plant commodities: Spirotetramat, enol metabolite 3-(2,5-dimethylphenyl)-4-hydroxy-8-methoxy-1-azaspiro[4.5]dec-3-en-2-one, ketohydroxy metabolite 3-(2,5-dimethylphenyl)-3-hydroxy-8-methoxy-1-azaspiro[4.5]decane-2,4-dione, monohydroxy metabolite cis-3-(2,5-dimethylphenyl)-4-hydroxy-8-

methoxy-1-azaspiro[4.5]decan-2-one, and enol glucoside metabolite glucoside of 3-(2,5-dimethylphenyl)-4-hydroxy-8-methoxy-1-azaspiro[4.5]dec-3-en-2-one, expressed as spirotetramat.

Definition of the residue (for compliance with MRL and estimation of dietary intake) for animal commodities: Spirotetramat enol metabolite, 3-(2,5-dimethylphenyl)-4-hydroxy-8-methoxy-1-azaspiro[4.5]dec-3-en-2-one, expressed as spirotetramat.

The residue is not fat-soluble.

CCN	Commodity	Recommended MRL mg/kg		STMR or STMR-P mg/kg	HR or HR-P mg/kg
		New	Previous		
VS 0620	Artichoke, globe	1		0.41	0.70
FB 2006	Bush berries	1.5		0.63	1.6
FB 0265	Cranberry	0.2		0.066	0.15

DIETARY RISK ASSESSMENT

Long-term intake

The ADI for spirotetramat is 0–0.05 mg/kg bw. The International Estimated Daily Intakes (IEDIs) for spirotetramat were estimated for the 13 GEMS/Food Consumption Cluster Diets using the STMR or STMR-P values estimated by the previous and present JMPR. The results are shown in Annex 3 of the 2013 Report. The IEDIs ranged 2–20% of the maximum ADI. The Meeting concluded that the long-term intake of residues of spirotetramat from uses considered by the JMPR is unlikely to present a public health concern.

Short-term intake

The ARfD for spirotetramat is 1.0 mg/kg bw. The International Estimate Short Term Intakes (IESTIs) for difenoconazole were calculated for the food commodities for which STMRs or HRs were estimated by the present Meeting and for which consumption data were available. The results are shown in Annex 4 of the 2013 Report. The IESTIs varied from 0–2% of the ARfD for children and 0–1% for general population.

The Meeting concluded that the short-term intake of residues of spirotetramat from other uses that have been considered by the present Meeting is unlikely to present a public health concern.

TOLFENPYRAD (269)*First draft was prepared by Prof. Dr. Árpád Ambrus**National Food Chain Safety Office, Hungary***EXPLANATION**

Tolfenpyrad is a broad spectrum pyrazole class insecticide and a miticide, with contact activity against target pests on eggs, larvae, nymphs and adults. It also has anti-feeding activity on larvae of lepidopteran insects. It has activity against several economically important insect pests of vegetables, fruits, nuts, vines and row crops.

At the Forty-fourth Session of the CCPR (2012), it was scheduled for toxicological and residue evaluation as a new compound by 2013 JMPR.

The residue studies were submitted by the manufacturers to support the following commodities: almonds, cantaloupes, cauliflowers, cherries, cucumbers, cotton seed, grapes (table), grapefruits, lemons, oranges, peaches, pears, pecans, peppers, plums, potatoes, summer squash, tea and tomatoes.

IDENTITY

ISO common name: tolfenpyrad

IUPAC name: 4-chloro-3-ethyl-1-methyl-N-[4-(p-tolyloxy)benzyl]pyrazole-5-carboxamide

Chemical Abstract name: 4-chloro-3-ethyl-1-methyl-N-[[4-(4-methylphenoxy)phenyl]methyl]-1H-pyrazole-5-carboxamide

CAS No.: 129558-76-5

Synonyms: OMI-88

Molecular Formula: C₂₁H₂₂ClN₃O₂

Structural Formula: 

Molecular Weight: 383.9

Formulation

Tolfenpyrad is formulated as a 15% SC and a 15% EC.

METABOLISM AND ENVIRONMENTAL FATE

Metabolism and fate studies in livestock, agriculture crops and soil were carried out with pyrazol-¹⁴C tolfenpyrad.

And [tolyl ring-U-¹⁴C] tolfenpyrad.

The codes, chemical names and structure of metabolites and the matrices in which they were found are given in Table 1.

Table 1 Metabolites of tolfenpyrad in animal, plant, soil and water/sediment

Code Name	Chemical name	Structure	Matrices
Tolfenpyrad (OMI-88)	4-chloro-3-ethyl-1-methyl-N-[4-(<i>p</i> -toloxy)benzyl]pyrazole-5-carboxamide		Active ingredient

CA-T-NH ₂	4-[4-(aminomethyl)phenoxy]benzoic acid		photodecomposition
T-AM	[4-(<i>p</i> -tolxyloxy)benzamide		plant
OH-T-AM	4-[4-(hydroxymethyl)phenoxy] benzamide		plant
CA-T-AM	4-(4-carbamoylphenoxy)benzoic acid		plant
T-CA	4-(<i>p</i> -tolxyloxy)benzoic acid		rat, plant
OH-T-OH	<i>bis</i> [4-(hydroxymethyl)phenyl]ether		plant
OH-T-CA	4-[4-(hydroxymethyl)phenoxy] benzoic acid		rat, plant
CA-T-CA	4,4'-oxydibenzoic acid		rat, plant
T-CA-Glu	glucose conjugate of 4-(<i>p</i> -tolxyloxy) benzoic acid		plant

Animal metabolism

The Meeting received information on the fate of [¹⁴C] tolfenpyrad in lactating goats and laying hens. Metabolism in laboratory animals are summarized and evaluated by the WHO panel of the present JMPR.

Lactating goats

[Pyrazole-¹⁴C]-tolfenpyrad and [tolyl-¹⁴C]-tolfenpyrad were administered orally (in gelatine capsules) to two lactating goats of 51–53 kg (one for each label) once daily for five consecutive days (Quistad, GB, Kovatchev, A, 2007b, Report no. R-10160). The administered daily dose was 12.3–12.5 mg/kg feed/day. Milk was collected twice daily and excreta were collected once daily. Goats were sacrificed approximately 21–22 hours after the last dose administration and samples of muscle, liver, kidney, fat, bile and gastrointestinal tracts with contents were collected for analysis.

Milk samples were extracted with ethyl acetate and portions of the combined extracts were cleaned up on a silica gel column for removal of fat. Each sample extract aliquot (1–2 g) was loaded in hexane on a 2-g silica gel SPE column that was eluted with hexane / ethyl acetate (9:1, 10 mL, then 5:1, 10 mL), ethyl acetate (10 mL), and methanol (10 mL). Milk samples with highest residues for each radiolabel were used for TLC analysis. Additional subsamples of milk (about 2 mL each) were added to scintillation cocktail for determination of the TRR.

Sample aliquots of muscle, liver and kidney were extracted twice with acetonitrile / water and once with acetonitrile by high speed homogenisation. The post extraction solids (PES) were separated by centrifugation. The clear water / acetonitrile extracts were evaporated for analysis by HPLC and TLC. The post extraction solid (PES) (except tolyl-label in kidney) was treated with 24% KOH, acidified, and partitioned into ethyl acetate. The ethyl acetate extract was analysed by LSC (muscle) and HPLC (liver and kidney). For the pyrazole-treated liver and kidney, 24% KOH treatment was preceded by treatment with 0.1 M KOH and 1.0 M KOH.

Fat samples were extracted by shaking the fat/solvent mixtures on a wrist-action shaker and the solids were separated by centrifugation. The fat was extracted sequentially twice with acetone / hexane and once with acetone. The TRR of each extract was determined by LSC. A representative composite was made of all three extracts and aliquots were evaporated to dryness and reconstituted in hexane. This sample was cleaned up by silica gel SPE eluted with hexane / ethyl acetate and ethyl acetate. The ethyl acetate fraction was subjected to TLC (pyrazole) or HPLC analysis.

Tissues including gastrointestinal tracts were homogenised in the presence of dry ice. For determination of the total radioactive residue (TRR) by liquid scintillation counting (LSC), tissues (liver, kidney, muscle and fat) were solubilised with Soluene™ tissue solubiliser and aliquots of milk were directly mixed with scintillation cocktail. Samples of faeces and gastrointestinal tract were analysed after combustion.

All samples were analysed within 51 days.

Total residue

The total recovery of radiolabel was 76.1% and 96.3% of the administered dose for the pyrazole-label and tolyl-label, respectively. Most of the administered dose (66.4% for the pyrazole-label and 82.7% for the tolyl-label) was recovered in the excreta and gastrointestinal tracts at sacrifice (Table 2).

Of the total administered dose 3.48% and 5.93% were excreted in urine and 43.3% and 43.9% in faeces for pyrazole and tolyl labelled compounds, respectively.

Characterisation of residues

In milk

Two milk samples with the highest concentrations for each radiolabel were selected for characterisation of the radioactive residues by TLC on silica gel. Most of the radioactivity (95 and 97%) was extracted (Table 4).

Table 4 Characterisation and identification of radioactive residues in milk

Fraction /metabolite	Pyrazole-labelled tolfenpyrad		Tolyl-labelled tolfenpyrad

Proposed metabolic/degradation pathway

Tolfenpyrad is oxidized at the tolyl-methyl group to PT-CA. Further oxidation at the pyrazole ethyl group of PT-CA produces OH-PT-CA. Both PT-CA and OH-PT-CA occur as free metabolites in milk, liver, kidney, and muscle. PT-CA and its hydrolysis metabolites (PCA and CA-T-NH₂) are converted into nonpolar lipids in milk and fat. Saponification of the lipid conjugates releases PT-CA, PCA, and CA-T-NH₂. The metabolic pathway for tolfenpyrad in goats is shown in Figure 1.

Figure 1 Proposed metabolic pathway of active substance in lactating goat

Laying hens

[Pyrazole-¹⁴C]-tolfenpyrad and [tolyl-¹⁴C]-tolfenpyrad were administered orally in gelatine capsules to two separate groups of hens comprised of 10 birds each once daily for seven consecutive days (Quistad, GB, Kovatchev, A, 2007b Report no. R-10161). The administered daily dose was 12.6–13.5 mg/kg feed/day. Eggs were collected twice daily and excreta were collected once daily. Hens were sacrificed approximately 22–23 hours after the last dose administration, and liver, muscle, fat and gastrointestinal tracts with contents were collected for analysis.

Tissues including gastrointestinal tracts were homogenised in the presence of dry ice. For determination of the total radioactive residue by liquid scintillation counting (LSC), tissues (liver, egg, muscle and fat) were solubilised with Soluene™ tissue solubiliser. Samples of faeces and gastrointestinal tract were analysed after combustion. The results are shown in Table 9.

Characterisation and identification of residues

Eggs were extracted sequentially with acetonitrile/water, acetonitrile and ethyl acetate. The PES was extracted with ethyl acetate (2 × 50 mL). All extracts were combined. For removal of fat, an aliquot was cleaned up by a silica column by elution with ethyl acetate and methanol. All fractions were evaporated to dryness and reconstituted in acetonitrile for TLC and HPLC analysis. A portion of the ethyl acetate fraction was evaporated to dryness and lipid conjugates were hydrolysed with 24% KOH. After acidification and partitioning into ethyl acetate, released acids were analysed by HPLC.

Muscle and liver were extracted with acetonitrile / water and acetonitrile. The post extraction solids (PES) were removed by centrifugation. The acetonitrile / water extracts were concentrated by rotary evaporation and analysed by HPLC and TLC. The remaining PES were weighed and their radioactive residues determined. The PES from liver was also treated with 24% KOH, acidified, and partitioned into ethyl acetate. The ethyl acetate extract was analysed by HPLC. For liver and muscle, the acetonitrile / water extracts were analysed by TLC and HPLC, the ethyl acetate fractions resulting from the partitioning of the alkaline extraction of the PES were analysed by HPLC.

Fat samples were extracted with acetone / hexane and acetone and the PES was separated by centrifugation. The four extracts were combined and the radioactive residue determined by LSC. A composite of the extracts was cleaned-up on silica gel SPE by elution with hexane / ethyl acetate, ethyl acetate and methanol. A portion of the ethyl acetate fraction was also saponified with 24% KOH. The hexane / ethyl acetate, ethyl acetate and methanol fractions eluting from the SPE clean-up were analysed by TLC.

All samples were analysed within 53 days

Two egg samples with the highest concentrations for each radiolabel (Day 8 AM for pyrazole-label, Day 6 PM for tolyl-label) were selected for characterisation of the radioactive residues. The characterisation of tolfenpyrad residues in eggs is summarized in Table 12.

The metabolic pathway for tolfenpyrad in hens is shown in Figure 2.

Figure 2 Proposed metabolic pathway of tolfenpyrad in poultry

Plant metabolism

Metabolism studies were carried out on cabbages, peaches and radishes applying tolyl and pyrazole ring labelled tolfenpyrad.

Cabbage

[Tolyl-¹⁴C]-tolfenpyrad was applied to individual cabbage plants in separate pots in a spray chamber (Ogawa, K and Koyama, T, 2000a Report no. R-10001). One application was made at a rate of 15 mg ai/m² plant surface corresponding to 750 g ai/ha.

Single cabbages in separate pots were sampled immediately after drying of the test formulation, and after 7, 14 and 28 days of application. The head and outer leaves of each cabbage were weighed and then subjected to analysis.

Each plant part (outer leaves and head) was cut into pieces and extracted with methanol by high-speed homogenisation. The homogenate was partitioned into the organo-soluble (OS), water-soluble (WS) and unextractable (PES) fractions. The WS fraction was diluted 1/10 with acetonitrile and partitioned into the acetonitrile-soluble (WS/OS) and aqueous (WS/WS) fractions.

TRRs in the soluble fractions were directly analysed by LSC, the PES was analysed by LSC after combustion. The distribution of tolfenpyrad equivalents in each plant part was calculated.

Organo-soluble (OS) and acetonitrile-soluble (WS/OS) extracts were analysed by HPLC with β -radiation detector or UV detection using the available reference standards for co-chromatography. The polar metabolites were analysed after acid hydrolysis treatment and β -glucosidation. Portions of the sample solutions were analysed after methylation with diazomethane or acetylation with acetic anhydride.

The samples were analysed within approximately seven months, nonetheless no storage stability test was carried out.

The TRRs found at different times after application are shown in Tables 16–17.

Study 2

In the second study [pyrazole-¹⁴C]-tolfenpyrad was applied once to individual cabbage plants, at the head formation stage, in separate pots in a spray chamber at a rate of 15 mg ai/m² plant surface corresponding to 750 g ai/ha (Ogawa, K 1999c, Report no. R-10002). Cabbage samples were collected on one occasion, 28 days after application. Head and outer leaves were collected; each part was weighed and then subjected to analysis.

Each plant part (outer leaves and head) was cut into pieces and extracted with methanol by high-speed homogenisation. The homogenate was partitioned into the organosoluble (OS), water-soluble (WS) and unextractable (PES) fractions. The WS fraction was partitioned into acetonitrile resulting in an organosoluble (WS/OS) and an aqueous (WS/WS) fraction.

Chlorophyll was removed from the organosoluble (OS) fraction by coagulation with an aqueous ammonium chloride / phosphoric acid solution. After removal of chlorophyll, radioactive residues were extracted with ethyl acetate.

TRRs in the soluble fractions were directly analysed by LSC, the PES was analysed by LSC after combustion. The distribution of tolfenpyrad equivalents in each plant part was calculated.

Organosoluble (OS) and acetonitrile-soluble (WS/OS) extracts were analysed by HPLC with β radiation detection or UV detection using the available reference standards for co-chromatography.

The polar metabolites were analysed after acid hydrolysis treatment. Portions of the sample solutions were analysed after methylation with diazomethane and acetylation with acetic anhydride.

All samples were analysed within 6 months of sampling. Of the 33 metabolites detected 19 compounds were consistent with authentic reference standards based on HPLC retention times and GC/MS analysis. The others were estimated based on their relative retention time. The results are summarized in Tables 20–22.

Peach

Study 1

[Tolyl-¹⁴C]-tolfenpyrad was applied to individual peach plants in separate pots in a spray chamber. One application was made at a rate corresponding to 750 g ai/ha (Ogawa, K and Koyama, T 2000b Report no. R-10003). Four peach plants were treated for use in the metabolism study. One branch with one fruit was treated from each plant. A fifth plant was treated by direct application on the leaves for examination of translocation in the leaves by autoradiography.

Leaves stem and the fruit of the treated branch of the plant were collected on four occasions following application; immediately after treatment and then 14, 28 and 56 days after treatment. Untreated leaves were also collected on the latter three occasions. The fruit collected 56 DAT was divided into peel, pulp and stone. After collection, each part was weighed and then subjected to analysis.

Each plant part (leaves, stem and whole fruit) and processed fraction of the fruit (peel, pulp and stone) was cut into pieces and extracted with methanol by high-speed homogenisation. The homogenate was partitioned into the organo-soluble (OS), water-soluble (WS) and unextractable (PES) fractions. The WS fraction was diluted 1/10 with acetonitrile and partitioned into the acetonitrile-soluble (WS/OS) and aqueous (WS/WS) fractions.

TRRs in the soluble fractions were directly analysed by LSC, the post extraction solid (PES) was analysed by LSC after combustion. The distribution of tolfenpyrad equivalents in each plant part was calculated.

Organo-soluble (OS) and acetonitrile-soluble (WS/OS) extracts were analysed by HPLC with β radiation detection. Analysis of unidentified and overlapping signals was enhanced by derivatization of functional groups by methylation with diazomethane or acetylation with acetic anhydride and subsequent analysis by HPLC. Identification was performed by comparing the HPLC chromatograms obtained with β radiation scanner and with UV detection using the available reference standards for co-chromatography. Some fractions containing polar metabolites were analysed after acid hydrolysis treatment and β -glucosidation. Portions of the sample solutions were analysed after methylation with diazomethane or acetylation with acetic anhydride.

Structural identification of main metabolites was performed by GC/MS.

Samples were analysed within 95 days.

The results of the analyses are summarized in Tables 23–28.

Study 2

In the second study [pyrazole-¹⁴C]-tolfenpyrad was applied to individual peach plants in separate pots in a spray chamber. One application was made at a rate corresponding to 750 g ai/ha (Ogawa, K 1999d, Report no. R-10004). Treated leaves and stem of the treated branch were collected 56 days after treatment. The treated fruit was collected at day 53 and divided into peel, pulp and stone. After collection, each part was weighed and then subjected to analysis. The analytical procedures were practically the same as described under the study with ¹⁴C-tolyl-tolfenpyrad. All samples were analysed within 6 months after sampling. The results are summarized in Tables 29–32.

In total 25 metabolite signals together with unchanged tolfenpyrad were detected in peaches (leaves, stem and fruits). Nine of them were identified by co-chromatography with reference standards. After β -glucosidation, one metabolite was identified to be a glucose conjugate of PT-CA. (Tables 33–35).

Radish

[Tolyl- ^{14}C]-tolfenpyrad or [pyrazole- ^{14}C]-tolfenpyrad were applied to separate plots of radishes located outdoors. Each plot received two applications, 14 days apart, at a nominal rate of 230 g ai/ha (Quistad, GB and Kovatchev, A 2008, Report no. R-10172

Samples of radish foliage and root were harvested at maturity, 1 day after last application. Mature radishes were pulled from the soil and the loose soil was removed. The tops were cut from the roots and the tap root and remaining top was snapped off.

Samples were transferred under deep frozen conditions to the analytical laboratory, where they were blended in the presence of dry ice. After sublimation of the dry ice, processed samples were stored in plastic bags under frozen conditions.

The pre-homogenised processed sample (20 g) was weighed into a centrifuge bottle. The sample was extracted twice with 80 mL of acetonitrile each by shaking on a wrist-action shaker for 20 minutes. Samples of radish foliage and root were harvested at maturity, 1 day after last application. Mature radishes were pulled from the soil and the loose soil was removed. The tops were cut from the roots and the tap root and remaining top was snapped off.

Samples were transferred under deep frozen conditions to the analytical laboratory, where they were blended in the presence of dry ice. After sublimation of the dry ice, processed samples were stored in plastic bags under frozen conditions. The sample was centrifuged, the supernatant was separated and, after combination of the extracts, an aliquot was taken for liquid scintillation counting (LSC). Extraction of the PES was repeated twice using 80 mL of acetonitrile/hydrochloric acid 0.2 M (1/1; v/v) and an aliquot was taken for LSC as mentioned above. Finally, the PES was extracted once using 80 mL of acetonitrile/KOH 0.2 M (1/1; v/v) and once with 80 mL of KOH (24% in water) by shaking and centrifugation as mentioned above.

For determination of soluble residues by HPLC or TLC all fractions obtained so far were combined using representative portions of each extract. Combined extracts were concentrated. For certain samples e.g. radish roots, a clean-up over silica gel SPE was performed. Extracts were analysed by TLC and/or HPLC using the available reference standards for co-chromatography. The presence of known metabolites was confirmed by TLC.

The samples were analysed within 62 days.

Table 36 Distribution of total radioactive residues (TRRs) in radish following two applications of [^{14}C] tolfenpyrad

Crop part	Pyrazole-label				Tolyl-label			
	by combustion		sum of fractions		by combustion		sum of fractions	
	mg/kg	%TRR	mg/kg	%TRR	mg/kg	%TRR	mg/kg	%TRR
Radish root	0.44	4.9	0.44	5.9	0.59	5.2	0.53	4.6
Radish foliage	8.58	95.1	6.96	94.1	10.77	94.8	10.95	95.4

Extraction with acetonitrile removed 79.7–90.0% of the TRR and acetonitrile/0.2 M HCl (1:1) removed an additional 8.3–12.9%. After further alkaline extraction with acetonitrile/0.2 M KOH (1:1) and 24% KOH that removed in total 1.1–4.6%, the post extraction solids (PES) contained only 0.6–2.9% of the TRR.

Table 37 Identification of metabolites in radish (root and foliage)

Metabolite	Foliage (HPLC)				Root (TLC)

^a The maximum of any other single metabolite was 0.03 mg/kg, 5.9% of TRR.

The metabolic pathways of tolfenpyrad in three different crops were essentially the same (Figure 3) and the metabolism of tolfenpyrad in all three crops is considered comparable.

Figure 3 Main metabolic pathways of tolfenpyrad in plants

Environmental fate in Soil and Water

The Meeting received information on photolysis on soil, aerobic degradation in soil, aqueous photolysis and confined and field rotational crop studies.

Soil photolysis

A photolysis study of [^{14}C] tolfenpyrad was conducted on a viable sandy loam soil from California (Ponte, M, 2008b. report no. E-10008). Artificial light (xenon lamp equipped with a UV filter at 290 nm) was applied continuously for 13 days (equivalent to 32 days of alternating day/night exposure) to the test substance. The soil was sieved through 2 mm sieve, placed in quartz containers of 50 mm diameter and treated at approximately double field rate (28.8 $\mu\text{g/g}$ soil). The temperature was maintained at $25 \pm 2^\circ\text{C}$. The samples were sealed and purged continuously with a gentle flow of sterile moisturised air into a series of traps including ethylene glycol and two 10% aqueous NaOH solutions. Samples were collected at time 0 and following approximately 2, 3, 4, 6, 9 and 13 days exposure. Concurrent dark control samples were maintained under equivalent conditions.

The soils were extracted with acetonitrile /0.01 M HCl (4:1). The extracts were analysed with HPLC and TLC, and the residual soil was combusted. The radiocarbon was quantified with LSC.

Half-life of tolfenpyrad was calculated based on its percent present in the soil extracts at each sampling interval, using pseudo-first order kinetics.

Aerobic soil metabolism

An aerobic soil metabolism study was conducted on a California sandy loam soil using [¹⁴C] tolfenpyrad (Ponte, M 2008, report no. E-10010). Approximately 50.55 g of the soil (50.00 g dry weight equivalent) were weighed into 120 mL amber bottles, deionized water was added to the soils to achieve 75% ± 10% field moisture capacity (FMC) at 1/3 bar, then the bottles were capped and placed in the Hotpack constant temperature chamber and pre-incubated at 25 ± 1 °C with a CO₂-free air flow for approximately 2–3 weeks prior to dosing. Individual samples were treated with pyrazole- and tolyl labelled [¹⁴C] tolfenpyrad at 0.681 mg/kg soil and 0.662 mg/kg soil, respectively. The bottles of treated soil were connected to the trapping system and maintained at 25 ± 1 °C and incubated in the dark at 25 °C for periods up to 365 days. All samples were aerated/ trapped continuously during the incubation period. Samples were collected immediately after treatment (time 0) and after 1, 2, 3, 8, 14, 21, 30, 63, 90, 181, and 365 days of exposure.

At sampling, the total soil sample weight was recorded, and the soil sample was transferred to a pre-weighed 250 mL centrifuge bottle. An aliquot (100 mL) of the extraction solvent (acetonitrile:0.01 M HCl, 4:1 v/v) was added to the bottle, with some of the solvent used to rinse the original sample container. The samples were placed on a Wrist-Action shaker for 60 minutes followed by centrifugation for 10 minutes at 2500 rpm. The supernatant soil extract was decanted and the extraction repeated twice more with fresh aliquots (75 mL) of extraction solvent. The soil extracts were combined, the total volume was measured and aliquots (3 × 1 mL) were taken for radio-assay.

For HPLC analysis an aliquot of soil extract was evaporated under nitrogen to remove acetonitrile.

All samples were extracted on the same day of collection, and initial HPLC analysis was performed within 48 hours of collection.

Confined Rotational Crop Studies

Study 1

A confined rotational crop study was conducted in Porterville, California, USA, in 2006–2008 (Quistad, GB, Kovatchev, A and Hilter, RL 2008) applying pyrazole [¹⁴C] tolfenpyrad and tolyl [¹⁴C]

tolfenpyrad evenly on bare sandy loam soil at a nominal rate of 350 g ai/ha, using an SC formulation containing 15% tolfenpyrad. There were eight treated test plot boxes of 1 m² each created for this study, four for each label. Lettuce, radish and wheat were planted at intervals of 30, 120 and 365 days after soil treatment representing crop failure conditions, a typical harvest interval and following year rotation.

Samples of lettuce, radish (foliage and roots) and wheat (forage, hay, grain and straw) were taken at appropriate harvest time, analysed by combustion to determine the total radioactive residue (TRR) and for residue determination of the post-extraction solid (PES). The pre-homogenised processed crop sample was weighed into a centrifuge bottle. Straw was soaked in water before extraction (20 mL, 30 min). The sample was extracted twice with acetonitrile (100 mL) by shaking on a wrist action shaker for one hour, then centrifuged or filtered, and an aliquot of the clear solution was taken for liquid scintillation counting (LSC). Extraction of the PES was repeated once or twice using a hydrochloric acid / acetonitrile-solution (1/1; v/v) by shaking on a wrist action shaker for one hour, then centrifuged or filtered, and an aliquot of the clear solution was taken for LSC.

When residues in PES were > 0.01 mg/kg (or > 10% TRR) a two-step alkaline extraction was performed with aqueous 0.2 N KOH/acetonitrile-solution (1/1; v/v) followed by 24% KOH-solution (50–100 mL each). In certain cases, these basic extracts were acidified and partitioned into ethyl acetate. The ethyl acetate fraction was analysed by HPLC as needed.

Representative portions of extracts were combined prior to analysis. The combined organic extracts were evaporated to dryness. Where required, samples were cleaned up by C₁₈-SPE. Samples with or without clean-up were reconstituted in acetonitrile/water and analysed by HPLC and TLC. Aliquots of the PES at the end of each extraction step were combusted to determine the radioactive residue.

The results are summarized in Tables 42–50.

Study 2

Two trials were carried on mustard greens as the primary crop grown in the USA in 2009. Two treatments with a 15EC formulation were made at 0.299 kg ai/ha with an interval of 14 days resulting in a maximum seasonal application rate of about 0.598 kg ai/ha (Carringer SJ, Report no. R-10218). The primary crop was removed from the trials at normal harvest with a PHI of one day after last application. Rotational crops (radish, lettuce and sorghum) were planted at intervals of 14, 28–30 and 58–60 days after last application.

The samples were analysed for parent tolfenpyrad and its metabolites OH-PAM, OH-PCA and PAM. The limit of quantification for each analyte in each matrix (radish, lettuce and sorghum) was 0.01 mg/kg and the limit of detection was 0.003 mg/kg.

From sampling to extraction, specimens were stored for up to 112 days for radish roots, 141 days for radish tops, 139 days for lettuce, 105 days for sorghum forage and grain and 85 days for sorghum stover. The results of storage stability test are presented in section on Stability of pesticide residue in stored analytical samples.

At normal harvest of the rotational crops, no residues of tolfenpyrad, OH-PAM, OH-PCA and PAM above the LOQ were found in radish roots, lettuce and sorghum forage, grain and stover. Residues of OH-PAM and OH-PCA at the LOQ (0.01 mg/kg) were found at rotational intervals of 14 and 30 days after last application only in radish tops from one trial site.

RESIDUE ANALYSIS

Analytical methods

Analytical methods have been developed for determination of residues of tolfenpyrad and its metabolites in plant and animal matrices. Each method has been validated at the stated LOQ.

Plant commodities

Tolfenpyrad and OH-PT were separated on the HPLC column and quantified with MS/MS.

The specificity of the detection was assured by monitoring of two mass transitions. Quantification by external standard was performed using the mass transitions $m/z = 384 \rightarrow 197$ (confirmation by $m/z = 384 \rightarrow 154$) for tolfenpyrad and $m/z = 400 \rightarrow 197$ (confirmation by $m/z = 400 \rightarrow 382$) for OH-PT. Linearity of detector response was demonstrated using five concentrations of external standard across the range of 0.01–0.2 ng/ml, with correlation coefficients in the range of 0.9934–1.0000 for both, tolfenpyrad and OH-PT. The LOQ was 0.01 mg/kg for both compounds, except tea (0.05 mg/kg).

The methods applied in supervised trials are briefly described hereunder.

Citrus-Method Meth-183, rev. 2 (Wyatt, DR, 2008a)

Residues of tolfenpyrad and its OH-PT metabolite were extracted from the sample with methanol using triplicate extractions. The crude extract from each extraction was vacuum filtered, then combined. The combined filtrates were brought to a final known volume. An aliquot of the combined extract was purified by means of an Oasis[®] HLB solid phase extraction (SPE) clean-up. The purified extract was evaporated to dryness, reconstituted in methanol, and then submitted to HPLC analysis. For the citrus oil samples, the extraction and Oasis[®] HLB SPE clean-up steps were eliminated and replaced with a direct dilution of the sample with methanol to a suitable sample concentration. The diluted samples were filtered then submitted to HPLC analysis. Determination and quantitation for both tolfenpyrad and its OH-PT metabolite were conducted with LC-MS/MS.

Apple, pear—Method Meth-183, rev. 2 (Carringer, SJ, 2009a)

Residues of tolfenpyrad and its OH-PT metabolite were extracted from the sample with methanol using triplicate extractions. The crude extract from each extraction was vacuum filtered, then combined. The combined filtrates were brought to a final known volume. An aliquot of the combined extract was purified with Oasis[®] HLB SPE clean-up. The purified extract was evaporated to dryness, reconstituted in methanol. Determination and quantitation of tolfenpyrad and OH-PT were conducted with HPLC-MS/MS.

Tree nuts and stone fruits—Method Meth-183, rev. 2 (Greenland, RG, 2009a)

The method allows for the quantitative determination of residues of tolfenpyrad and OH-PT in or on almond nutmeat, almond hulls and pecan nut meat samples. It is based on Meth-183, (rev. 2). An aliquot of the homogenised sample (approximately 5 g) was transferred to a 250 mL Nalgene[®] bottle and methanol (60 mL) and Celite (10 g) were added. The sample was allowed to sit for 15 minutes then blended using a high speed homogenizer for one minute. The sample was centrifuged. The supernatant was decanted and vacuum filtered into a 250 mL graduated cylinder. Sample extraction was repeated twice as mentioned above; all extracts were combined and brought to volume (200 mL) with methanol. For determination of residues by HPLC-MS/MS, the sample was diluted with methanol (1:5; v/v).

Stone fruit (sweet cherries, peaches and plums)—Method Meth-183, rev. 2 (Greenland, RG, 2009b)

The method is effectively the same as described for tree nuts.

Potatoes—Method Meth-183, rev. 2 (Carringer, SJ, 2008)

The method is effectively the same as described for apples and pears.

Fruiting vegetables (tomatoes and processed fractions, pepper) Method Meth-183, rev. 2 (Carringer, SJ, 2009b)

The method is effectively the same as described for apple and pear.

Fruiting vegetables (cucumbers, cantaloupes and summer squash) Method Meth-183, rev. 2 (Greenland, RG, 2009c)

The method is effectively the same as described for tree nuts.

Tea (Yabusaki, T, 2010a and 2010b)

After swelling with water, residues of tolfenpyrad were extracted from the sample with acetone by high speed homogenisation and mechanical shaking. After filtration the combined extracts were brought to volume and an aliquot was rotary evaporated to an aqueous remainder. After addition of acetone, a coagulation reagent and Celite 545 the solution was briefly mixed and filtrated. The sample solution was diluted with an aqueous sodium chloride solution and residues were partitioned into

hexane. The solvent was exchanged with acetone and the sample was cleaned up over ENVI-Carb and subsequently over Sep-Pak Plus silica after a second solvent exchange with hexane. Finally the sample solution was evaporated to dryness and residues were re-dissolved in acetone for final determination by GC-NPD.

Oilseeds (cotton seed) Method Meth-183, rev. 2 (Wyatt, DR, 2008b)

The method is practically the same as described for apples and pears with exception of refined oil. Refined oil samples were extracted four times with methanol. Extracts were combined without filtration and further processed as stated in the analytical method for apples and pears.

A summary of recoveries obtained during method validation and procedural recoveries for commodities included in this evaluation are summarized in Table 51.

The validation of analytical method no. 1898W for tolfenpyrad, OH-PAM, OH-PCA, and PAM in plant material (radish, lettuce and grain sorghum) was performed as part of the field rotational crop study (Carringer SJ 2010, Report no. R-10218). The samples were extracted with 100 mL and 2 × 50 mL 5:1methanol:water. Citric acid was added to an aliquot of the concentrated extracts the residues were partitioned into ethyl acetate, concentrated and subjected to SPE on ENVITM-Carbo Pack. A further aliquot of the sample solution was evaporated to dryness and reconstituted in hydrochloric acid (6 N, 5.0 mL). Samples were hydrolysed over night at 50 °C. After reaction the sample was transferred into a separating funnel by rinsing with 10 mL water, and then partitioned into ethyl acetate (20 mL) four times. The organic layers were combined, evaporated to dryness and reconstituted in ethyl acetate (10 mL). The sample was subjected to SPE-clean-up as mentioned above and subjected to HPLC-MS/MS analysis. Quantification and confirmation by external standard was performed using the following mass transitions.

Table 53 Mass transitions used for identification and quantification

Tolfenpyrad	OH-PAM	OH-PCA	PAM
384 → 198	204 → 144	203 → 159 ^a	188 → 118
384 → 154	204 → 107	203 → 88	188 → 145
	414 → 145	203 → 73 ^b	

^a Not used for stover analysis

^b Used for stover analysis only

For each analyte the sum of the response for each ion transition was monitored. The precision and accuracy data are given in Tables 54–57.

Animal commodities

Animal tissues—Method 1841 W (Ref: 1841 W-1; R-10215, A-10042e)

Residues of tolfenpyrad and its metabolites PT-CA, OH-PT-CA and PCA were extracted twice from the sample with either methanol (milk) or a methanol /water mixture (muscle, liver, kidney and fat) by high speed homogenisation. The crude extract from each extraction was vacuum filtered, then combined. The combined filtrates were reduced to below the aqueous remainder and subjected to a liquid-liquid partition into ethyl acetate. The organic phases were combined and the muscle, kidney and fat extracts were evaporated dryness. The extract of muscle and kidney were reconstituted in methanol and subjected to HPLC-MS/MS analysis. Fat samples were reconstituted in hexane and subjected to SPE clean-up. For milk and liver samples, the extracts were split into two equivalent aliquots. The first was evaporated to dryness, reconstituted in methanol and subjected to HPLC-MS/MS analysis; the second was subjected to hydrolysis.

SPE Clean-up for fat only:

The fat sample was cleaned-up on Bond Elute SPE cartridge. The eluate containing the residues was split into two equivalent aliquots. The first was evaporated to dryness and reconstituted in methanol for direct HPLC-MS/MS analysis. The second was subjected to hydrolysis.

Hydrolysis (milk, liver and fat)

The sample extract was evaporated to dryness and reconstituted in an aqueous potassium hydroxide solution and subjected to hydrolysis for at least 15 hours at room temperature. The solution was adjusted to pH < 3, and the residues were partitioned into ethyl acetate four times. The combined organic layers were evaporated to dryness and reconstituted in methanol.

HPLC-MS/MS-analysis

Final sample extracts were analysed by high performance liquid chromatography with tandem mass specific detection (LC MS/MS) using specific mass transitions for tolfenpyrad (384 → 197; 384 → 154) and three transitions for PT-CA (414 → 117; 414 → 227; 414 → 145), OH-PT-CA (430 → 412; 430 → 394; 430 → 227) and PCA (189 → 117; 189 → 129; 189 → 145).

Linearity of detector response was demonstrated using five concentrations of external standard across the range of 2.0–120 ng/ml, with correlation coefficients of > 0.994.

The method allows the determination of tolfenpyrad and its metabolites PT-CA, OH-PT-CA and PCA. The LOQ for both compounds in all matrices is 0.01 mg/kg.

The method was also subjected to independent laboratory validation with muscle, liver fat and milk matrices (Class, T, Göcer, M 2010. Report no A-10042). The results concurred with those of initial validation.

A summary of the method validation and procedural recoveries for commodities included in this evaluation are summarized in Table 58.

Stability of pesticide residues in stored analytical samples

Plant commodities

The studies were conducted in a similar manner. Aliquots of pre-homogenised commodities (5 g) were spiked with test solutions and stored at about -20 ± 5 °C for various intervals ranging from 5 month to 18 months. With exception of the day zero interval, samples for frozen storage were fortified individually with either tolfenpyrad or OH-PT. The samples were analysed with Method 183-rev 2.

Study 1 (Reed, RL., Report no. R-10183)

Table 59 Summary of freezer storage stability data for tolfenpyrad in tomatoes, apples, head lettuce, grapes, oranges, almonds (nutmeat and hulls), potato flakes and cottonseed oil spiked at 0.1 mg/kg level

		2.0	–	94 (n=2)
Tea	2 / 71	1.0	100 (n=2)	–
		1.0	–	96 (n=2)
	2 / 71	1.0	99 (n=2)	–
		1.0	–	95 (n=2)

*Animal commodities**Study 8 (Arndt, T 2010, Report no. R-10215)*

The stability of residues in bovine tissues and milk was determined as part of the animal feeding study.

Fortification solutions containing tolfenpyrad, PT-CA, OH-PT-CA and PCA were added to aliquots of pre-homogenised commodities (10 g) at a fortification level of 0.10 mg/kg. After evaporation of the solvent, samples were stored frozen (< 0 °C) for intervals of 177 days for milk, 85 days for muscle and kidney, 111 days for liver and 99 days for fat. With exception of the day zero interval, samples for frozen storage were fortified individually with either tolfenpyrad or one of the metabolites. Residue analysis of stored samples was performed with *Method 1841 W*, as described under residue analytical methods.

Table 69 Summary of freezer storage stability data for tolfenpyrad in bovine tissue and milk

Matrix	Storage Interval months / days	Fortification (mg/kg)	Procedural recovery (%)	Residues remained (%)
Muscle	2.8 / 85	0.10	85 (n=2)	75 (n=3)
Liver (without hydrolysis)	3.6 / 111	0.10	62 (n=2)	58 (n=3)
Liver (with hydrolysis)	3.6 / 111	0.10	71 (n=2)	68 (n=3)
Kidney	2.8 / 85	0.10	86 (n=2)	73 (n=3)
Fat (without hydrolysis)	3.3 / 99	0.10	79 (n=2)	78 (n=3)
Fat (with hydrolysis)	3.3 / 99	0.10	75 (n=2)	71 (n=3)
Milk (without hydrolysis)	5.8 / 177	0.10	93 (n=2)	82 (n=3)
Milk (with hydrolysis)	5.8 / 177	0.10	78 (n=2)	74 (n=3)

Table 70 Summary of freezer storage stability data for PT-CA in bovine tissue and milk

USE PATTERN

The compound was only registered in Japan on teas. One foliar application of 15% EC formulation can be performed with 0.01–0.015 kg ai/ha using 2000–4000 L/ha water. The PHI is 14 days.

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received information on supervised field trials involving foliar applications of tolfenpyrad to the following crops.

Group	Crop	Country	Table
Citrus fruits	Orange, grapefruit, lemon	USA	73
Pome fruits	Pears	USA	74
Stone fruits	Cherry (sweet), peach, plum	USA	75
Fruiting vegetables–cucurbits	Cucumber, cantaloupe, summer squash	USA	76
Fruiting vegetables–other than cucurbits	Pepper (bell and chilli) tomato	USA	77
Root and tuber vegetables	Potato	USA	No residue
Tree nuts	Almond, pecan	USA	78
Oilseed	Cotton	USA	79
Processed food of plant origin	Tea	Japan	80
Animal feed	Almond hulls	USA	81
	Cotton gin trash	USA	82

The supervised trials were well documented with laboratory and field reports. Laboratory reports included method validation and provided information on procedural recoveries with spiking at residue levels similar to those occurring in samples from the supervised trials. Dates of analyses or duration of residue sample storage were also provided. No residues were detected in any of the control samples. The residues of OH-TP were looked for in all samples, but none of the samples contained it in detectable amounts, except cotton gin trash. These results are not included in the summary tables hereunder. In cotton gin trash, residues of OH-PT residues were in the range of 0.01–0.05 mg/kg. Residue data are recorded unadjusted for analytical recoveries.

Results from replicated field plots are presented as individual values. Results of repeated analyses are reported with the mean value. When residues were below the limit of quantification, they are reported as < LOQ (*e.g.* < 0.01 mg/kg).

Citrus fruits

Twenty-three residue trials were conducted on citrus fruit in the USA during 2007 and 2008 (Wyatt, DR 2008a, Report no. R-10173), 12 trials on oranges, six on grapefruit and five on lemons. In each trial, two treatments were applied by air blast sprayer (mist blower) at a rate of 0.3 kg ai/ha with an interval of 14 days. Two formulations of tolfenpyrad were used: 15% EC formulation, and a 15% SC formulation.

One untreated control and one or two treated plots were established at each test site. Five trials tested the 15EC formulation only (two orange and three grapefruit trials) and seven trials tested the 15% SC formulation only (four orange and three lemon trials). Eleven bridging trials (six orange, three grapefruit and two lemon) tested both formulations in a side-by-side comparison.

All crops were harvested at commercial maturity, 14 or 15 days after the second application. Each RAC sample was comprised of 24 fruit weighed a minimum of 2 kg. The citrus RAC samples were generally placed on dry ice or in freezer storage within approximately 3.0 hours after collection from the field.

Procedural mean recoveries at fortification levels in the range of 0.01 mg/kg to 1.0 mg/kg were in the range of 82% to 103%. Citrus samples were stored for 162 days prior to analysis.

^a Trials resulted in the highest residues from the side by side treatments carried out with EC or SC formulation on different varieties

Pome fruits

Pears

Six residue trials were performed on pears grown in the USA in 2008 (Carringer, SJ 2009a, Report no. R-10177). Two treatments were applied by air blast sprayer (mist blower) with an interval of 14 days. The first application was performed at about 300 g ai/ha and the second at about 150 g ai/ha ending up in a maximum seasonal application rate of about 0.448 kg ai/ha. Two formulations of tolfenpyrad were used: 15% EC and a 15% SC formulation.

One untreated control and two treated plots were established at each test site. All trials were performed as bridging trials testing both formulations in side-by-side comparisons.

All trials were harvested at commercial maturity, 14 days after the second application. One trial was conducted as a decline trial with samples taken 0, 14, 28 and 35 days after the second application.

A single control sample and duplicate treated RAC samples were harvested by hand at each location at normal crop maturity 14 days after the last application (DALA). Additionally, one trial collected duplicate treated decline samples 0, 14, 28 and 35 DALA. The pear samples were comprised of 24 fruit weighing at least 2 kg. Samples were collected from all quadrants of the trees and from at least four centre trees in the treated plots.

Pear samples were stored for 93 days prior to analysis. All samples were analysed for tolfenpyrad and its metabolite OH-PT. No quantifiable residues of OH-PT were present in any samples.

Stone fruits

Twenty-one residue trials were conducted on stone fruit in the USA during 2008 (Greenland, RG, Report no. R-10175), six trials on sweet cherries, nine on peaches and six on plums. In each trial, two treatments were applied by air blast sprayer (mist blower) application at a rate of 0.31 kg ai/ha each with an interval of 10 days. Tolfenpyrad was used as a 15% SC formulation.

One untreated control and one treated plot were established at each test site. Two of the plum trials had an additional plot treated at an exaggerated rate (5×) to provide samples for processing.

All trials were harvested at commercial maturity, 14 days after the second application. Samples of minimum 2 kg were taken from 24 positions at random areas across the plots. Samples were taken to deep-freezer within 3.6 hours. One trial for peach was conducted as a decline trial with samples taken 6, 10, 14, 18 and 22 days after the second application.

All samples were analysed for tolfenpyrad and its metabolite OH-PT within 101 days after sampling. No OH-PT was detected in any of the samples.

^a Trials resulted in the highest residues from the side by side treatments carried out on different varieties

Fruiting vegetables, Cucurbits

Seventeen residue trials performed on cucurbits grown in the USA in 2008 (Greenland, RG, Report no. R-10179), six on cucumbers (including one decline trial), five on summer squash and six on melons (cantaloupe). In each trial, four treatments were performed by foliar application at a rate of 0.23 kg ai/ha each with an interval of seven days. Tolfenpyrad was applied as a 15% EC formulation.

One untreated control and one treated plot were established at each trial site. All trials were harvested at commercial maturity, one day after the last application. One trial on cucumber was conducted as a decline trial with samples taken 1, 4, 7, 10 and 13 days after the last application.

Samples of cucumber fruits, cantaloupe fruits and summer squash fruits (a minimum of 12 fruit per sample weighing at least 1.4 kg per sample) were taken from random areas across the plots. To reduce bulk, some large fruit were sectioned from top to bottom into two (2) or four (4) parts and ½ or ¼ of each fruit was randomly collected for the sample. Details of handling individual samples were not reported.

The untreated plot was sampled first, followed by the treated plot. Samples were placed in freezers (-20 °C ± 5 °C) within 2.3 hours after collection.

The samples were analysed within 131 days after collection.

No quantifiable residues of OH-PT were present at any PHI.

Fruiting vegetables, other than cucurbits

Twelve residue trials were performed on tomatoes and pepper grown in the USA in 2007 (Carringer, SJ Report no. R-10167), six trials on tomatoes and six trials on pepper. In each trial, two treatments were performed by foliar application at a rate of 0.23 kg ai/ha each with an interval of 14 days. Two formulations of tolfenpyrad were used: a 15% EC formulation, and a 15% SC formulation.

The pepper trials used the 15SC formulation only and the tomato trials were performed as bridging trials testing both formulations in side-by-side comparisons. One of the tomato trials had an additional plot treated at an exaggerated rate (5×) with the EC formulation to provide samples for processing.

All trials were harvested at commercial maturity, one day after the second application. One trial in each type of fruit was conducted as a decline trial with samples taken 0, 1, 7 and 14 days after the second application. Tomato and pepper samples were comprised of a minimum of 12 fruits weighing at least 2.2 kg. The samples were stored before analyses for a maximum of 184 days.

All samples were analysed for tolfenpyrad and its metabolite OH-PT.

No quantifiable residues of OH-PT were present in any samples.

*Root and tuber vegetables**Potatoes*

Sixteen residue trials conducted on potatoes in the USA in 2007 (Carringer, SJ 2008, Report no. R-10166). In each trial, two treatments were performed by foliar broadcast ground application at a rate of 230 g ai/ha with an interval of 27–29 days. Tolfenpyrad was used as a 15% EC formulation.

The harvest was at commercial maturity, 13–14 days after the second application. Two trials were conducted as decline trials with samples taken 7, 14, 21 and 28 days after the second application. One trial had an additional plot treated at an exaggerated rate (5×) with the EC formulation to provide samples for processing.

The samples were comprised of a minimum of 12 (if large) or 24 tubers. All samples were analysed for tolfenpyrad and its metabolite OH-PT.

The potato RAC samples were stored frozen (below freezing at the field sites, -17 ± 8 °C at the processing facility, and -20 ± 5 °C at the analytical laboratory) for a maximum of 179 days from collection to analysis.

In potatoes harvested 7 to 28 days after application, all residues of tolfenpyrad and OH-PT were below the LOQ (< 0.01 mg/kg).

Since the tolfenpyrad metabolites, PT-CA was detected more than 10% TRR in the metabolism study with tolfenpyrad in radishes (Quistad and Kovatchev, 2008), potatoes as root vegetables were selected for the confirmation of the residues of additional tolfenpyrad metabolites, OH-PAM, PT-CA, and PAM (Carringer, JS 2012, Report no. R-10255). The potato raw agricultural commodity and processing commodity samples generated in a previous study (Carringer, JS 2008) were analysed. The residues of relevant metabolites were below the limit of detection (< 0.01 mg/kg) in all treated samples.

Tree nuts

Ten residue trials were performed on tree nuts grown in the USA in 2008 (Greenland, RG 2009a, Report no. R-10178); five on almonds and five on pecans. Two treatments with a 15% SC formulation were performed at a rate of 300 g ai/ha by air blast sprayer with an interval of 10 days. Both applications were performed at about 300 g ai/ha.

All trials were harvested at commercial maturity, 13–14 days after the second application. One trial was conducted as a decline trial with samples taken 5, 9, 13, 17 and 21 days after the second application. Samples of almond nutmeat, almond hulls and pecan nutmeat weighing at least 2 kg were taken from random areas across the plots. Some of the samples were placed in a freezer more than 4 hours after collection because of the time it took to shell the nuts. The samples were stored at -20 °C $\pm$ 5 °C before and after homogenization in the freezers of the analytical facility. The samples were analysed within 60 days following their collection.

All samples were analysed for tolfenpyrad and its metabolite OH-PT. No quantifiable residues of OH-PT were present in any samples.

Cotton

Twelve residue trials were conducted on cotton in the USA in 2007 (Wyatt, DR 2008b, Report no. R-10159). In each trial, two treatments were performed by foliar application with 15% EC formulation at a rate of 0.23 kg ai/ha each with an interval of 14 days.

One trial had an additional plot treated at an exaggerated rate (5×) with the SC formulation to provide samples for processing.

All trials were harvested at commercial maturity, 13 or 14 days after the second application. One trial was conducted as a decline trial with samples taken 7, 14, 21 and 28 days after the second application.

All samples were analysed for tolfenpyrad and its metabolite OH-PT.

No quantifiable residues of OH-PT were present at a PHI of 13–14 days in undelinted seed.

In cotton gin trash, 13–14 days after second application, residues of tolfenpyrad were in the range of 1.17–5.90 mg/kg. Residues of OH-PT were in the range of 0.01–0.05 mg/kg.

Processed food of plant origin***Tea***

Four residue trials were conducted on green tea during 1997 in Japan (Yabusaki, T 2010a, R-10027 and R-10028). One foliar application of tolfenpyrad was made with 0.0015 kg/ha following the design

of reverse decline trials. The treated plots of each trial were harvested at a PHI of 7, 14, 21 and 30 days after treatment and the samples were analysed twice in two laboratories. The LOQ was 0.04 mg/kg.

FATE OF RESIDUES IN STORAGE AND PROCESSING*In processing**Study 1 – Citrus (Wyatt, DR 2008a Report no. R-10173)*

One processing trial was conducted on oranges in 2008. The treated plot received two air-blast applications at an exaggerated rate of 1.5 kg ai/ha with an interval of 14 days. Samples were harvested at maturity 14 days after the last application.

The oranges were batch tub-washed for 5 minutes. The washed oranges were transferred to the modified Hobart Abrasive Peeler for scarifying. Approximately 2.20 kg of oranges per batch were

abraded for approximately 1 minute to scarify the flavedo for oil recovery. The scarified fruits were weighed and retained for juice processing.

The collected oil-water emulsion was transferred to the Sweco Sifter and screened using an (approximately) 180 µm screen to separate any flavedo fragments from the oil-water emulsion.

The scarified flavedo was set aside for later addition to the shredded peel. The first run oil-water emulsion was processed through the cream separator and IEC centrifuge to separate the oil. The free oil was removed. The residual emulsion was frozen overnight, thawed, centrifuged and the oil removed and added to the previously collected oil sample. The entire oil sample recovered was weighed and stored frozen until analysis.

An aliquot of the scarified oranges was weighed and transferred to the Hollymatic Juice Extractor to separate the juice from the peel. The juice and peel recovered were weighed and the Brix-degree taken on the fresh juice.

The collected juice was transferred to the pulper finisher and screened using an (approximately) 1.19 mm screen for removal of vesicular membranes, seeds, segment membranes and peel fragments from the juice. The collected rag and seeds were set aside for later addition to the shredded peel.

A representative aliquot of the fresh juice was sampled and stored frozen until analysis. The remaining juice was discarded.

The peel from the Hollymatic Juice Extractor was shredded using the Robot Coupe Food Processor. The shredded peel was combined with the scarified flavedo from the scarification process and rag and seeds from the juice finisher extraction process to generate wet peel.

Lime (approximately 95% CaO) was added to the wet peel and mixed on the Hobart mixer for 17 minutes. The limed peel was pressed using a Suntech Fruit press. The expressed liquid was weighed, checked for pH and Brix-degree and discarded.

The wet peel pulp was placed on the Laboratory Bin Air Dryer for removal of moisture to < 10%. The dried pulp was milled using the Suntech Fruit Press hammermill. Moisture of treated and untreated samples averaged between 3.1% and 3.5%.

A representative sample of the dried pulp was sampled and stored frozen until analysis. The remaining dried pulp was discarded.

The processed fractions were analysed with the method described under residue analysis.

Table 83 Summary of residues of tolfenpyrad and OH-PT in oranges and processed products

Compound	Total Treatment Rate (kg ai/ha)	PHI (days)	Sample	Residues (mg/kg) ^a	Processing Factor
Tolfenpyrad	2.98	14	RAC fruit	0.91	—
			juice	0.02	0.022
			dried pulp	8.03	8.8
			oil	74.4	82
OH-PT	2.98	14	RAC fruit	< 0.01	—
			juice	< 0.01	—
			dried pulp	0.02	—
			oil	0.08	—

Study 2 – Plums

Two processing trials were conducted on plums in the USA in 2008 (Greenland, RG 2009b, Report no. R-10175). The treated plots received two air-blast applications of about 1.5 kg ai/ha with an interval of 10 days. Samples were harvested at maturity 14 days after the last application.

Representative unwashed plum sample aliquots (treated and untreated) were used for processing. The plum samples were placed in model D-10 dehydrators (Homestead Harvest products). The dehydrators first were set to 57.2 °C for 10 hours and temperature was risen to 73.9 °C for additional 20 hours. The actual temperature range for the drying process was 22.8–49.4 °C. The loss of moisture was 55.4% for the untreated sample and 61.2% for the treated sample. Sample aliquots were taken and stored frozen until analysis. The samples were analysed with the method described under residue analysis.

Table 84 Summary of residues of tolfenpyrad and OH-PT in plums (fresh and dried)

Study 3 – Potatoes

One trial was conducted at an exaggerated application rate to obtain RAC samples of potato tubers for processing (Carringer, SJ Report no. R-10166). The treated plot received two foliar broadcast applications, of about 1.05 kg ai/ha with an interval of 14 days. Samples were harvested at maturity 14 days after the last application.

Potato flake production

After washing, the potatoes were peeled (steam and scrub peeling). The potato peel was collected from the peeling and scrubbing process. Peeled potatoes were inspected and trimmed to remove peel, rot, green or other damages. The collected peel was hydraulically pressed and blended together with the collected cut trim waste. A sample aliquot was taken and stored frozen until analysis.

An aliquot of peeled potatoes was removed, cut into slabs using a LanElec slicer and spray-washed (tap water). The potato slabs were pre-cooked (steam) at approximately 70–77 °C for 21 minutes and cooled to less than 32 °C. An aliquot of the potato slabs was steam-cooked at 94–100 °C for 40–42 minutes, mashed and mixed with an emulsion of pre-weighed food additives. The sample was placed in a Drum Dryer for production of large flakes that were milled to uniform potato flakes by a hammermill. Moisture content of the flakes was ≤ 9%. Sample aliquots were taken and stored frozen until analysis.

Potato chip production

After washing and sugar analysis, potatoes were batch peeled using a restaurant-style Toledo Peeler. The collected peel was discarded. The peeled potatoes were inspected and trimmed as necessary to remove rot, green or otherwise damaged potato tissue. The peeled potatoes were cut into thin slices (1.6 mm) using a restaurant-style LanElec Slicer. Adhering free starch was removed with hot water and slices were drained over a screen to remove excess water. Chips were oil-fried at 163–191 °C for about 120 seconds, drained, salted and inspected. Sample aliquots were taken and stored frozen until analysis.

Flakes, chips and wet peel samples were analysed according to the analytical process for potatoes described under residue analysis. Neither the RAC nor the processed fractions contained residues of tolfenpyrad and OH-PT above LOQ of 0.01 mg/kg.

Study 4 – Tomatoes

One trial was conducted at an exaggerated application rate to obtain samples of tomato RAC fruits for processing (Carringer, SJ 2009b). The treated plot received two foliar broadcast applications, of about 1.15 kg as/ha with an interval of 14 days. Samples were harvested at maturity one day after the last application (DALA).

Juice production

After washing, tomato fruits were crushed and the crush was heated to a temperature of 91–100 °C in a hot break system. The hot crush was processed through a finisher equipped with a screen with 0.84 mm perforations that removed peel and seeds from the crush. The resulting juice was collected for further processing. The pomace was discarded.

Purée production

The juice was concentrated to puree using a vacuum evaporator. During concentration, the juice was recirculated through the evaporator until it was condensed to a natural tomato soluble solids (NTSS) content of 10%. A portion of puree was transferred to a steam jacketed kettle, heated while stirring to a minimum temperature of 88 °C and poured into cans. After heating the NTSS was 11–12%. The cans were sealed, inverted and water cooled. When cooled, the cans were dried and stored frozen until analysis.

Paste production

The remaining puree in the vacuum kettle evaporator was condensed to paste. The NTSS for the paste fraction was 27.5–30.0%. A portion of the paste was transferred into a small steam jacketed kettle and heated to 88–93 °C. The NTSS after heating was 31–45.5%. The paste was poured into cans that were sealed and inverted. After 5 minutes, the cans were water cooled, dried, and stored frozen until analysis. Puree and paste samples were analysed according to the analytical process for tomatoes described under residue analysis.

Table 85 Summary of residues of tolfenpyrad and OH-PT in tomato and tomato processed products

Study 5 – Cotton

One processing trial was conducted on cotton in 2007 (Wyatt, DR 2008b, Report no. R-10159). The treated plot received two applications with an interval of 14 days, the first at 1.18 kg ai/ha, the second at 1.15 kg ai/ha. Samples were harvested at maturity 13 days after the last application.

Delinting

Seed cotton was saw ginned (Continental Eagle 20 saw gin) to remove most of the lint from the seed. Remaining lint (11–15%) was mainly removed by saw delinted in a Carver delinter to produce

delinted cottonseed with approximately 3% lint remaining on the seed. Processed fractions obtained so far were delinted cottonseed, linters and linter motes.

Cotton seed hulls

A roller mill (AT Ferrell) cracked the delinted seed and most of the hull material was removed from the kernel by screening (10/64" and 12/64"). Aliquots of hull material were taken and stored frozen until analysis.

Cotton seed meal

The kernel fraction was heated in a Marion mixer to 79–90 °C for 15–30 minutes. Thereafter, kernels were flaked (AT Ferrell flaking roll) and fed into an extruder (Readco Manufacturing). By extruding, steam was injected directly on the product reaching a temperature of 77–113 °C (collets). Collets were dried in a tray oven (66–82 °C; 30–40 min.) and thereafter solvent extracted with hexane at 49–60 °C for 30 minutes. After draining of the solvent, extraction was repeated twice. After separating the extract the remaining hexane was removed from the cotton seed meal by heating to 99–104 °C in a paddle mixer. Aliquots of meal were taken and stored frozen until analysis.

Refined oil

Crude oil and hexane were separated by passing the sample through a laboratory vacuum evaporator. Remaining hexane was removed from the oil by heating to 91–96 °C. An aliquot of the crude oil was filtered and mixed with vigorously with sodium hydroxide solution (16° Baumé) for 15 minutes at 20–24 °C and for 12 minutes at 63–67 °C. After centrifugation, refined oil was decanted and vacuum filtered. Aliquots of refined oil were taken and stored frozen until analysis.

Undelinted cotton seed and the processed fractions cotton seed hulls and meal were analysed according to the analytical process described under residue analysis. Refined oil samples were extracted four times with methanol. Extracts were combined without filtration and further processed as mentioned in section 6.3.9/01.

Table 86 Summary of residues of tolfenpyrad and OH-PT in cotton and cotton processed products

Compound	Total Treatment Rate (kg ai/ha)	PHI (days)	Sample	Residues (mg/kg) ^a	Processing Factor

Study 7 – Tea

Tea samples for processing were taken from the supervised field trials conducted for determining the magnitude of residues in tea (Haigo, S, Report no. R-10029). A sample of homogenised tea (6 g) was placed in a beaker and boiling water (360 mL) was added. The sample was infused for 5 minutes. The infusion was filtered by gravity.

An aliquot of the infusion (120 mL) was transferred into a separating funnel, diluted with saturated aqueous sodium chloride solution (15 mL) and partitioning into hexane (50 mL). After phase separation, the hexane phase was washed with ethanol (1.5 mL) which was subsequently added to the aqueous phase. Partitioning was repeated once, as described above, with hexane (25 mL). The

hexane layers were combined by filtration over sodium sulphate and evaporated to dryness by rotary evaporation.

The sample was re-dissolved in hexane (2 mL) and cleaned up over Sep-Pak Plus Silica. The sample was loaded to the column and washed with ethyl acetate/hexane (1:9; 10 mL). Tolfenpyrad was eluted with ethyl acetate/hexane (15:85; 10 mL). The sample solution was evaporated to dryness by gentle stream of air.

The sample was re-dissolved in hexane (1 mL). Determination of residues was performed by GC-NPD.

For tolfenpyrad procedural recoveries were in the range of 88–93%. Samples were stored for up to 97 days prior to analysis.

Study 8 – Tea

Two residue trials were conducted on tea in Japan during 2005 (Otsubo, S 2012, Report no. R-10099).

One broadcast foliar application of a “flowable” formulation (Hachi-Hachi) at a nominal rate of 0.60 kg as/ha was performed. Trials were set-up as reverse decline trials with sampling after PHIs of 7, 14 and 28 days after application. Processing to tea infusion was done for samples of both trials at each PHI.

RESIDUES IN ANIMAL COMMODITIES

Farm animal feeding studies

Cattle feeding studies

The magnitude of tolfenpyrad residues was determined in tissues and milk in a dairy cattle feeding study (Arndt, T, 2010, report no. R-10215). Tolfenpyrad was administered orally by gelatine capsules for 28 consecutive days to three groups of three cows at dose levels equivalent to 2.5, 7.5 and 25 ppm based on a weekly averaged feed consumption (dry weight). A single dose capsule was administered to each cow following the morning milking. The untreated control animals were dosed with empty placebo capsules.

Milk was collected twice daily (morning and evening) to produce daily milk composites every day for 28 days of treatment. Mean daily milk production levels observed during the acclimation period for the cows in the control, low, medium and high dose groups were consistent throughout the study period. Analysis was conducted on samples generated on dose days 1, 2, 3, 4, 5, 6, 7, 10, 13, 16, 19, 22, 25 and 28. Milk was also collected from four cows during the depuration phase for days 3, 7 and 14 after the final dose. An aliquot of the composite milk sample was mixed thoroughly and stored

frozen divided into three equivalent portions. From the control group (1), group 2 and group 4 extra pooled milk samples were separated into cream and skim milk on study days 13 and 28.

One control and three cows from each dose group were sacrificed within 24 hours after their last dose, while the depuration treated cows were sacrificed at days 3, 7 and 14 after termination of dosing. The second control cow was sacrificed at day +14.

Samples of muscle (loin and leg), liver (representative sampling from each lobe), kidney (representative sample from each), and perinephric, abdominal and subcutaneous fat were removed. After weighing, composite tissue samples from each animal were stored frozen in labelled storage bags.

The milk and fat analyses determined tolfenpyrad, The PT-CA, OH-PT-CA and PCA residues were determined with a non-hydrolysis and a hydrolysis method. The hydrolysis method was used to cleave conjugated metabolites and allow for the analysis of the free metabolites. The LOQ was 0.01 mg/kg for each analyte.

In muscles and kidneys tolfenpyrad, PT-CA and OH-PCA residues were determined using a nonhydrolysis method only with an LOQ of 0.01 mg/kg for each analyte. In liver tolfenpyrad, PT-CA and OH-PT-CA residues were determined using both a non-hydrolysis method and a hydrolysis method with LOQ of 0.01 mg/kg for each analyte.

The storage durations were longer than the longest storage period for the milk and tissue samples. The residues determined in various samples are summarized in Tables 90–95.

APPRAISAL

The toxicological and residue evaluation of tolfenpyrad was scheduled for the 2013 JMPR by the Forty-fourth Session of the CCPR.

Tolfenpyrad is a broad spectrum insecticide and a miticide, with contact activity against target pests on eggs, larvae, nymphs, and adults. It also has anti-feeding activity on larvae of lepidopteran insects. It belongs to the pyrazole class of insecticides. It has activity against several economically important insect pests of vegetables, fruits, nuts, vines and row crops.

The Meeting received information from the manufacturer on identity, the animal and plant metabolism, environmental fate analytical methods, storage stability, effect of processing, animal feeding studies, and results of supervised trials on almonds, cantaloupe,, cauliflower, cherries, cucumbers, cotton seed, grapes (table), grapefruits, lemons, oranges, peaches, pears, pecans, peppers, plums, potatoes, summer squash, tea and tomatoes.

Chemical name and structure

4-chloro-3-ethyl-1-methyl-*N*-[4-(*p*-tolylxy)benzyl]pyrazole-5-carboxamide

Chemical names and structures of metabolites referred to in the appraisal by codes:

Code Name	Chemical name	Structure	Matrices
PT-CA	4-[4-[(4-chloro-3-ethyl-1-methylpyrazol-5-yl)carbonylaminomethyl]phenoxy]benzoic acid		rat, plant, soil animal commodities
OH-PT-CA	4-[4-[[4-chloro-3-(1-hydroxyethyl)-1-methylpyrazol-5-yl]carbonylaminomethyl]phenoxy] benzoic acid		rat, plant, animal
CA-T-NH ₂	4-[4-(aminomethyl)phenoxy]benzoic acid		Photodecomposition, animal

Code Name	Chemical name	Structure	Matrices
OH-PAM	4-chloro-3-(1-hydroxyethyl)-1-methylpyrazole-5-carboxamide		rat, plant, soil, eggs
PCA	4-chloro-3-ethyl-1-methylpyrazole-5-carboxylic acid		Plant, soil, eggs
OH-PT	4-chloro-3-(1-hydroxyethyl)-1-methyl-N-[4-(p-tolyloxy)benzyl] pyrazole-5-carboxamide		rat, plant
CO-PT	3-acetyl-4-chloro-1-methyl-N-[4-(p-tolyloxy)benzyl] pyrazole-5-carboxamide		plant
PT-OH	4-chloro-3-ethyl-N-[4-[4-(hydroxymethyl)phenoxy]benzyl]-1-methylpyrazole-5-carboxamide		rat, plant, soil, photodecomposition
PT-CHO	4-chloro-3-ethyl-N-[4-[4-(formylphenoxy)benzyl]-1-methylpyrazole-5-carboxamide		rat, plant, soil, photodecomposition
PT-CA	4-[4-[(4-chloro-3-ethyl-1-methylpyrazol-5-yl)carbonylaminomethyl]phenoxy]benzoic acid		rat, plant, soil animal commodities
OH-PT-OH	4-chloro-3-(1-hydroxyethyl)-N-[4-[4-(hydroxymethyl)phenoxy]benzyl]-1-methylpyrazole-5-carboxamide		rat, plant, animal commodities
CO-PT-OH	3-acetyl-4-chloro-N-[4-[4-(hydroxymethyl)phenoxy]benzyl]-1-methylpyrazole-5-carboxamide		plant
CO-PT-CA	4-[4-[(3-acetyl-4-chloro-1-methylpyrazol-5-yl)carbonylaminomethyl]phenoxy]benzoic acid		plant
CA-PT-OH	[4-chloro-5-[N-[4-(4-hydroxymethyl)phenoxy]benzyl]carbonyl]-1-methylpyrazol-3-yl]acetic acid		rat, plant
CA-PT-CA	4-[4-[3-(carboxymethyl)-4-chloro-1-methylpyrazol-5-yl]carbonylaminomethyl]phenoxy]benzoic acid		rat, plant
DM-PT	4-chloro-3-ethyl-N-[4-(p-tolyloxy)benzyl]pyrazole-5-carboxamide		plant
DM-PT-OH	4-chloro-3-ethyl-N-[4-[4-(hydroxymethyl)phenyl]benzyl] pyrazole-5-carboxami		plant

Code Name	Chemical name	Structure	Matrices
PAM	4-chloro-3-ethyl-1-methylpyrazole-5-carboxamide		rat, plant, soil
OH-PAM	4-chloro-3-(1-hydroxyethyl)-1-methylpyrazole-5-carboxamide		rat, plant, soil, eggs
T-AM	[4-(<i>p</i> -toloxy)benzamide		plant
OH-T-AM	4-[4-(hydroxymethyl)phenoxy] benzamide		plant
CA-T-AM	4-(4-carbamoylphenoxy)benzoic acid		plant
T-CA	4-(<i>p</i> -toloxy)benzoic acid		rat, plant
OH-T-OH	<i>bis</i> [4-(hydroxymethyl)phenyl]ether		pant
OH-T-CA	4-[4-(hydroxymethyl)phenoxy] benzoic acid		rat, plant
CA-T-CA	4,4'-oxydibenzoic acid		rat, plant
T-CA-Glu	glucose conjugate of 4-(<i>p</i> -toloxy) benzoic acid		plant

Animal metabolism

The Meeting received reports of animal metabolism studies in lactating goats and laying hens. The studies were conducted with [^{14}C] tolfenpyrad labelled on the pyrazole and tolyl rings.

Metabolism in laboratory animals is summarized under toxicology.

Lactating goats

[Pyrazole- ^{14}C]-tolfenpyrad and [tolyl- ^{14}C]-tolfenpyrad were administered orally (12.3–12.5 mg/kg feed/day) to two lactating goats once daily for five consecutive days. Milk was collected twice daily and excreta were collected once daily. The total recovery of radiolabel was 76.1% and 96.3% of the administered dose (AD) for the pyrazole- and tolyl-labels, respectively. Most of the administered dose was recovered in the excreta (46.8–49.8%) and gastrointestinal tracts (19.2–32.6%) at sacrifice.

Administration of [tolyl- ^{14}C]-tolfenpyrad resulted in consistently higher residues in tissues than the administration of [pyrazole- ^{14}C]-tolfenpyrad. The total radioactive residues (TRR) expressed as tolfenpyrad mg equivalents/kg were in liver (25 mg/kg, 12%AD) and kidney (6.93 mg/kg, 0.7%AD) and substantially lower in the fat (0.36 mg/kg, 0.4%AD), milk (0.17 mg/kg, 19% AD) and muscle (0.14 mg/kg, 0.1–0.2%AD). No free metabolite unique to only one of the radiolabels was found.

The parent tolfenpyrad was present up to 4.1% TRR (< 0.01 mg/kg) in milk, 10% TRR (0.01 mg/kg) in muscle, 17.3%TRR (0.06 mg/kg) in fat, and was not detected in liver and kidney.

Following the administration of pyrazole- and tolyl- labelled tolfenpyrad, the predominant residues were PT-CA in free and its conjugated form. The free and conjugated PT-CA, respectively, amounted up to 7.6% and 48% of TRR (0.01–0.08 mg/kg) in milk, 68% TRR (0.09 mg/kg) (its conjugate was not detected (nd) in muscle from the tolyl label), 52% and 9.0% of TRR (13–1.74 mg/kg) in liver, 63% and 3.5% of TRR (4.33–0.21 mg/kg) in kidney and nd–34.1% of TRR(nd–0.09 mg/kg) in fat. PT-CA is rapidly conjugated in the liver. But in the gastrointestinal tract it is deconjugated.

OH-PT-CA was present in free form 17% TRR (0.03 mg/kg), in milk, 8.9%TRR (< 0.01 mg/kg,) in muscle, 27% TRR (6.69 mg/kg,) in liver, 19.3% TRR (1.34 mg/kg)in kidney, and in conjugated from 1.2%TRR (0.21 mg/kg) in liver and 0.3%TRR in kidney (0.02 mg/kg,). It was not detected in fat.

In addition, CA-T-NH₂ could be released by hydrolysis from milk (19.4%TRR) and fat (5.3%TRR).

In summary, tolfenpyrad is oxidized at the tolyl-methyl group to PT-CA. Further oxidation at the pyrazole ethyl group of PT-CA produces OH-PT-CA. Both PT-CA and OH-PT-CA occur as free metabolites in milk, liver, kidney, and muscle. PT-CA and its hydrolysis metabolites (PCA and CA-T-NH₂) are converted into nonpolar lipids in milk and fat. Saponification of the lipid conjugates releases PT-CA, PCA, and CA-T-NH₂.

Laying hens

[Pyrazole-¹⁴C]-tolfenpyrad and [tolyl-¹⁴C]-tolfenpyrad were administered orally (in gelatine capsules) to two separate groups of hens once daily for seven consecutive days. The administered daily dose was 12.6–13.5 mg/kg feed/day. Eggs were collected twice daily and excreta were collected once daily. Hens were sacrificed approximately 22–23 hours after the last dose administration. Liver, muscle, fat and gastrointestinal tracts with contents were collected for analysis.

The total recovery of radiolabel was 85.4% and 91.4% of the administered dose (AD) for the pyrazole- and tolyl-labels, respectively. Of the total dose 2.3–2.4% remained in the gastrointestinal tract one day after the last dose. The total identified residues were 66–78% in eggs, 85–89% in muscle, 84–96% in liver and 62–73% in fat. In tissues, the total radioactive residue (TRR) was highest in liver (up to 1.94 mg/kg; 0.8% AD) and lower in eggs (0.3% AD), fat (0.1% AD) and muscle (0.1% AD).

The parent tolfenpyrad was only present at 0.06 mg/kg concentration in fat (15% TRR) and < 0.01 mg/kg concentration in eggs (2.4%TRR), muscle (1.8% TR) and liver (0.2% TRR).

Following the administration of pyrazole- and tolyl-labelled tolfenpyrad, the predominant residues were PT-CA in free and its conjugated form. The free PT-CA amounted up to 40.5% TRR (0.07 mg/kg) in eggs, 85%TRR (0.1 mg/kg) in muscle and conjugated PT-CA, respectively, amounted up to 40.5–29% TRR (0.07–0.04 mg/kg) in eggs, 79% TRR (1.3 mg/kg) in liver, and 15% TRR ((0.07 mg/kg) in fat. The conjugated PT-CA was present in eggs, liver and fat at 29, 11.4, and 34.5% of TRR, respectively.

OH-PAM was present in free form at 12.6% TRR (0.02 mg/kg) in eggs, and 12.4% TRR (0.02 mg/kg) in muscle. It was not detected in liver and fat.

OH-PT-CA was detected at 2.7% TRR (< 0.01 mg/kg) in muscle, 5.2% TRR (0.09 mg/kg) in liver. It was not detected in eggs and fat.

In summary, the initial metabolite of tolfenpyrad is PT-CA occurring as a major residue in eggs, liver, kidney, muscle, and fat. Further oxidation at the pyrazole-ethyl group of PT-CA produces OH-PT-CA that occurs in liver and muscle. OH-PAM occurs as a free metabolite in eggs and muscle. Tolfenpyrad is a trace residue in eggs, liver, and muscle but was more abundant in fat. PT-CA and its hydrolysis product (PCA) are incorporated into non-polar lipid conjugates occurring in eggs and fat.

Plant metabolism

Cabbage

[Tolyl-¹⁴C]-tolfenpyrad was applied to individual cabbage plants in a spray chamber. One application was made at a rate corresponding to 750 g ai/ha. Samples were taken at day 0 (immediately after the spray dried) and at 7, 14 and 28 days.

Twenty eight days after application 99.7% of the TRR (8.39 mg tolfenpyrad equivalent/kg) was on the outer leaves, 78.7% in the organo-soluble fraction and 15.9% in the water-soluble fraction, and only 0.3% of the TRR (0.03 mg equiv./kg) was in the heads, distributed between the water soluble (0.2%) and organo soluble fraction (0.1%).

Tolfenpyrad was found in the outer leaves at levels of 12.6 mg/kg (89% of TRR) immediately after application decreasing to 4.6 mg/kg (55.0% of TRR) after 28 days. In samples taken 28 days after application, OH-PT, OH-T-CA, OH-T-OH, and CA-T-AM were present at 0.54 mg/kg (6.4% of TRR), 0.33 mg/kg (3.9% of TRR), 0.31 mg/kg (3.7% of TRR), and 0.20 mg/kg (2.4% of TRR), respectively. Other metabolites were present at lower proportions. In cabbage head without outer leaves neither the parent compound nor any of the identified metabolite were detected (< 0.01 mg/kg).

In a second cabbage study, [pyrazole-¹⁴C]-tolfenpyrad was applied once to individual cabbage in a spray chamber at a rate corresponding to 750 g ai/ha. Cabbage samples were collected at 28 days after application. At that time 97.2% of the AD (9.22 mg/kg) was distributed on the outer leaves and 2.8% (0.23 mg/kg) in the heads.

Tolfenpyrad was found in the outer leaves at levels of 4.7 mg/kg (49.8% of TRR). The identified metabolites, expressed as TRR, were 7.9% OH-PT (0.75 mg/kg), 3.4% OH-PT-OH and 2.9% OH-PT-CA. Other metabolites were detected at levels of ≤ 0.20 mg/kg (≤ 2.1% of AD). In the head, levels of metabolites did not exceed 0.1% of TRR.

Peach

[Tolyl-¹⁴C]-tolfenpyrad was applied to individual peach plants in a spray chamber. One branch and one fruit were treated on each plant. One application was made at a rate corresponding to 750 g ai/ha.

Immediately after application, 83.5% of the AD was distributed on the leaves with 11.8% on the stem and 4.7% on the fruit. There was no significant change in distribution 56 days after application; TRRs remained were 83.1%, 7.5% and 9.3%, respectively.

In the fruit, parent tolfenpyrad was found at 3.0 mg/kg (100% of AD) immediately after application decreasing to 0.79 mg/kg (77% of TRR) by day 56. The majority of residues (8.4% TRR) were in the peel while only 0.4% TRR in the pulp. The metabolites did not exceed 2.8% TRR throughout the study period, except the glucose conjugate of T-CA at 6.1% TRR.

In the second peach study [pyrazole-¹⁴C]-tolfenpyrad was applied to individual peach plants in a spray chamber. One branch and one fruit were treated on each plant. One application was made at a rate corresponding to 750 g ai/ha. Peach fruits were collected 53 days after application. At that time, 86.1% of the AD was distributed on the leaves, 7.3% on the stem and 6.6% (0.77 mg/kg) on the fruit concentrated mainly in the peel (11 mg/kg) with low concentration (0.12 mg/kg) in the pulp.

In the fruit, parent tolfenpyrad was found at levels of 0.53 mg/kg (65% of TRR) 53 days after application. The only identified metabolite, OH-PAM, was found in the pulp at 0.03 mg/kg (4.0% of TRR).

In the leaves, parent tolfenpyrad was found at levels of 21.1 mg/kg (32.7% of TRR) after 56 days. Free PT-CA was the main metabolite found at 10.0 mg/kg (15.5% of TRR) with a contribution of glucose-conjugated PT-CA at 0.94 mg/kg (1.5% of TRR) followed by other metabolites present at less than 10% TRR.

The studies indicated that the translocation of unchanged tolfenpyrad was very limited. The predominant part of the TRR was located in the peel (86.4–94.6%) of the fruit residue.

Radish

[Tolyl-U-¹⁴C]-tolfenpyrad or [pyrazole-¹⁴C]-tolfenpyrad were applied to radish located outdoors. Each plot received two applications, 14 days apart, at a nominal rate of 230 g ai/ha. Radish plants were sampled 1 day after the second application and separated into root and foliage samples.

Labelled tolfenpyrad distributed into the roots (0.44–0.59 mg/kg, 4.9–5.2% of AD) and the foliage (7.0–11 mg/kg, 94.8–95.1% of TRR).

The major residues in radish roots were tolfenpyrad (0.24 mg/kg, 54.0% of TRR), PT-CA (0.11 mg/kg, 21.5% of TRR). Other metabolites amounted to less than 10%TRR except conjugated OH-PAM and PAM which were the major metabolite found in radish roots at 32.2% and 26.7% TRR respectively.

The major residue in foliage was tolfenpyrad (9.31 mg/kg, 85.0% of TRR) with a much lesser amount of metabolites amounting to less than 4% of TRR.

In summary, the metabolic pathways of tolfenpyrad in three different crops were considered comparable. In each case, unchanged parent accounted for a very significant proportion of the residue. All three crops contain the identified metabolites OH-PT (not observed but assumed in radish as an intermediate to OH-PAM), OH-PAM, PAM and PT-CA.

Environmental fate in soil and water

The Meeting received information on photolysis on soil, aerobic degradation in soil, aqueous photolysis and confined and field rotational crop studies.

Soil photolysis

A photolysis study of [¹⁴C] tolfenpyrad was conducted in sandy loam soil exposed to artificial light (290 nm) for 13 days. In the light exposed samples, unextracted radiocarbon increased slowly reaching an average of 3.2% (pyrazole label) and 10.7% (tolyl label) of applied radioactivity (AR) by day 313. Only minimal radiocarbon was recovered (0.3%) in traps of organic volatiles for light exposed samples, and none in dark control samples. Photoproducts consisted mainly of PT-CHO, PAM and OH-PAM present at a maximum of 6.6%, 11.3% and 3.5% AD, respectively in both labels. Tolfenpyrad showed negligible degradation in dark control samples with an average of 90% still present as parent in both labels at the end of the study. The PT-CA was the major degradate (2.0% in pyrazole labelled material and 4.7% in tolyloxy labelled material). The calculated half-life of tolfenpyrad was 444 days from tolyl label and 624 days from pyrazole label. The results indicate that photolysis is a very minor route of the degradation of tolfenpyrad

Aerobic soil metabolism

An aerobic soil metabolism study was conducted on a California sandy loam soil using [¹⁴C] tolfenpyrad. The treated samples were incubated in the dark at 25 °C for periods up to 365 days. Tolfenpyrad degraded rapidly in soil under aerobic conditions and represented an average of 30.0% AR by day 21, declining to an average of 1.6% at the end of the incubation period. The primary degradates observed in the study were CO₂, PT-Cam PCA and soil bound residues. The soil bound residues were completely mineralised within one year. The calculated DT₅₀ and DT₉₀ values were maximum 14 and 78 days, respectively, indicating that tolfenpyrad is not persistent.

Confined rotational crop study

Tolfenpyrad radiolabelled in two positions (pyrazole- and tolyl-rings) was applied to test plots at a target application rate of 350 g ai/ha. Lettuce, radish and wheat were planted at intervals of 30, 120 and 365 days after single bare soil application. Samples were taken at appropriate harvest times and analysed for residues.

Metabolites at ≥ 0.01 mg/kg were OH-PAM (free and conjugated), OH-PCA (free and conjugated), and PAM (radish foliage and root only). A number of other metabolites were detected in combined extracts, but each was < 0.01 mg/kg or $< 10\%$ of TRR. Conjugates of OH-PAM and OH-PCA were liberated by acid hydrolysis.

Following pyrazole labelled tolfenpyrad application the detected metabolites in lettuce amounted up to 0.02 mg tolfenpyrad equivalent. The free and conjugated OH-PAM, OH-PCA and PAM were the major metabolites, each was less than 26% TRR. No other single metabolite represented more than 2.5% TRR (< 0.01 mg/kg).

In radish foliage the detected metabolites (at 0.02–0.03 mg tolfenpyrad equivalent/kg) were the OH-PAM conjugates (20%TRR) the OH-PCA conjugates (24% TRR) as well as free OH-PAM and PAM with lesser amounts of OH-PCA and PT-CA.

In radish roots, the only detected metabolites were the OH-PCA conjugates (27% TRR) as well as free OH-PAM (8.5%TRR) and PAM (24.5%TRR).

In wheat grain, none of the metabolites were detected (< 0.01 mg/kg).

In wheat forage the predominant metabolites were the OH-PAM conjugates (≤ 0.16 mg eq/kg, 29.7% TR at 30 days PBI) the OH-PCA conjugates (0.17 mg eq/kg) as well as free OH-PCA (0.09) with lesser amounts of OH-PAM, PAM and PCA. No other single metabolite represented more than 5.2% TRR (0.01 mg/kg).

In wheat hay and straw the maximum concentrations were for OH-PAM conjugates (0.4 mg eq/kg, 32%TR) and OH-PCA conjugates (0.17 mg eq/kg). With exception of OH-PAM conjugates in wheat hay, all identified metabolites show a decrease with increasing aging of the soil.

Following the treatment with tolyl- labelled compound no relevant concentration of any individual compounds were found in lettuce, radish, wheat forage, hay, straw and grain at any plant-back interval. Only trace amounts of PT-CA were found in radish (120-day) and wheat hay (30-day) samples. In summary, tolfenpyrad is a minor residue (< 0.01 mg/kg) in confined rotational crops (lettuce, radish, and wheat). Most radiolabelled residues derived from cleavage of the amide bond, resulting in pyrazole and diphenyl ether fragments.

Field rotational crop studies

Two field trials were carried on mustard greens as the primary crop treated at about maximum seasonal rate of 0.598 kg ai/ha. The primary crop was removed from the trials at normal harvest with a PHI of one day after last application. Rotational crops (radish, lettuce and sorghum) were planted at intervals of 14, 28–30 and 58–60 days after last application.

At normal harvest of the rotational crops, no residues of tolfenpyrad, OH-PAM, OH-PCA and PAM were found above the LOQ in radish roots, lettuce and sorghum forage, grain and stover. Residues of OH-PAM and OH-PCA at the LOQ (0.01 mg/kg) were found at rotational intervals of 14 and 30 days after last application only in radish tops from one trial site.

Methods of analysis

The HPLC methods for determining the parent compound and OH-PT metabolite residues in plant matrices are based on three repeated extractions with methanol, followed by various solid phase extraction clean-up(s). The cleaned samples either concentrated or diluted to known volume before determination with HPLC-MS/MS. The LOQ for both compounds in all matrices is 0.01 mg/kg, except tea (0.05 mg/kg). The specificity of the detection was assured with two mass transitions. Average recoveries were all within the acceptable range of 70–120%, with relative standard deviations (RSD) below 20%.

For the rotational crop study the method used was validated for the determination of tolfenpyrad, OH-PAM, PAM and OH-PCA. Recovery data were generated from three samples fortified at the LOQ and three samples fortified at $10 \times$ LOQ for each matrix. The mean percentage recoveries at 0.01 mg/kg and 0.1 mg/kg were generally between 70–110% with RSD $< 20\%$. There

were some deviations especially when the extracts were hydrolysed. The mean recoveries and RSD values were in some cases outside the nominal ranges, but the differences were not significant taking into account the limited number of tests.

The HPLC-MS/MS methods were developed for determination of tolfenpyrad and its metabolites PT-CA, OH-PT-CA and PCA in animal commodities with an LOQ of 0.01 mg/kg. The milk samples were extracted with methanol, the tissues with methanol/water (5/1). The extracts were partitioned into ethyl acetate after adding either citric acid (milk and fat) or sodium chloride (muscle, liver and kidney). After evaporation to dryness the extracts were taken up in methanol or hexane and partly subjected to SPE clean-up. The other part of the milk, liver and fat extracts was hydrolysed. The final extracts were analysed by HPLC/MS/MS. The specificity of the detection was assured by two mass transitions for tolfenpyrad and three transitions for the metabolites. Repeatability data was generated from three samples fortified at the LOQ and three samples fortified at $10 \times$ LOQ for each matrix. The mean percentage recoveries at each fortification level were within 70–110, except PT-CA in liver with hydrolysis (65% at 0.01 mg/kg), fat with hydrolysis (60% at 0.1 mg/kg) and OH-PT-CA in fat with hydrolysis (64% at 0.01 and 69% at 0.1 mg/kg). In spite of some deviations, the methods applied in the studies are considered suitable for the intended purpose.

Stability of residues in stored analytical samples

In plant matrices, freezer storage stability (at about -20 ± 5 °C) of tolfenpyrad and OH-PT has been demonstrated in tomatoes, apples, lettuce, grapes, oranges, almonds (nutmeat and hulls), cottonseed oil and potato flakes (18 months), peaches (4 months), prunes (dried) (5 months), cucumbers (5.5 months), cauliflower (6 months), and tea (12 months).

Freezer storage stability of tolfenpyrad, OH-PAM, OH-PCA and PAM has also been demonstrated in radish (roots) (112 days), lettuce (150 days) and sorghum forage (114 days), stover (87 days) and grain (109 days). This covers high acid, high water, high starch and high oil content crops.

When stored < 0 °C tolfenpyrad, PT-CA and OH-PT-CA were stable in bovine muscle (85 days), kidney (85 days), fat (99 days) and milk (177 days). The average OH-PT-CA residue remained in liver was 39% after 111 days storage, but the procedural recoveries (41%) were similar. PCA was stable in fat and milk.

Definition of the residue

In goat, the parent tolfenpyrad was not detected in liver, and kidney, but it was found at < 0.01 mg/kg in milk (2.9–4.1% of TRR) and muscle (10% TRR) and at 0.04–0.06 mg/kg in fat (13.6–17.3% TRR).

The major radioactive residue derived from the administration of pyrazole and tolyl labelled tolfenpyrad was PT-CA being present up to 0.03 mg/kg (16.9% TRR) in milk, 0.09 mg/kg (63.3% TRR) in muscle, 13.1 mg/kg (51.8% TRR) in liver, 4.33 mg/kg (62.6% TRR) in kidney, and 0.06 mg/kg (16.3% TRR) in fat.

The concentration and % proportion of TRR of OH-TP-PCA derived from administration of pyrazole- or tolyl-labelled tolfenpyrad was up to 0.03 mg/kg (16.9%) in milk, < 0.01 mg/kg (8.9%) in muscle, 6.8 mg/kg (26.9%) in liver, 1.3 mg/kg (19.3%) in kidney, and it was not detected in fat. The other metabolites identified were present at substantially lower concentrations.

Dairy cattle feeding study revealed that in milk, the only detected residue (> 0.01 mg/kg) is PT-CA which can be recovered after hydrolysis with maximum concentration of 0.27 mg/kg. In cream derived from 2.5 and 25 ppm dose groups the parent tolfenpyrad was present in about 0.01–0.02 mg/kg, respectively, and PT-CA were present at approximately 25 times higher concentration in conjugated form than in free form. In muscle, fat, liver and kidney the PT-CA is the major residue. Hydrolysis of samples revealed that only free PT-CA is present in the liver.

In the study with laying hens administered with labelled tolfenpyrad the parent tolfenpyrad was found at low concentrations < 0.01 mg/kg, (1.2–1.8% TRR) in eggs, muscle and liver, but it was present at 0.06 mg/kg (14–15%TRR) in fat.

The PT-CA occurs as a major residue up to 0.07 mg/kg (41%TRR) in eggs, 0.10 mg/kg (85%TRR) in muscle, 1.4 mg/kg (79%TRR) in liver, and 0.07 mg/kg 15% TRR) in fat. PT-CA is converted to OH-PT-CA, which was found up to 0.09 mg/kg (5.2% TRR) in liver and < 0.01 mg/kg (2.7%TRR) muscle.

Analytical methods are available for the simultaneous determination of tolfenpyrad, and free PT-CA, OH-PT-CA and PCA in one step and the conjugates can be released in a separate step after alkaline hydrolysis. However, the latter procedure could be carried out with sometimes low and varying recovery and it is not considered suitable for routine analyses.

Taking into account the relative proportions and concentration of the parent tolfenpyrad and its metabolites, and the availability suitable analytical method, the sum of tolfenpyrad and the free PT-CA are considered suitable marker compounds for enforcement purposes. For dietary risk assessment the free and the conjugated PT-CA, OH-PT-CA should be considered, because they have a toxic potency similar to PT-CA and OH-PT-CA.

PT-CA, the major residue component is present in higher concentration in muscle than in fat. OH-PT-CA was not present in fat. The Meeting concluded that the residue is not fat soluble.

The parent tolfenpyrad was present in outer leaves of cabbage at 4.71 mg/kg 28 days after treatment while the concentrations of all the identified metabolites were below 0.3 mg/kg

The concentrations of parent tolfenpyrad were 3.95 mg/kg (89.4%TRR) and 0.37 mg/kg (70% TRR) in peach fruits 14 and 28 days after treatment. In the same samples and sampling time T-AM, PT-OH, PT-CA were present at 0.12 and < 0.02 mg/kg, 0.06 and nd mg/kg, and 0.06 and nd mg/kg, respectively.

Radish leaves and roots on day 1 after the 2nd application contained 5.7 mg/kg and 0.24 mg/kg parent residue respectively, while any of the identified metabolites were present at less than 10% and 20% of the parent compound, respectively.

No residue is expected above 0.01 mg/kg in any rotational crops.

The Meeting noted that the parent tolfenpyrad is the major residue in plant commodities and it is a good marker for compliance with GAP.

The Meeting recommended the following residue definitions for tolfenpyrad:

Definition of the residue for compliance with the MRL and estimation of dietary intake for plant commodities: *tolfenpyrad*.

Definition of the residue for compliance with the MRL and estimation of dietary intake for animal commodities: *sum of tolfenpyrad, and free and conjugated PT-CA (4-[4-[(4-chloro-3-ethyl-1-methylpyrazol-5-yl)carbonylamino]methyl]phenoxy]benzoic acid and OH-PT-CA (4-[4-[(4-chloro-3-(1-hydroxyethyl)-1-methylpyrazol-5-yl]carbonylamino]methyl]phenoxy] benzoic acid) (released with alkaline hydrolysis) expressed as tolfenpyrad*.

The residue is not fat soluble.

Results of supervised trials on crops

The Meeting received supervised trials for a number of commodities from the USA for which there were no authorised uses. Trials were received from Japan where tolfenpyrad is authorised for use on tea. The residues obtained from supervised trials not supported by GAP are summarized in the JMPR Monograph but were not used for the estimation of STMR, HR and maximum residue levels.

Tea

Four residue trials were conducted on green tea in 1997–98 in Japan. One foliar application of tolfenpyrad was made with spray solutions of 0.0015 kg/hL following the design of reverse decline

trials. The treated plots of each trial were harvested at a PHI of 7, 14, 21 and 30 days after treatment and the samples were analysed twice at intervals of about 1 year.

The GAP in Japan permits one foliar application of 15% EC formulation in 1000 times dilution using 2000–4000 L/ha water. The PHI is 14 days.

The average residues obtained in replicate samples taken at 14 days were: 3.77, 4.29, 7.05 and 12.1 mg/kg.

The Meeting estimated a maximum residue level of 30 mg/kg, an STMR value of 5.65 mg/kg and 13.8 mg/kg of STMR and HR values for green tea, respectively

Fate of residues during processing

Following one application of tolfenpyrad at rates of 0.30 kg ai/ha or 0.45 kg ai/ha, mean residues of tolfenpyrad were substantially reduced in tea infusion to the levels of 0.20 mg/kg, 0.06–0.08 mg/kg, 0.01 mg/kg and < 0.01 mg/kg, respectively, at PHIs of 7, 14, 21 and 30 days.

In a second study tolfenpyrad was applied at a rate of 0.6 kg ai/ha. Tolfenpyrad residues were substantially reduced in tea infusion to the levels of 1.12–2.21 mg/kg, 0.14–0.49 mg/kg and < 0.01 mg/kg, respectively, at PHIs of 7, 14 and 28 days. The two sets of trials gave about four times different average processing factors, therefore the larger factor (0.043) is used for dietary intake assessment.

The Meeting estimated for green tea infusion an STMR value of 0.24 mg/kg.

Residues in animal commodities

Farm animal dietary burden

As there are no registered uses on animal feed, the animal burden cannot be calculated.

Farm animal feeding studies

In a dairy cattle feeding study, tolfenpyrad was administered orally by gelatine capsules for 28 consecutive days to 3 groups of 3 cows at dose levels equivalent to 2.5 (2×), 7.5 (6×) and 25 (20×) ppm in feed. Residues of tolfenpyrad and its metabolites PT-CA, OH-PT-CA or PCA were determined in milk and tissues. Neither the parent compound nor any of the metabolites were detected in any samples derived from control animals.

Residues in Milk

No quantifiable residues of tolfenpyrad, PT-CA, OH-PT-CA or PCA were detected in milk from cows treated with tolfenpyrad at the 2× and 6× dose levels, except PT-CA (0.02 mg/kg and 0.08 mg/kg, respectively) released by hydrolysis. In milk samples of the 6× dose group, no quantifiable free or conjugated residues were detected for tolfenpyrad, OH-PT-CA or PCA, whereas free or conjugated residues of PT-CA were present with maximums of 0.01 mg/kg and 0.27 mg/kg. In general the free metabolite corresponds to approximately 5–10% of the conjugated metabolite.

In milk samples of the 20× dose group, no free PCA and only trace levels of tolfenpyrad and OH-PT-CA averaging below LOQ were detected. Free PT-CA close to the LOQ was found after day 13. Conjugated PT-CA was found at significantly higher concentrations, reaching a plateau near 0.25 mg/kg by day 16. During two weeks of depuration no metabolites were detected in milk with the exception of a residue of 0.07 mg/kg PT-CA in the 31 days milk sample of the 20× dose group.

Residues in Cream and Skim Milk

In cream samples from the 2× dose group, only conjugated PT-CA residues were detected averaging 0.02 mg/kg and 0.01 mg/kg for days 13 and 28, respectively. No quantifiable residues were found in skimmed milk samples from the 2× dose group. In cream samples from the 20× dose group, comparable levels were found for free and conjugated tolfenpyrad corresponding to approximately

0.02 mg/kg for both 13 and 28 days. Conjugated PT-CA in cream was approximately 25 times higher than free PT-CA being present at a level of about 0.02 mg/kg. In skimmed milk only PT-CA was found in samples of the 20× dose group at levels of 0.01 mg/kg for free and 0.04–0.05 mg/kg for the conjugated form.

Residues in Muscle

Tolfenpyrad and OH-PT-CA residues were not present in quantifiable concentrations in the samples of every dose groups. The average PT-CA residues were present at 0.01 mg/kg, 0.02 mg/kg and 0.05–0.09 mg/kg in samples of dose groups of 2.5 ppm, 7.5 ppm and 25 ppm.

Residues in Liver

No parent tolfenpyrad residues were found in any treated liver sample. Residues of PT-CA were found in all dose levels in approximate proportion to the level of dosing. Free PT-CA residues after 28 days of dosing averaged for 0.65 mg/kg for the 2× dose level, 2.0 mg/kg for the 6× dose level, and 4.8 mg/kg for the 20× dose level. Conjugated residues of PT-CA were at a similar level, suggesting that only free PT-CA is present in the liver. After fourteen days of depuration, PT-CA residues (0.03 mg/kg) were reduced by a factor > 100 compared to the 28 days level (4.8 mg/kg). Also OH-PT-CA was found at a lesser extent than PT-CA. Residues of free OH-PT-CA averaged at 0.03 mg/kg, 0.07 mg/kg and 0.27 mg/kg for the 2×, 6× and 20× dose levels, respectively. Conjugated residues were less than or equal to residues of free OH-PT-CA, suggesting that only free metabolite is present in liver.

Residues in Kidney

No parent tolfenpyrad residues were found in kidney samples of the 2× and 6× dose groups. In the 20× dose group tolfenpyrad was present at the LOQ (0.01 mg/kg). Residues of PT-CA were found in all dose levels in approximate proportion to the level of dosing. PT-CA residues after 28 days of dosing were averaged for 0.13 mg/kg for the 2× dose level, 0.49 mg/kg for the 6× dose level, and 1.3 mg/kg for the 20× dose level. Residues of OH-PT-CA were less than the LOQ (< 0.01 mg/kg) for the 2× dose level and averaged at 0.02 mg/kg and 0.09 mg/kg for the 6× and 20× dose level, respectively. After fourteen days of depuration, residues of tolfenpyrad were below the LOD, and residues of PT-CA and OH-PT-CA were below the LOQ (< 0.01 mg/kg).

Residues in Fat

For the 2× dose level, no residues of tolfenpyrad, OH-PT-CA or PCA were found. Residues of free tolfenpyrad in the 6× and 20× dose levels averaged for 0.01 mg/kg and 0.065 mg/kg, respectively. Residues of free PT-CA in fat were below the LOQ (< 0.01 mg/kg) for the 2× dose level and averaged at 0.01 mg/kg and 0.04 mg/kg for the 6× dose level and the 20× dose level, respectively. Residues of OH-PT-CA and PCA were only detected in the 20× dose group samples at levels below the LOQ (< 0.01 mg/kg). Residues after sample hydrolysis were in a similar order indicating that no conjugated residues were present in fat. The depuration period showed a steady decline in residues with no determinable residues present by day 14 after last dosing.

Considering the residues in samples derived from the highest (20×) dose group, the free and conjugated PT-CA released with hydrolysis were the major residues in muscle (0.09 mg/kg), liver (6.9 mg/kg) kidney (1.8 mg/kg), and fat (0.04 mg/kg)

Parent tolfenpyrad was only present in milk cream and fat in the highest dose group.

PT-CA concentration rapidly decreased during depuration.

Animal commodity maximum residue levels

Without calculated animal burden no residue levels can be calculated for animal commodities.

RECOMMENDATIONS

On the basis of the data from supervised trials, the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI assessment.

Definition of the residue for compliance with the MRL and estimation of dietary intake for plant commodities: *tolfenpyrad*.

Definition of the residue for compliance with the MRL and estimation of dietary intake for animal commodities: *sum of tolfenpyrad, and free and conjugated PT-CA (4-[4-[(4-chloro-3-ethyl-1-methylpyrazol-5-yl)carbonylaminomethyl]phenoxy]benzoic acid and OH-PT-CA(4-[4-[[4-chloro-3-(1-hydroxyethyl)-1-methylpyrazol-5-yl]carbonylaminomethyl]phenoxy] benzoic acid) (released with alkaline hydrolysis) expressed as tolfenpyrad.*

The residue is not fat soluble.

Commodity		Recommended MRL, mg/kg	STMR or STMR-P (mg/kg)	HR or HR-P (mg/kg)
CCN	Name	New		
	Green tea	30	5.65	—
	Green tea infusion		0.24	—

DIETARY RISK ASSESSMENT

Long-term intake

The evaluation of tolfenpyrad resulted in recommendations for STMR-P value for green tea infusion which was used for the calculation. The results are shown in Annex 3 of the 2013 JMPR Report. The International Estimated Daily Intake for the 13 GEMS/Food diet based on estimated STMR value was up to 0–11% of maximum ADI of 0.006 mg/kg bw. The Meeting concluded that the long-term intake of residues of tolfenpyrad from green tea is unlikely to present a public health concern.

Short-term intake

The International Estimated Short-term Intake (IESTI) for tolfenpyrad was calculated for green tea infusion for which STMR-P value was estimated. The results are shown in Annex 4 of the 2013 JMPR Report. The IESTI was 50 to 100% of the ARfD (0.01 mg/kg bw) for the general population.

Meeting concluded that the short-term intake of residues of tolfenpyrad resulting from its use on green tea is unlikely to present a public health concern.

TRIAZAPHOS (143)

First draft prepared by Ms T. van der Velde-Koerts, Centre for Nutrition, Prevention and Health Services (VPZ), National Institute of Public Health and the Environment, The Netherlands

EXPLANATION

Triazophos is an organophosphorus insecticide and acaricide and shows a broad-spectrum activity against a wide range of insect pests after soil or foliar treatment of crops. Triazophos was first evaluated by the JMPR in 1982 for toxicology and in 1983 for residues. Since then, triazophos has been evaluated several times. Triazophos has been evaluated within the periodic review programme by the 2002 JMPR for toxicological aspects and by the 2007 JMPR for residue aspects. The 2002 JMPR established an ADI of 0–0.001 mg/kg bw and ARfD of 0.001 mg/kg bw. The 2007 JMPR confirmed its previous residue definition: triazophos (for compliance with the MRL and for estimation of dietary intake). The 2007 JMPR evaluated the triazophos residues in food and withdrew its previous recommendations except for cotton seed, cotton seed oil and soya bean (immature seeds). The 2010 JMPR evaluated additional residue data on rice and soya bean (immature seeds).

The 2010 JMPR Meeting estimated a maximum residue level of 2 mg/kg in/on husked rice (brown rice), and a median residue of 0.421 mg/kg based on 15 trials conducted in China in 2008 and 2009. Triazophos was applied at the target rate of 3–4× 0.506 kg ai/ha (ME formulation) or 3–4× 0.45 kg ai/ha (EC formulation) with a 28 day PHI each. No recommendation of MRL was made because the short-term intake from residues in rice was 260 % of the ARfD for children and general population. There was no alternative GAP to be considered. The JMPR 2010 considered studies on the effect of processing (polishing, cooking, frying) desirable to obtain more realistic information on residue levels in food actually consumed. It was listed by the Forty-fourth Session of CCPR for the 2013 JMPR for reconsideration of MRL for rice.

China submitted processing data from rice, which were evaluated by the present Meeting.

RESIDUE ANALYSIS***Analytical methods***

The Meeting received additional information on the analytical method used in the processing study on rice.

In the analytical method used in the rice processing study, rice commodities of 20.0 g were immersed in 40 mL water for 30 min and extracted with 80 mL acetone by shaking for 30 min. The filtered solution was evaporated to 50 mL and extracted with ethyl acetate. The extract was evaporated at 40 °C to remove the ethyl acetate. Triazophos (parent) was determined with GC-FPD. The recoveries were within 70%–120% at 0.004–3.0 mg/kg for rice (paddy, husked, polished). Precision (RSD) was less than 20% at each level. The valid LOQ was 0.004mg/kg for each commodity [Lifen, 2011].

Stability of pesticide residues in stored analytical samples

No storage stability studies were submitted for rice or its processed commodities.

Storage stability studies were provided to the 2007 Meeting demonstrating the stability of residues in stored samples of cotton fibre, cotton seed, oranges, carrots and soil. No significant decrease of triazophos was observed in analytical samples of cotton fibre, cotton seed, oranges and carrots stored at ≤ -18 °C for up to 24 months. Therefore storage stability for rice commodities is covered up to 24 months.

FATE OF RESIDUES IN STORAGE AND PROCESSING

In processing

The Meeting received a processing study on rice.

Paddy rice plants were treated in the field in two locations in China in 2011 [Lifen, 2011]. In each location, two pre-harvest applications of 0.45 kg ai/ha with an interval of 10 days were conducted with an EC formulation. Rice plants were harvested at maturity at DAT 28 and 35. The rice plants were left to dry for 10 days in the field. Dried rice grains (10 kg) from each plot were processed into husked and polished rice in two locations in China (Hebei and Zhejiang).

Husked rice: Replicate 1 kg samples of dried rice grains were processed into husked rice (Longgu rice huller), resulting in 0.83 kg husked rice and 0.16–0.17 kg hulls.

Polished rice: A 3 kg sample of dried rice grains was processed into husked rice (Longgu rice huller). Then replicate 400 g samples of husked rice were processed into polished rice using a local-made rice polisher. Three polish times were used (50, 60 and 70 sec). Processing resulted in 330–335 g polished rice and 58–64 g rice bran (50 sec), 321–329 g polished rice and 64–71 g rice bran (60 seconds) and 306–307 g polished rice and 80–82 g rice bran (70 sec).

Polished rice 1 step: In reality, most of the rice grain is stored in China as rice grains (i.e. un-husked rice), then husked and milled together in one step before selling in the market. So a second processing experiment was conducted where replicate 10 kg dried rice grain samples were processed into polished rice in one step using a local-made rice polisher.

All samples (rice grains, husk, husked rice, polished rice, rice bran) were stored at -20 °C and were analysed within 30 days of storage. Samples were analysed using a GC-FPD method. Results are summarized in table 1. The average values for the rice grains (RAC) were 3.71 and 3.15 mg/kg in Hebei at 28 and 35 days PHI, respectively, and 4.14 and 4.86 mg/kg in Zhejiang at 28 and 35 days, respectively at 2× 0.45 kg ai/ha with an interval of 10 days.

Table 2 gives an overview of processing factors in rice grains into husked rice and polished rice. Since the maximum residue level recommendation was given for husked rice (brown rice), also the processing factors from husked rice to polished rice are indicated. Several processing studies were conducted on polished rice. The processing study in Zhejiang resulted in significantly higher processing factors for polished rice than in Hebei. Therefore only the processing data from Zhejiang were taken.

Table 2 Overview of processing factors for triazophos

APPRAISAL

Triazophos is an organophosphates insecticide and acaricide and shows broad-spectrum activity against a wide range of insect pests via soil or foliar treatment of crops. Triazophos was first evaluated by the JMPR in 1982 for toxicology and in 1983 for residues and has been evaluated several times since. Triazophos was evaluated within the periodic review programme by the 2002 JMPR for toxicology and by the 2007 JMPR for residues. The 2002 Meeting established an ADI of 0–0.001 mg/kg bw and an ARfD of 0.001 mg/kg bw. The 2007 JMPR confirmed its previous residue definition: *triazophos* (for compliance with the MRL and for estimation of dietary intake). The 2007 JMPR evaluated the triazophos residues in food and withdrew its previous recommendations except for cotton seed, cotton seed oil and soya bean (immature seeds). The 2010 JMPR evaluated additional residue data on rice and soya bean (immature seeds).

The 2010 JMPR Meeting estimated a maximum residue level of 2 mg/kg in/on husked rice (brown rice), and a median residue of 0.421 mg/kg based on 15 trials conducted in China in 2008 and 2009. Triazophos was applied at the target rate of either 3–4 × 0.506 kg ai/ha (ME formulation) or 3–4 × 0.45 kg ai/ha (EC formulation) both with PHIs of 28 days. No maximum residue level recommendation could be made because the estimated short-term intake from residues in rice was 260% of the ARfD for children and general population. There was no alternative GAP available. The 2010 JMPR considered that studies on the effect of processing (polishing, cooking, frying) to be desirable as they would enable a more realistic estimation of residue levels in food actually consumed. Triazophos was listed by the Forty-fourth Session of CCPR for the 2013 JMPR for reconsideration of residues in rice.

China submitted processing data for rice, which were evaluated by the present Meeting.

Methods of analysis

The Meeting received a description and validation data for an analytical method of triazophos on processed commodities of rice. The analytical method was based on extraction with acetone and

determination of triazaphos with GC-FPD. The Meeting considered the method valid in the range 0.003–3.0 mg/kg triazaphos in rice grains, husked rice, polished rice and rice bran.

Stability of residues in stored analytical samples

No storage stability data were received for rice or its processed commodities. Storage stability studies were provided to the 2007 Meeting which demonstrated stability of residues in stored samples of cotton fibre, cotton seed, oranges, carrots and soil for a period of up to 24 months. The Meeting agreed that these studies covered storage stability for rice commodities.

Results of supervised residue trials on crops

The 2010 JMPR Meeting estimated a maximum residue level of 2 mg/kg in/on husked rice (brown rice), and a median residue of 0.421 mg/kg based on 15 trials in/on paddy rice conducted in China in 2008 and 2009.

An additional two trials on paddy rice were submitted to the present Meeting. The trials were conducted in China with 2 applications at 0.45 kg ai/ha instead of 3 applications at 0.45 kg ai/ha (cGAP in China). Since the residues were higher compared to the JMPR 2010 data, the Meeting decided to include the mean value per location (3.7 and 4.9 mg/kg) from these trials with the JMPR 2010 data. This resulted in the following dataset: 0.059, 0.059, 0.060, 0.087, 0.13, 0.34, 0.35, 0.42, 0.51, 0.68, 0.76, 0.81, 0.89, 1.0, 1.2, 3.7, 4.9 mg/kg (n=17).

Based on the 17 trials conducted in China, the Meeting estimated a maximum residue level of 7 mg/kg in/on rice grain and a median residue of 0.51 mg/kg. As rice grains (i.e., rice with hulls) are not traded, the Meeting agreed that a maximum residue level recommendation for rice was not appropriate and decided to use the residue values for rice, to estimate maximum residue levels for husked rice and polished rice.

Fate of residues during processing

Information on the fate of triazaphos during processing was provided for rice. In the table below, relevant processing factors for this commodity are summarized based on the residue definition of *triazaphos*. Hydrolysis studies under cooking conditions or processing studies for cooking of rice were not submitted to the present or previous Meetings.

Using the $STMR_{RAC}$ obtained from triazaphos use, the Meeting estimated STMR-Ps for processed commodities as listed below. An HR-P is not required for processed rice commodities.

Commodity	Processing factors (triazaphos)	Max level = $Max_{RAC} \times PF$	$STMR-P = STMR_{RAC} \times PF$ mg/kg
rice grains – husked, dry	0.24 (n=15, mean)	$7 \times 0.24 = 1.68$	$0.51 \times 0.24 = 0.12$
rice grains – polished, dry	0.080 (n=6, median)	$7 \times 0.080 = 0.56$	$0.51 \times 0.080 = 0.041$

The Meeting confirmed its previous recommendation of 2 mg/kg in/on husked rice, and estimated an STMR-P of 0.12 mg/kg.

The Meeting estimated a maximum residue level of 0.6 mg/kg in polished rice and an STMR-P of 0.041 mg/kg.

Residues in animal commodities

The 2007 JMPR concluded that because of the lack of appropriate animal livestock metabolism study, a residue definition for animal products could not be determined and therefore the Meeting could not make use of the results of the feeding studies. Consequently, the residues in animal products derived from the use of triazaphos on rice and its processed commodities were not considered by the present Meeting.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for use in dietary risk assessment.

Definition of residue (for compliance with the MRL and for estimation of dietary intake): *triazophos*.

CCN	Commodity name	MRL mg/kg	STMR or STMR-P mg/kg	Notes
CM 0649	Rice, husked	2	0.12	A public health risk cannot be excluded
CM 1205	Rice, polished	0.6	0.041	-

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Daily Intakes (IEDI) of for triazophos was calculated from recommendations for STMRs for raw and processed commodities in combination with consumption data for corresponding food commodities by the 2007, 2010 and 2013 JMPR. The IEDI of in the 13 GEMS/Food cluster diets, based on the estimated STMRs were in the range 1–40% of the maximum ADI of 0.001 mg/kg bw. The 2013 Meeting concluded that the long-term intake of residues of triazophos from uses considered by the 2007, 2010 and 2013 Meeting is unlikely to present a public health concern. The results are shown in Annex 3 of the 2013 Report.

Short-term intake

The International Estimated Short Term Intake (IESTI) for triazophos was calculated for rice and its processed commodities for which maximum residue levels were estimated and for which consumption data were available. For those processed commodities, where no processing data were available, the STMR-P for polished rice was used for rice flour, rice beer and rice wine, while the STMR-P for husked rice was used on all other processed commodities. Since husked rice and polished rice are not consumed raw, but in cooked form and consumption data are available for the cooked form, a default dilution factor of 0.4 was used to compensate for the swelling during cooking. A default dilution factor of 0.04, 0.19 and 0.15 was used on rice milk, rice beer, and rice wine respectively. The results are shown in Annex 4 of the 2013 Report.

The IESTI for rice and its processed commodities and based on the 2012 consumption data and an ARfD of 0.001 mg/kg bw represents 0–130% of the ARfD for cooked husked rice consumption of children of 1–6 years in Japan, and 0–100% of the ARfD for all other processed rice commodities by children or general population.

The Meeting concluded that the short-term intake of residues of triazophos resulting from its uses that have been considered by JMPR might present a public health concern. There was no alternative GAP to be considered and refinement of the dietary risk assessment by using processing factors for husked rice still showed a potential public health concern. Processing studies from rice (husked and polished) are desirable for further refinement of the exposure.

The 2002 Meeting established an ARfD of 0.001 mg/kg bw on the basis of the NOAEL of 0.0125 mg/kg bw per day in the 3-week study in humans and a safety factor of 10. Hence, further refinement is unlikely in the toxicological assessment.

TRIFLUMIZOLE (270)

Draft prepared by Dr Michael Doherty, U.S. Environmental Protection Agency, Washington, DC USA

EXPLANATION

Triflumizole is a broad-spectrum foliar fungicide that controls a variety of fungal diseases in fruits and vegetables. It acts as a protectant and as an eradicant by preventing disease symptoms after infection has occurred. The anti-sporulant activity of triflumizole reduces spores after lesions become visible. Triflumizole belongs to the demethylation inhibitor (DMI) group of fungicides classified as Group 3 by the Fungicide Resistance Action Committee (FRAC). Triflumizole has protective and curative actions, and acts as an inhibitor of chitin biosynthesis. The product is mixed with water and applied as a foliar spray using ground equipment equipped for conventional spraying on crops.

Triflumizole was scheduled by the Forty-fourth Session of the CCPR for evaluation as a new compound by the 2013 JMPR. The Meeting received information on identity, animal and plant metabolism, environmental fates in soil, rotational crops, analytical methods, storage stability, use patterns, supervised trials, dairy cattle feeding studies, and fates of residues in processing.

IDENTITY

Common name	Triflumizole
IUPAC	(E)-4-chloro- α,α,α -trifluoro-N-(1-imidazol-1-yl-2-propoxyethylidene)-o-toluidine
CAS	[N(E)]-4-chloro-N-[1-(1H-imidazol-1-yl)-2-propoxyethylidene]-2-(trifluoromethyl)benzenamine (formerly 1-[(1E)-1-[[4-chloro-2-(trifluoromethyl)phenyl]imino]-2-propoxyethyl]-1H-imidazole)
CAS Registry No	68694-11-1 (formerly 99387-89-0)
CIPAC No	730
Synonyms	NF-114, A815

Structural formula:

Molecular formula	$C_{15}H_{15}ClF_3N_3O$
Molecular weight	347.5 g/mol

Formulations

Triflumizole is available in the following formulations:

- Suspension concentrate (SC) nominally containing 480 g/L active ingredient;
- Water soluble concentrate (WS) nominally containing 500 g/kg active ingredient;
- Emulsifiable concentrate (EC) nominally containing 150 g/L active ingredient.

The common trade names are Procure[®] 480SC, Procure[®] 50WS, Terraguard[®] SC, and Rocket[®] EC.

METABOLISM AND ENVIRONMENTAL FATE

The metabolism of triflumizole was investigated in animals, plants, and environmental systems using test material universally labelled with ¹⁴C in the phenyl ring (Figure 1). The major metabolites/degradation products from these studies are shown in the table below.

Figure 1 Test material for the studies using radiolabelled triflumizole

Chemicals identified as major components in the metabolic and degradation pathways of triflumizole

Identifier	Chemical Name	Chemical Structure	Test System
Triflumizole	(E)-4-chloro- α,α,α -trifluoro-N-(1-imidazol-1-yl-2-propoxyethylidene)-o-toluidine		Primary Crops
FM-6-1	N'-[4-chloro-2-(trifluoromethyl) phenyl]-2-propoxyethanimidamide		Primary Crops, Soil
FA-1-1	4-chloro-2-(trifluoromethyl)aniline		Egg and Milk
FM-8-1 (Free and sulphate conjugate)	N'-[4-chloro-2-(trifluoromethyl) phenyl]-2-hydroxyethanimidamide		Milk
FA-1-glucuronide	6-[4-chloro-2-(trifluoromethyl) phenoxyethyl]-3,4,5-trihydroxyoxane-2-carboxylic acid		Milk
FA-1-5 (Free and sulphate conjugate)	2-amino-5-chloro-3-(trifluoromethyl)phenol		Milk

Identifier	Chemical Name	Chemical Structure	Test System
FD-2-1	N-[4-chloro-2-(trifluoromethyl) phenyl]-2-hydroxyacetamide		Milk
FD-7-1	{[4-chloro-2-(trifluoromethyl) phenyl]carbamoyl} formic acid		Milk, Soil
FD-9-1 (IV)	[4-chloro-2-(trifluoromethyl) phenyl]urea		Rotational Radish Top Wheat Grain Wheat Hay Wheat Straw
FM-5-1	N-(1-{[4-chloro-2-(trifluoromethyl) phenyl]imino}-3-propoxypropyl)formamide		Egg
XIV	(2Z)-4-hydroxyhex-2-enedioic acid		Rotational Lettuce Radish Top
XXV	1-[4-chloro-2-hydroxy-6-(trifluoromethyl)phenyl]-3-hydroxyurea		Rotational Radish Root
XXVIII	3-(2-aminoprop-2-enoyl)-1-[4-chloro-2-(trifluoromethyl) phenyl]urea		Rotational Wheat Grain
XXIII	Glucose conjugate of FM-8-1		Rotational Lettuce

Identifier	Chemical Name	Chemical Structure	Test System
V	[4-chloro-2-hydroxy-6-(trifluoromethyl)phenyl]urea		Rotational Wheat Straw
XXVI	Glucose conjugate of V		Rotational Wheat Forage

Animal metabolism

The meeting received studies investigating the metabolism of triflumizole in rats, lactating goats and laying hens.

Rats

The metabolism of [^{14}C]triflumizole by rats was evaluated by the WHO Core Assessment Group.

Lactating Goats

The metabolism of [^{14}C]triflumizole by lactating goats was investigated by Knipe and Harned (1985), with a continuation by Knipe (1986). A single goat was orally dosed for 5 consecutive days with [^{14}C]triflumizole labelled in the phenyl ring. Dosing was twice daily by gelatin capsule at 500 $\mu\text{Ci}/\text{dose}$, amounting to 14.3 mg/kg/day (280 ppm in feed). Milk, urine, and faeces were collected twice daily for 6 days, and tissue samples (muscle, fat, kidney and liver) were obtained at sacrifice, which was 6 days after the first dose.

Total radioactive residue (TRR) was determined by direct liquid scintillation counting (LSC) of urine and milk, and by combustion/LSC of faeces, blood, and tissues. Characterization of the metabolite profiles of the various matrices was accomplished by solvent extraction, HPLC fraction collection, enzymatic digestion, thin-layer chromatography, and comparison with known standards.

Levels of radiolabel material reached a plateau in milk within approximately 24 hours. Radioactivity in urine and faeces showed an initial rapid increase for the first 36–48 hours after dosing, followed by a gradual increase for the remainder of the study (Table1).

Radioactivity in tissues was generally low (Table 2). Liver contained the highest concentration of residue at approximately 11 mg/kg (0.4% of the cumulative dose). The stomach contents accounted for 8.63 ± 1.01 mg/kg triflumizole-equivalents; radioactivity in the small and large intestines was not determined. Of the radioactivity in the liver tissue, slightly more than half occurred as bound residue. Digestion with protease released approximately 70% of the bound radioactivity.

Characterization of the radioactivity showed that glucuronide- and sulphate-conjugated forms of metabolites FA-1-1 and FA-1-5 occur in urine, milk, liver and kidney; parent compound was not observed. Additional work, using an analytical system with higher resolution, was performed with milk and liver extracts. Those analyses (Table 3) showed major milk metabolites to be FA-1-5-sulphate, FA-1-5-glucuronide, and FM-8-1-sulphate. Minor residues in the milk extract were FD-6-1, FD-2-1, FD-7-1, and FM-6-1. Liver extracts were shown to contain primarily FA-1-5-sulphate and species yielding FA-1-1 after proteolytic digestion. Insufficient data were provided to derive quantitative residue levels for metabolites in milk.

Table 1 Cumulative radiocarbon residues in excreta and milk from a goat orally administered [^{14}C]triflumizole

Hours after First Dosing	% of Cumulative Dose ^{a, b}		
	Urine	Faeces	Milk
4	6.7	< LOD	< LOD
8	11.3	< LOD	< LOD
12	24.4	0.3	0.07
24	36.0	5.3	0.15
36	33.8	8.0	0.15
48	43.0	11.4	0.15
60	41.8	13.4	0.15
72	49.7	16.5	0.16
84	48.4	16.7	0.16
96	53.7	17.7	0.18
108	53.1	17.9	0.16
120	56.0	19.9	0.18

^a Cumulative dose is total administered dose up to indicated time point.

^b Based upon 10 equal doses of 500 μCi

Table 2 Radiocarbon residues in tissues of a goat orally administered [^{14}C]triflumizole

Tissue	% TAR	Triflumizole Equivalents (mg/kg $\pm$ Std. Dev.)
Kidney	0.01	3.36 $\pm$ 0.13
Liver	0.40	11.26 $\pm$ 0.59
Muscle	0.18	0.30 $\pm$ 0.20
Fat	0.06	0.66 $\pm$ 0.05

Table 3 Identification of radioactivity in goat liver and milk following administration of [^{14}C]triflumizole

Metabolite	Matrix	% TRR	Triflumizole Equivalents (mg/kg ^a)
FA-1-1	Liver (chloroform fraction)	24.4	2.75
FA-1-1	Liver (dried pellet)	54.8	6.17
FA-1-5-Sulphate	Liver (acetone fraction)	12.4	1.40
	Milk	29.1	—
FA-1-5-Glucuronide	Milk	11.8	—

FD-7-1	Milk	3.2	—
FM-6-1	Milk	5.2	—
FM-8-1-Sulphate	Milk	12.6	—

^a Based on a total concentration of triflumizole-equivalent residue in liver of 11.26 mg/kg. Total triflumizole-equivalent residue in milk was not provided.

The proposed metabolic pathway of triflumizole in livestock is shown in Figure 2

Laying hens

The metabolism of [^{14}C]triflumizole by laying hens was investigated by Knipe and Lengen (1986) using triflumizole universally labelled in the phenyl ring. Five hens were dosed, orally, for five consecutive days. Three birds were dosed with 39 ppm in feed and two were dosed with 53 ppm in feed. Eggs and excreta were collected once daily during the dosing period. The birds were killed on the 6th day after the initial dosing and liver, kidneys, fat and muscle were collected for analysis.

Total radioactivity in excreta and tissues was determined by combustion and LSC; radioactivity in egg was determined by LSC directly and was on a whole-egg basis for the three low-

dose birds and separately for egg white and egg yolk for the two high-dose birds. Metabolic profiles of the collected matrices were investigated using solvent extraction, and, for skin-with-fat and liver samples, base or enzymatic digestion. Extracted residues were subjected to HPLC, TLC, and MS analysis, with comparison against known standards.

Analysis of total radioactivity indicates that the majority of the administered dose was excreted (Table 4 4) and that levels did not plateau in eggs within the dosing period (Table 5 5). By the fifth day of dosing, levels of radioactivity in the egg yolk were greater than those in the whites. That pattern may have been evident as early as Day 3 of dosing; however, insufficient samples were collected to make a firm conclusion. In tissues, total radioactivity was approximately an order of magnitude greater in liver and kidney than in fat or muscle (Table 6).

Table 4 Recovery of administered radioactivity in the excreta of chickens administered [^{14}C]triflumizole for 5 days

Chicken # ^a	μCi Excreted						% TAR
	Day 1	Day 2	Day 3	Day 4	Day 5	Total	
6 (control)	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01
1	18.81	18.63	21.19	23.35	22.08	104.16	93.0
2	18.90	21.99	16.59	23.18	18.06	98.72	88.1
3	18.35	18.80	13.95	20.38	19.92	91.40	81.6
7	34.69	27.75	27.05	27.95	28.02	145.46	83.4
8	24.26	19.09	30.20	31.08	35.79	140.42	80.5

^a The dose administered to Chickens 1, 2, and 3 was 112 μCi (22.4 $\mu\text{Ci}/\text{day}$ for 5 days), while the dose administered to Chickens 7 and 8 was 174.5 μCi (34.90 $\mu\text{Ci}/\text{day}$ for 5 days).

Table 5 Radiocarbon residues in the eggs of chickens administered [^{14}C]triflumizole for 5 days

Chicken # ^a	Triflumizole equivalents (mg/kg)				
	Day 1	Day 2	Day 3	Day 4	Day 5
1	NS ^b	0.028	NS	NS	0.215
2 ^c	0.003	0.053	0.135	0.148	0.242 / 0.303
3	0.024	NS	NS	0.270	0.431
7 ^c Yolk	0.006	0.197	1.080	NS	2.312 / 1.706
White	0.009	0.111	0.072		0.401 / 0.408
8 ^c Yolk	0.002	0.095	NS	0.224 ^d	0.899 / 1.187
White	0.011	0.081			0.133 / 0.074

^a Chickens 1, 2, and 3 received 39 mg/kg/day while chickens 7 and 8 received 53 mg/kg/day.

^b No egg sample obtained.

^c Chickens 2, 7 and 8 each gave two eggs per day.

^d This egg was broken when received, so the analysis was performed on the whole egg.

Table 6 Tissue radiocarbon residues in chickens administered [^{14}C]triflumizole for 5 days

Chicken # ^b	Triflumizole Equivalents (mg/kg ^a)				
	Liver	Kidney	Fat	Muscle (leg)	Muscle (breast)
1	1.107	0.677	0.067	0.047	0.049
2	0.989	0.537	0.050	0.017	0.026
3	1.232	0.600	0.058	0.026	0.029
7	— ^c	1.115	0.358	0.066	0.087
8	— ^c	0.781	0.312	0.073	0.054

^a Values obtained for control tissues have been subtracted to obtain the tissues values given.

^b Chickens 1, 2 and 3 received 39 mg/kg/day, while Chickens 7 and 8 received 53 mg/kg/day.

^c The livers of these birds were used for metabolite identification and were not analysed for total radioactivity.

HPLC analysis of chicken excreta resulted in three peaks with higher levels of radioactivity at retention time fractions of 8–9 minutes, 24–26 minutes, and 27.5–29 minutes. The first peak was identified as FM-8-1-sulphate based on co-chromatography with an authenticated standard. The second peak was identified as FD-7-1 based on co-chromatography, stability to β -glucuronidase and sulfatase hydrolysis, and cleavage to FA-1-1 after overnight incubation with HCl at 37 °C. The third peak was resistant to both β -glucuronidase and sulfatase and was not further investigated. Based on retention time, the third peak may have been FM-6-1.

Analysis of egg yolk and egg white from a high-dose chicken (Chicken #7, Day 5) by HPLC and protease treatments resulted in identification of a number of metabolites (Table 7). The primary components were triflumizole, FD-6-1/FD-4-1 (white), and FA-1-1 (yolk).

Livers from Chickens 7 and 8 (composited) and from Chicken 2 were processed through either a Bligh-Dyer extraction protocol or exhaustive pentane extractions, respectively. For both extraction schemes, the majority of radioactivity in liver was associated with bound residues in the dried pellet (Table 8). HPLC analysis and proteolytic digestion indicate that chicken liver contained a single metabolite: Metabolite FA-1-1 or a metabolite converted to FA-1-1 during proteolytic digestion.

Table 7 Distribution of radioactivity in chicken egg (Chicken #7, day 5)

Total	Egg white (0.401 mg/kg) ^a		Egg yolk (2.312 mg/kg) ^a	
	mg/kg	% TRR	mg/kg	% TRR

Unextractable	0.069	17.2	0.921	39.8

^a Data from Table 55.

^b Extractable prior to concentration and resultant losses of ¹⁴C (attributable to FA-1-1).

^c Percent of total after correction made for loss of ¹⁴C after extract concentration

^d Poor HPLC resolution of the standards did not allow further assignment of peaks in the egg samples.

^e Evaporative losses of ¹⁴C from the extract are most likely FA-1-1; based on that compound's known volatility and the HPLC analysis of the extract of acidic digestion of egg yolk. These residues were characterized by protease digestion (see text) and by acidic Bleidner digestion.

^f Radioactivity not clearly distinguishable as a definite peak or too low to assign a definite peak identity.

^g Other-5.7% of yolk was extractable with acetone but could not be separated from the sample matrix for HPLC analysis.

^h Losses - Additional loss of material balance presumed to be volatiles as FA-1-1

Table 8 Distribution of radioactivity in chicken liver extracts

Fraction	% TRR
Bligh-Dyer Extraction (Chickens 7 and 8)	
Chloroform	15.4
Methanol/water	6.8
Acetone	7.8
Dried Pellet	70.0
Extensive Pentane Extractions (Chicken 2)	

Fraction	% TRR
Pentane	13.7
Acetonitrile	12.9
Dried Pellet	73.4

Summary of animal metabolism

The metabolism of ^{14}C labelled triflumizole has been studied in lactating goats and laying hens. In both studies, the majority (> 80%) of the administered triflumizole was excreted. Livers and kidneys of both species had the highest amount of the retained material. In livers, the predominant residue was FA-1-1. Triflumizole was observed as a major residue, at approximately 13% of the total residue, in egg white only.

Figure 2 Proposed metabolic pathways of triflumizole in livestock

Plant metabolism

Plant metabolism studies were performed on cucumbers, apples, pears and grapes. Treatment was with triflumizole ^{14}C - universally labelled in the phenyl ring. Metabolites were identified using solvent partitioning and thin-layer chromatography with authentic standards.

Apples

The metabolism of triflumizole in apple trees grown in a greenhouse was investigated (Soeda and Hashimoto, 1987b). Triflumizole, uniformly labelled with ^{14}C in the phenyl ring, was applied as uniformly as possible to four leaves of a branch cluster containing 16–18 leaves. The application rate was approximately 0.127 mg triflumizole/4-leaf cluster. Branches were harvested and separated into treated leaves and upper and lower untreated leaves at 0, 1, 3, 7, 14, 21, 31, 60, and 90 DAT.

Treated leaves were surface washed with chloroform and then extracted three times with methanol:water (7:3, v/v) and the resulting extract was partitioned three times against chloroform. Radioactivity in the washes and extracts was determined by LSC. Radioactivity in the extracted fibrous material was determined by combustion followed by LSC. For samples other than treated leaves, the plant parts were each homogenized in a blender in the presence of dry ice and the radioactivity determined by combustion/LSC. Thin-layer chromatography was used to further analyse leaf washes as well as aqueous and chloroform extracts. Prior to TLC, the aqueous extracts were concentrated *in vacuo* to remove methanol and the residues transferred to 1-butanol. For TLC, the locations of radioactive compounds were determined by autoradiography and identification of residues was by comparison to authentic standards. Quantification of residues was made by collecting the silica gel from the TLC plates and counting by LSC. In the case of the metabolite FA-1-1, which is extremely volatile, TLC scraping and LSC was done immediately after two-dimensional co-chromatography with authentic standards, using UV light to locate the residue for scraping.

Radiocarbon residues in chloroform washes, extracts, and plant material are summarized below (Table 9). The data show that most of the radiocarbon residues were removed in the chloroform wash through the early stages of sampling and that there was very little translocation of radioactivity from treated to untreated leaves. The data also show a rapid decline in radiocarbon residues, with an initial half-life of approximately 4 days.

^a Not determined.

The TLC analysis shows that the only major (> 10% TRR) identified compounds that appear consistently in the residue data are triflumizole and FM-6-1. As overall residues of radiocarbon decline with increasing time after treatment, FD-2-1 and unidentified metabolites ("Others" in Table 10) become more prominent in the residue profile in terms of %TRR.

Residues of treatment-related compounds in apple fruits were not reported in the study.

Pears

The metabolism of triflumizole in pear trees grown in a greenhouse was investigated (Soeda and Hashimoto, 1987a). Treatments were with triflumizole, uniformly labelled with ^{14}C in the phenyl ring, applied either as uniformly as possible to four leaves of a branch cluster containing 8–12 leaves or to the surface of a pear fruit. The leaf application rate was approximately 1 mg triflumizole/4-leaf cluster and the fruit application rate was approximately 0.166 mg triflumizole/fruit. Branches from leaf-treated trees were harvested at 0, 1, 3, 7, 14, 21, 31, 60, and 90 DAT and were divided into treated leaves, untreated leaves and fruit. Treated fruits were harvested 0, 1, 3, 7, and 14 DAT. After harvest, the treated leaves and fruits were surface washed with chloroform. The fruits were then peeled and sectioned into flesh and core. The leaves and fruit peel were separately homogenized and extracted with methanol:water (7:3, v/v). The methanol extract was diluted and partitioned with chloroform. Radioactivity in the extracts was determined directly by LSC. Radioactivity in fibrous residue (PES) was determined by combustion/LSC. The chloroform surface washes, the chloroform partition phases, and the water partition phases were concentrated. The water phases of leaf extracts were extracted with 1-butanol and the solvent was evaporated. All remainders were subjected to quantitative and qualitative 1-D TLC analysis using co-chromatography with known standards. The location of radioactivity on the TLC plates was determined by autoradiography and the activity in ^{14}C spots was determined by LSC of the scrapings derived from the TLC plates. The nature of the aglycones in the combined water phases of all leaf samples from 7 DAT onwards was investigated by means of column chromatography and subsequent treatment of the water-soluble metabolites with β -glucosidase, cellulase, acid- or alkali pectinase. The reaction products were also subjected to 1-D TLC. In the case of the metabolite FA-1-1, which is extremely volatile, TLC scraping and LSC was done immediately after two-dimensional co-chromatography with authentic standards, using UV light to locate the residue for scraping.

Radiocarbon residues in chloroform washes, extracts, and plant material from pear leaves are summarized below (Table 11). The data show that most of the radiocarbon residues were removed in the chloroform wash through the early stages of sampling and that there was very little translocation of radioactivity from treated to untreated leaves. The data also show a rapid decline in radiocarbon residues, with an initial half-life of approximately 4 days.

Radiocarbon residues in chloroform washes, extracts, and plant material from pear fruit are summarized below (Table). The data show that through the two-week sampling period, nearly all of the radiocarbon residues were associated with the peel of the fruit and that most of that radioactivity was removed in the chloroform wash from fruit at the first three sampling intervals. The data also show a rapid decline in radiocarbon residues, with an initial half-life of between 1 and 3 days, and a slower rate of decline between 3 and 14 DAT.

The metabolic profile in pear fruits is summarized in Table 214. Major residues in pear fruit were triflumizole (through 3 DAT), FM-6-1, and FD-1-1 (3 DAT only). Residues of FM-6-1 and FA-1-1 were greater in fruit than in leaves. Individual unknown metabolites (Others) were < 5% TRR.

Grapes

The metabolism of triflumizole in grape vines grown in a greenhouse was investigated (Soeda and Hashimoto, 1987c). Treatments were with triflumizole, uniformly labelled with ¹⁴C in the phenyl ring, applied either to a branch of approximately 10 leaves and blossoms at the berry crossing time (67 days prior to harvesting mature fruit) or to a bunch of young fruits 35 days before harvesting mature fruit. For both treatments, the rate was equivalent to 280 g ai/ha. Branches were harvested 0, 3, 7, 14, 31, and 67 DAT and were divided into treated leaves and fruit. In the second experiment, treated fruits were harvested 0, 3, 7, 14, and 35 DAT. Samples were surface washed with dichloromethane (DCM) and then extracted with methanol:water (8:2, v/v). The methanol extract was partitioned against DCM. Radioactivity in the washes and extracts was determined by LSC directly and in PES by combustion/LSC. The concentrated DCM wash, DCM partition phase, and the water partition phase were subjected to 1D-TLC analysis using co-chromatography of known standards. The activity in ¹⁴C-spots was determined by LSC of the scrapings derived from the TLC plates.

Most of the radioactivity in leaves was recovered from the surface wash. Residues decreased from 99% of the applied dose (AD) to 15% TAR at 67 DAT (Table). Radioactivity was translocated to fruits at less than 2% TAR. The parent compound was found to be the major residue (decreasing from 98% TRR at 0 DAT to 7.5% TRR at 67 DAT). The only other major residue was FM-6-1 (11.1% TRR at 67 DAT). Post-extraction residues in leaves gradually increased from 3.1% TRR (1.73 mg eq/kg) to 26.02% TRR (1.79 mg eq/kg) over the course of the study. Minor metabolites and those remaining at the origin increased to 39% TRR at 67 DAT (

Table).

^a Expressed as percentage of total radioactivity at sampling time^b From surface wash and methanol extracts; Other includes minor components and TLC-origin activity.

After fruit application, most of the radioactivity was recovered from the surface wash, and decreased to approximately 7.5% TAR at 35 DAT (Table 17 317). Triflumizole decreased from 95.45% TRR (7.44 mg eq/kg) to 31% TRR (0.31 mg eq/kg) at 35 DAT, and the metabolite FM-6-1 increased to 7.6% TRR (0.07 mg eq/kg) at 35 DAT. Post-extraction solids increased to 17.1% TRR at 35 DAT. The results are summarized in Table 18.

Cucumbers

The metabolism of triflumizole in cucumbers was studied under greenhouse conditions by Soeda (1983). Three types of treatment were made: Foliar treatment to investigate metabolism, fruit treatment to investigate metabolism, and foliar treatment to investigate translocation.

In the foliar metabolism study, radio-labelled triflumizole was applied to leaves (0.13 mg/plant) of multiple plants at the 2nd-to-3rd leaf stage. At sampling times of 1, 3, 7, 14, 21, and 45 (one plant) days after treatment (DAT), two whole plant was harvested, the roots were washed with water, and the plants were sectioned into root, lower part (below the treated leaf), treated leaf, upper part (above the treated leaf), and fruit. Treated leaves were surface washed with chloroform and then the leaf was homogenized with methanol (80%). The methanol extract was adjusted to 50% with distilled water and then partitioned against chloroform. Chloroform leaf wash and extract were assayed, separately, by 1-D and 2-D TLC for residue identification. The aqueous extract was assayed for radioactivity by LSC, and the extracted treated leaf and the remaining plant parts (post-extraction solids, PES) were assayed for radioactivity by combustion followed by LSC. Levels of total radioactivity in the various washes, extracts, and tissues demonstrate that the majority of the applied material is recovered in the surface wash of treated leaves and that very little is distributed throughout the plant (Table19). Residue in the leaves decreased with increasing DAT. The decrease was most significant for triflumizole, with no concomitant increase seen in any of the identified metabolites (Table). Residue levels (mg eq/kg) were not provided in the study.

In the fruit metabolism study, radio-labelled triflumizole (0.041 mg/plant) was applied as small droplets to a small fruit. Two fruits were harvested at each sampling time of 1, 3, 7, and 14 DAT. Total radioactive residues and residue identification and characterization was by the same methods used for treated leaves. The behaviour of total residues (Table) and the distribution of residues (Table 22) is similar to that observed for leaves.

^c Sum of minors and origin materials.

To investigate translocation, an application of radio-labelled triflumizole (0.16 mg/plant) was made to the surface of a leaf which had a young fruit growing at the base of its petiole. Fruits were harvested 3, 7, and 14 DAT, weighed, and total radioactive residue determined by combustion/LSC. The results (Table) show that very little radioactivity was translocated from the treated leaf to the adjacent fruit.

Summary of plant metabolism

The metabolism of triflumizole was studied in apples (leaves only), pears, cucumbers and grapes. The metabolic profile observed in these studies was similar across all four crops (

). The most abundant residue was parent triflumizole. Generally triflumizole decreased rather rapidly (half-life on the order of 3 days), with the exception of grapes where metabolism was considerably

slower. Loss of triflumizole was accompanied by an increase in the FM-6-1 metabolite, which was the only metabolite to consistently occur at $\geq 10\%$ TRR.

Figure 3 Proposed metabolic pathways of triflumizole in plants

ENVIRONMENTAL FATE

The Meeting received information on aqueous and soil-surface photolysis, soil dissipation, aerobic soil metabolism, and confined and field rotational crop studies.

Environmental fate in soil

The fate and behaviour of triflumizole in soil were investigated using [^{14}C] triflumizole labelled in the phenyl ring.

*Aerobic degradation**Study 1*

The metabolism and degradation rate (DT₅₀ and DT₉₀) of triflumizole was investigated in a sandy loam soil (Harned, 1985; Doc. No. 84253). Soil was added to incubation flasks and adjusted to 75% 1/3-bar moisture. Radio-labelled triflumizole was added to achieve a concentration of 0.60 mg eq/kg (approximately 0.56 kg/ha in the top 7.6 cm of soil). The flasks were capped with trapping towers and incubated, in darkness at 25 °C. Samples for extractable, bound, and volatile ¹⁴C were collected at 0, 0.33, 1, 2, 3, 4, 8, 12, 24, and 42 days after treatment.

Table 24 Soil characteristics

Parameters	Soil
pH	5.6
Organic matter (%)	7.34
Cation exchange capacity (meq/100 g soil)	43.5
Soil type (USDA)	Sandy loam
Clay (%)	6.4
Silt (%)	26.0
Sand (%)	67.6

Total extractable residues were determined by acetone extraction and LSC. Extracts were examined by HPLC, using known standards, to identify individual components. Quantification of extracted components was by fraction collection and LSC. Bound residues were determined by combustion/LSC. Total volatile organics were determined by combustion/LSC of the foam plugs in the trapping towers and ¹⁴CO₂ was determined by ascarite traps in the trapping towers. The results are summarized below (Table). The residue profile of the extracted radiocarbon is summarized in Table . The profile shows and increasing proportion of bound residues with increased incubation time and also indicates that the majority of the volatile radioactivity is not in the form of CO₂.

Study 2

In a second study (Shiotani, 1982), the residue profile from two Japanese soils (Odawara or Oiso) was investigated. In this study, soils treated with [¹⁴C] triflumizole were incubated indoors at 15 °C or

25 °C for 1 hr, 7, 14, 21, 28, 42, 56, 70, 84, and 98 days after treatment. Extractable, bound, volatile residues and $^{14}\text{CO}_2$ were examined. In the case of extractable residues, methanol:water (8:2, v/v) extracts were partitioned against dichloromethane and cleaned-up on silica gel columns. Residue identification was by HPLC. In a separate part of the study, the Odawara and Oiso soils were treated and incubated outdoors during the day and inside at night and during rainy days. The soils were sampled at intervals of 1, 3, 7, 14, and 28 days after treatment and extracted in the same manner as those incubated indoors (polyurethane plugs and CO_2 traps were not used with the outdoor-incubated soils).

Residue profiles by soil, incubation temperature, and time are summarized in Table –32.

Figure 4 Proposed metabolic pathway of triflumizole in soil

Residues in rotational crops*Confined rotational crop studies*

The metabolic profile of triflumizole in rotational lettuce, radish (roots and tops), and wheat (forage, hay, straw, and grain) was investigated (Yu *et al.*, 2001). The study consisted of two untreated control plots, six plots treated at 1× GAP, and two plots treated at 10× GAP with [¹⁴C] triflumizole. The rotational crops were planted into the 1× treated plots at plant-back intervals (PBIs) of 30, 120, and 365 days after treatment. The 10× plots had a single PBI of 30 days.

For each PBI, samples were harvested and homogenized in the presence of dry ice. In the case of radish samples, the roots were washed to remove soil particles prior to homogenization. Homogenized samples were extracted with methanol:water and assayed by LSC to determine extractable residues. Post-extraction solids were dried for several days and then assayed by combustion/LSC to determine non-extractable radioactivity. Metabolite characterization and identification was done using the 10× matrices (30-day PBI) except for wheat forage, for which the 1× 30-day PBI samples were used. Metabolite characterization and identification was accomplished via HPLC (multiple systems) with known standards. Structural information for unknown metabolites was evaluated using mass spectrometry techniques including ESI/LC/MS, ESI/MS/CID/MS (CID chemical ionization positive ion/negative ion modes), and TOF/LC/MS. Enzymatic hydrolysis with β-glucosidase was used to elucidate structures where MS analysis indicated the presence of glucoside conjugates (lettuce and wheat hay samples). Finally, PES samples were subjected to fractionation and derivatization procedures to determine the distribution of non-extractable residues in natural components such as starch, cellulose, and lignin.

Table 35 Total radiocarbon residues in rotational crop matrices

Crop	Total Radiocarbon Residues as Triflumizole-Equivalents (mg eq/kg)		
	30 DAT	120 DAT	365 DAT
Lettuce	0.0824	0.0861	0.0206
Radish Root	0.2336	0.1882	0.0320
Radish Top	0.1944	0.1449	0.0960
Wheat Forage	0.4420	0.3729	0.1263
Wheat Hay	0.9958	0.5834	0.3208
Wheat Straw	1.6495	0.6095	0.4784
Wheat Grain	0.1051	0.0554	0.0672

Forty-nine metabolites were identified, five of which were > 10% TRR and > 0.01 mg eq/kg in at least one matrix (Table). Five of the remaining forty-four metabolites were identified as having a hydroxide (or O-conjugate) appended at the Number 6 position of the aniline ring.

Table 36 Major metabolites identified in the confined rotational crop study at a 30-day plant-back interval. See Figure 5 for chemical structures.

Metabolite Identification	Molecular Weight	Crop Commodity	% TRR	Triflumizole Equivalents (mg eq/kg)
XIV (2Z)-4-hydroxyhex-2-enedioic acid	160	Radish Tops	12.54	0.2464
		Wheat Grain	61.35	0.3999
		Wheat Hay	14.87	0.8757
		Wheat Straw	11.06	1.1877
FD-9-1 [4-chloro-2-(trifluoromethyl) phenyl]urea	238	Lettuce	34.87	0.425
		Radish Tops	30.62	0.6016
		Wheat Straw	11.7	1.2564
XXVI 1-[4-chloro-2-hydroxy-6-	270	Radish Roots	11.36	0.1087

Across the two site locations, residues of triflumizole in treated cucumbers ranged from 0.12 to 0.20 mg eq/kg. Residues in rotational crops are summarized in Table ; residues in samples from untreated plots were < 0.01 mg eq/kg for all matrices.

Table 37 Triflumizole-equivalent residues in rotational lettuce, turnip, and wheat

In the second study (Puhl, 2005), triflumizole (as Procure[®] 50 WS) was applied to squash at approximately 30 days prior to harvest followed by four subsequent applications at 7 ± 1 day intervals. Trials were in Yuma, Arizona and Uvalde, Texas. Applications were each 0.28 kg ai/ha for a total rate of 1.4 kg ai/ha. At approximately 30, 60, 90, 180, and 270 days after the last application, cabbage, cotton, onion, tomato, and wheat were planted into treated and untreated plots. Samples were analysed by a common-moiety method that converts triflumizole and its aniline-containing metabolites to FA-1-1, as described in the residue methods section below. Results are expressed as triflumizole-equivalents. The limit of quantitation (LOQ) was 0.01 mg eq/kg. Average procedural recoveries of triflumizole and FA-1-1 ranged from 79 to 95%, with a maximum standard deviation of 13%.

In the rotational crops, quantifiable residues were found only in wheat forage, wheat straw, wheat hay, and onion; residues in wheat grain, cabbage, tomato, and cottonseed were < 0.01 mg eq/kg in all samples (Table).

RESIDUE ANALYSIS

Analytical methods

The Meeting received analytical methods and validation data for analysis of triflumizole in plant and animal commodities. These methods fall into two classes. The first are common-moiety methods which analysed for residues of triflumizole and its aniline-containing metabolites, FM-6-1, FM-5-1, FD-1-1, FD-2-1, FM-8-1, and FA-1-1 by converting each of the metabolites to FA-1-1. The second

class are residue specific methods which were developed to analyse, separately, triflumizole and FM-6-1 in crops or FA-1-5 (free and sulphate-conjugated) in animal matrices. For both classes, alterations have been made as necessary to resolve analytical issues and to permit use of different separation/detection strategies. Limits of quantitation and detection are reported as being 0.01 to 0.02 mg eq/kg, with no consistent distinction between the two. Descriptions are provided below.

Common-moiety methods

The analytical method described by Ball (1986a) is the basis for the common moiety methods for crop commodities. In this method, extraction of residues begins by macerating the sample in distilled water for 5 minutes. Concentrated glacial acetic acid and sodium acetate are added to the homogenate and the mixture is then refluxed at boiling for 90 minutes. A sodium hydroxide solution (20%) is added to the flask, which is then fitted with a distillation head and heated until a volume of 100 mL is distilled into hexane. The distillate is shaken against 0.1 N HCl. The organic phase is collected, concentrated, and an aliquot taken for analysis. Separation/quantification strategies that have been used with this extraction method include GC-MSD, GC-FTD, GC-NPD, HPLC-UV (254 nm), and HPLC-Amperometric detector. Residues are analysed as FA-1-1 and expressed in terms of triflumizole.

A common-moiety method was also developed for animal commodities (Perkins and Polakoff, 1986). This method uses 20% NaOH and a Bleidner extractor to digest/distil/extract residues into hexane. The hexane is passed over anhydrous sodium sulphate and concentrated prior to analysis. As with the common-moiety method for crops, the terminal residue is the FA-1-1 metabolite. Parameters are described for GC-NPD analysis.

Residue-specific methods

A method for the analysis of triflumizole and FM-6-1 is described by Gomyo *et al.* (1990). In this method, residues are extracted from crop matrices with methanol by shaking for 30 min. The extract is then filtered and partitioned against dichloromethane. Residues in the organic phase are cleaned up by column chromatography, concentrated to dryness, and then reconstituted in dichloromethane for HPLC determination or acetone for GC determination.

Corley (2012) describes a method for the analysis of triflumizole and FM-6-1 in hops by HPLC-MS/MS. In that study, residues were extracted with acetonitrile, the extract cleaned up by polymeric and NH₂ solid-phase extraction, and the extract analysed by HPLC-MS/MS. Transitions for triflumizole were m/z 346.1 $\Rightarrow$ 73 (quant.) and 346.1 $\Rightarrow$ 278 (conf.). Transitions for FM-6-1 were m/z 295.1 $\Rightarrow$ 215 (quant.) and 295.1 $\Rightarrow$ 73 (conf.).

Analysis of FA-1-5 (free and sulphate-conjugate) in animal matrices is described in Perkins and Polakoff (1986). In this method, residues are extracted from milk and liver with 0.2 N HCl (boiling, 1 hr). Following extraction, the residues are cleaned up by solid-phase extraction (C-18) and analysed by HPLC with amperometric detection.

Table 39 Summary of method validation recovery results for triflumizole and metabolites in crop and livestock matrices

Stability of pesticide residues in stored analytical samples

The Meeting received data on the stability of residues of triflumizole and its metabolites in crops (apples, grapes, strawberries, cucumbers, cherries, muskmelons, squash, lettuce, and wheat forage) and livestock. In many cases, the storage stability data were submitted as an integral part of the field trial study rather than as a separate storage stability study volume. The storage stability data are summarized in Table . Compounds, as listed in Table 40 were added to control samples and placed into frozen storage for the time indicated. For all matrices except cherries and strawberries, the fortification was to homogenized sample matrix. The state of the cherry and strawberry storage stability matrices was not described in the study report. Samples were stored frozen (-20 °C).

n.s.=Not Specified.

^a FA-1-1 was subject to evaporative loss in the hen metabolism study. That phenomenon may account for the low recovery from cucumber considering the long storage time involved.

^b The 0 Day samples were quantitated using external standards. FA-1-5-S was shown to be not stable in the acid used to digest the samples, leading to inaccurate quantitation. Recovery at other time points in this study were quantitated based on procedural standards only (i.e., no correction for 0-day recovery).

USE PATTERN

Labels for triflumizole were provided for registrations in the USA and the Netherlands. Triflumizole is a broad-spectrum foliar fungicide that controls a variety of fungal diseases in fruits and vegetables. It acts as a protectant and as an eradicant by preventing disease symptoms after infection has occurred. Triflumizole's anti-sporulant activity reduces spores after lesions become visible. Triflumizole belongs to the demethylation inhibitor (DMI) group of fungicides classified as Group 3

by the Fungicide Resistance Action Committee (FRAC). Triflumizole displays protective and curative action, and acts as an inhibitor of chitin biosynthesis. The product is mixed with water and applied as a foliar spray using ground equipment equipped for conventional spraying on crops as listed in Table .

^b Numbers in parentheses are implied based on the maximum seasonal rate divided by the per-application rate.

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received information on triflumizole supervised field trials for the following crops.

Crop Group	Commodity	Table
Pome fruits	Apple	Table 42
	Pear	Table 43
Stone fruits	Cherry	Table 44
Berries and other small fruits	Grape	Table 45
	Strawberry	Table 46
Assorted tropical and sub-tropical fruits - inedible peel	Papaya	Table 47
Brassica (cole or cabbage) vegetables, Head cabbages,	Broccoli	Table 48
Flowerhead brassicas	Cabbage	Table 49
Fruiting vegetables, Cucurbits	Cucumber	Table 50
	Muskmelon	Table 51
	Squash	Table 52
Fruiting Vegetables, other than Cucurbits	Tomato	Table 53
Leafy Vegetables	Lettuce (Head and Leaf)	Table 54
	Mustard Green	Table 55
	Swiss Chard	Table 56
	Turnip Green	Table 57
Tree Nuts	Filberts	Table 58
Dried Herbs	Hops	Table 59

For all crops, triflumizole was applied as a foliar spray. Each field trial site consisted of an untreated control plot and at least one treated plot; at some locations, a second plot was treated at an exaggerated rate.

Parameters of the supervised residue trials were generally well reported in the detailed field reports and study volumes, including application equipment, environmental conditions, dates of application and harvest. The study volumes also include post-harvest treatment of the samples, shipping dates and conditions, method validation data from the analytical laboratories, and sufficient details regarding the analytical method. Information on varieties was not always available.

The supervised residue trials and results are summarized below. Residue data are corrected for concurrent recovery. Residues in samples from control plots were < LOQ and are not shown. Formulations in the tables below are as reported in the study volume and may not correspond to the submitted labels (e.g., “Procure W” or “Procure WP” reported vs. “Procure WS” label submitted. Residues in bold typeface are the highest residues considered appropriate for assessment where replicate residues have been identified. Labels from the USA do not specify the number of applications that may be made per growing season.

In the tables that follow, the GAP number of applications from USA labels are expressed in parenthesis to denote that they are implied based on the application rates and the maximum allowed seasonal rate. Also, residues in bold are the highest residue in a given data set appropriate for estimating short-term dietary intake and underlined residues are those for consideration in MRL and STMR estimations.

*Pome fruits**Apples*

A total of 18 supervised trials on apples were conducted in the USA from 1984 to 1987. Trials were conducted in Washington (four), Michigan (two), Ohio (three), Vermont (four), California (three), Pennsylvania (one), and New York (one) and are reported in Ball 1986c and Ball 1988b.

Trials reported by Ball 1986c consisted of four foliar applications of the triflumizole 50W formulation containing 500 g ai/kg (nominal), except for one trial each in Yakima, Washington; Wapato, Washington; and Lodi, California, which each consisted of two sets of four foliar applications at two different application rates. Trials reported by Ball 1988b consisted of four to six foliar applications of the triflumizole 50W formulation containing 498 to 523 g ai/kg, except for the trial located in Smith Flat, California, which consisted of one foliar application. All applications were made at a rate of approximately 0.56 kg ai/ha per application or 1.12 kg ai/ha per application. Applications were made on a 4-day to 109-day schedule until apples were ready to be harvested. The apples were harvested 7 and 14 days after the last treatment (PHI=7, 14 days), except for the trials located in Bennington, Vermont, and Smith Flat, California, which were residue decline trials with PHIs of 0, 7–9, 13–14, 20–21, and 28–29 days. One to three samples of apples were collected from the treated plots and untreated plots. Samples were stored for less than 2 years (Ball 1986c) or less than 10 months (Ball 1988b) before analysis.

The method for analysis was a common moiety method with gas chromatography. The LOQ was not determined, and the LOD was 0.02 mg eq/kg. Average recovery of all fortifications was $96.4 \pm 19.5\%$ for Ball 1986c (n=8) and $81.4 \pm 12.9\%$ for Ball 1988b (n=10). All control samples had residues below the limit of quantitation of the method, with two exceptions (in Wooster, Ohio, one control sample had residues of 0.04 mg eq/kg, and in Zillah, Washington, one control sample had residues of 0.03 mg eq/kg), and these are not considered significant. Apples treated with the triflumizole 50W formulation had detectable residues.

A total of two supervised trials on apples were conducted in Japan from 1982 to 1983. Trials were conducted in Aomori (one) and Nagano (one). Trials were reported by Gomyo 1992. None of the trials were conducted at the critical GAP.

The trial located in Aomori received eight foliar applications of the triflumizole WP formulation containing 300 g ai/kg, and the trial located in Nagano had three treated plots that received eight foliar applications of the triflumizole WP formulation containing 300 g ai/kg. Application volume was 6000 L/ha. Applications were made on a 9-day to 34-day schedule until apples were ready to be harvested. The apples were harvested 1, 7, and 21 days after the last treatment.

Apple samples were collected from treated plots and untreated plots. Specimens were stored frozen until analysis (approximately 1–3 months after harvest) by The Institute of Environmental Toxicology, Ibaraki, Japan. Samples were analysed for triflumizole and FM-6-1, and reported as the sum of both.

The method for analysis was high performance liquid chromatography. The LOQ was 0.008 mg eq/kg. Average recovery at 0.4 mg eq/kg was $86.4 \pm 1.00\%$ (n=4). All control samples had residues at or below the limit of quantitation of the method, and these are not considered significant. Apples treated with the triflumizole WP formulation had detectable residues.

Table 42 Summary of triflumizole residues in apple trials

Pears

A total of seven supervised trials on pears were conducted in the USA from 1985 to 1987. Trials were conducted in Washington (two), California (two), Vermont (one), Oregon (one), and New York (one). Trials were reported in Ball 1986d and Ball 1988d.

Trials reported by Ball 1986d consisted of four foliar applications of the triflumizole 50W formulation containing 500 g ai/kg, except for one trial located in Ryde, California, which consisted of three sets of four foliar applications. Trials reported by Ball 1988d consisted of four to six foliar applications of the triflumizole 50W formulation containing 500 to 514 g ai/kg. All applications were made at a rate of approximately 0.56 kg ai/ha per application or 1.12 kg ai/ha per application. Applications were made on a 7-day to 100-day schedule until pears were ready to be harvested. The pears were harvested 14 days after the last treatment (PHI=14), except for the trial located in Ryde, California, which had a PHI of 15 days.

One to two samples of pears were collected from each of the treated and untreated plots and shipped, frozen, to the analytical laboratories. At each laboratory, samples were processed in a Hobart food processor and stored frozen until analysis. Samples were stored for less than 14 months (Ball 1986b) or less than 7 months (Ball 1988d) before analysis.

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/ECD. The LOQ was not determined, and the LOD was 0.02 mg eq/kg. Average recovery of all fortifications was $78.4 \pm 21.1\%$ for Ball 1986d (n=7) and $79.2 \pm 13.6\%$ for Ball 1988d (n=10). All control samples had residues below the limit of quantitation of the method. Pears treated with the triflumizole 50W formulation had detectable residues.

A total of two supervised trials on pears were conducted in Japan in 1985. Trials were conducted in Niigata (one) and Hiroshima (one). Trials were reported in Gomyo 1992.

The trials each had two plots that received eight foliar applications of the triflumizole WP formulation containing 300 g ai/kg. Application volume was 5000 L/ha, resulting in a rate of 0.75 kg ai/ha. Applications were made on a 4-day to 10-day schedule until pears were ready to be harvested. The pears were harvested 1, 7, and 21 days after the last treatment (PHI=1, 7, and 21). None of the trials were conducted at the critical GAP.

Pear samples were collected from treated plots and untreated plots. Specimens were stored frozen (approximately 1–2 months) until analysis by The Institute of Environmental Toxicology, Ibaraki, Japan. Samples were analysed for triflumizole and FM-6-1, and reported as the sum of both.

The method for analysis was high performance liquid chromatography. The LOQ was 0.02 mg eq/kg. Average recovery at 0.5 mg eq/kg was 87.3% (n=2). All control samples had residues at or below the limit of quantitation of the method, and these are not considered significant. Pears treated with the triflumizole WP formulation had detectable residues.

Cherries

A total of eight supervised trials on cherries were conducted in the USA in 1995. Trials were conducted in California (one), Michigan (three), New York (two), Washington (one), and Utah (one). Trials were reported in Gaydosh 1997 and Maselli 1997.

Each trial site, with the exception of California, contained two treated plots. One plot received six airblast applications of the triflumizole 50WS formulation containing 522.5 g ai/kg in 750 litres of water, and the second plot received six airblast applications of the triflumizole 50WS formulation containing 500 g ai/kg in 2340 litres of water. The treated plot in California received six airblast applications of the triflumizole 50WS formulation containing 522.5 g ai/kg in 2340 litres of water. All applications were made at a rate of approximately 0.52 to 0.57 kg ai/ha per application on a 1-day to 34-day schedule until cherries were ready to be harvested. The cherries were harvested 1, 3, and 7 days after the last treatment (PHI=1, 3, and 7).

Two samples of cherries each were collected from two treated plots (one treated plot in California) and one untreated plot. Specimens were stored frozen and shipped frozen to Morse Laboratories, Sacramento, California. Samples were de-stemmed, pitted, and ground in the presence of dry ice in a Hobart food grinder. Samples were stored frozen until analysis (< 12 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/ECD. The LOQ was 0.05 mg eq/kg, and the LOD was not reported. Average recovery of all fortifications was $76.5 \pm 5.59\%$ (n=11) for Gaydosh 1997 and $76.9 \pm 7.77\%$ (n=24) for Maselli 1997. All control samples had residues below the limit of quantitation of the method. Cherries treated with the triflumizole 50WS formulation had detectable residues.

Berries and other small fruits

Grapes

A total of 18 supervised trials on grapes were conducted in the USA from 1985 to 1987. Trials were conducted in Washington (three), California (six), New York (eight), and Ohio (one). Trials were reported in Ball 1986b and Ball 1988c.

Trials reported by Ball 1986b received four foliar applications of the triflumizole 50W formulation containing 500 g ai/kg, except for the trials located in Portland, New York, which received three foliar applications. Trials reported by Ball 1988c received four foliar applications of the triflumizole 50W formulation containing 500 g ai/kg (nominal), with the exception of one site in Selma, California, which received one foliar application. All applications were made at a rate of approximately 0.28 kg ai/ha per application or 0.56 kg ai/ha per application. Applications were made on a 14-day to 78-day schedule until grapes were ready to be harvested. The grapes were harvested 7 days after the last treatment (PHI=7), except for the 44852 trial, which has PHIs of 0, 3, 7, 14, and 21 days.

Samples of grapes were collected from treated plots and untreated plots. Specimens were stored frozen and shipped frozen to the analytical laboratories. Samples were processed in a Hobart grinder and stored frozen until analysis (< 9 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by HPLC/UV or GC/NPD. The LOD was 0.02 mg eq/kg. Average recovery of all fortifications was $80.0 \pm 14.1\%$ (n=11) for Ball 1986b and $95.8 \pm 16.0\%$ (n=13) for Ball 1988c. Three control samples had residues at or below the limit of detection (in Madera, California, one control sample had residues of 0.03 mg eq/kg, and in Selma, California, two control samples had residues of 0.03 mg eq/kg each), and these are not considered significant. Grapes treated with the triflumizole 50W formulation had detectable residues.

Strawberries

A total of eight supervised trials on strawberries were conducted in the USA in 1999. Trials were conducted in Pennsylvania (one), Georgia (one), Florida (one), Indiana (one), California (three), and Oregon (one). Trials were reported in Gaydosch 2001.

At each trial, plots received three foliar applications of the triflumizole 50WS formulation containing 500 g ai/kg. All applications were made at a rate of approximately 0.41 to 0.43 kg ai/ha per application. Applications were made on a 10-day to 14-day schedule until strawberries were ready to be harvested. The strawberries were harvested 1 and 3 days after the last treatment (PHI=1 and 3 days).

Two samples of strawberries were collected from one treated plot and one sample was collected from one untreated plot. Specimens were stored frozen and shipped frozen to Morse Laboratories, Inc., Sacramento, California. Samples were processed with dry ice in a Hobart grinder and stored frozen until analysis (< 9 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/MSD. The LOQ was 0.02 mg eq/kg, and the LOD was not reported. Average recovery of all fortifications was $80.5 \pm 5.0\%$ (n=12) for strawberries. All control samples had residues at or below the limit of quantitation of the method. Strawberries treated with the triflumizole 50WS formulation had detectable residues.

Assorted Tropical and Sub-Tropical Fruits-Inedible Peel

Papaya

A total of four supervised trials on papaya were conducted in the USA from 2005 to 2006. Trials were conducted in Hawaii (three), and Florida (one). Trials were reported by Barney 2007f.

At each trial, plots received five foliar applications of the triflumizole 480SC formulation containing 453 g ai/L. All applications were made at a rate of approximately 0.41 to 0.44 kg ai/ha per application. Applications were made on a 12-day to 14-day schedule until papaya was ready to be harvested. The papaya was harvested 0 days after the last treatment (PHI=0).

Two samples of papaya were collected from one treated plot and one untreated plot. Specimens were stored frozen and shipped frozen to IR-4 Western Region Satellite Laboratory, Honolulu, Hawaii. Samples of whole fruit were processed with dry ice in a Hobart food cutter and stored frozen until analysis (< 19 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/MSD. The LOQ was 0.033 mg eq/kg, and the LOD was 0.011 mg eq/kg. Method validation results for triflumizole averaged $82 \pm 7\%$ at 0.050 mg eq/kg, $76 \pm 6\%$ at 1.0 mg eq/kg and $81 \pm 4\%$ at 10 mg eq/kg. Method validation results for FM-6-1 averaged $81 \pm 4\%$ at 0.050 mg eq/kg, $72 \pm 5\%$ at 1.0 mg eq/kg and $73 \pm 4\%$ at 10 mg eq/kg. Method validation results for FA-1-1 averaged $85 \pm 4\%$ at 0.050 mg eq/kg, $79 \pm 3\%$ at 1.0 mg eq/kg and $75 \pm 1\%$ at 10 mg eq/kg. All control

samples had residues at or below the limit of quantitation of the method. Papaya treated with the triflumizole 480SC formulation had detectable residues.

Brassica (cole or cabbage) vegetables, Head cabbages, Flowerhead brassicas

Broccoli

A total of 10 supervised trials on broccoli were conducted in the USA from 2003 to 2007. Trials were conducted in Texas (two), Maryland (one), California (five), New Mexico (one), and Oregon (one). Trials were reported in Gaydosh 2004a and Barney 2007c.

The trial reported in Gaydosh 2004a received five foliar applications of the triflumizole 50WS formulation containing 501 g ai/kg. Trials reported in Barney 2007c received four to six foliar applications of the triflumizole 480SC formulation containing 430 g ai/l. All applications were made at a rate of approximately 0.27 to 0.57 kg ai/ha per application. Applications were made on a 6-day to 8-day schedule until broccoli was ready to be harvested. The broccoli was harvested 0 days after the last treatment (PHI=0), except for the AWD-03907 trial, which had PHIs of 1, 3, and 7 days, and the 06-CA11 trial, which had PHIs of 0, 1, 4, 7, and 11 days.

Samples of broccoli were collected from treated plots and untreated plots. Specimens were stored frozen and shipped frozen to Morse Laboratories, Sacramento, California, where they were processed with dry ice in a Hobart food grinder and stored frozen until analysis (approximately 9 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/MSD. The LOQ was 0.05 mg eq/kg (Gaydosh 2004a) or 0.032 mg eq/kg (Barney 2007c), and the LOD was not determined (Gaydosh 2004a) or 0.011 mg eq/kg (Barney 2007c). Average recovery of all triflumizole fortifications was $74 \pm 4\%$ (Gaydosh 2004a) and $81 \pm 10\%$, $82 \pm 3\%$, and $84 \pm 4\%$, for the three validation levels. All control samples had residues at or below the limit of quantitation of the method. Broccoli treated with the triflumizole 50WS formulation and the triflumizole 480SC formulation had detectable residues.

Cabbages, Head

A total of nine supervised trials on cabbage were conducted in the USA from 2006 to 2007. Trials were conducted in Maryland (one), New Jersey (one), New York (one), Wisconsin (one), Florida (one), Texas (one), Tennessee (one), Colorado (one) and California (one). Trials were reported in Barney 2007d.

At each trial, plots received four foliar applications of the triflumizole 480SC formulation containing 430 g ai/kg, except for the Tennessee trial, which received five foliar applications. All applications were made at a rate of approximately 0.27 to 0.30 kg ai/ha per application. Applications

were made on a 6-day to 8-day schedule until cabbage was ready to be harvested. The cabbage was harvested 0 days after the last treatment (PHI=0).

Two samples of cabbage (with wrapper leaves) each were collected from one treated plot and one untreated plot. Specimens were stored frozen and shipped frozen to Morse Laboratories, Sacramento, California, where they were processed with dry ice in a Hobart food grinder and stored frozen until analysis (< 9 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/MSD. The LOQ was 0.030 mg eq/kg, and the LOD was 0.010 mg eq/kg. Average recovery of all fortifications was $83 \pm 7\%$ (n=16) for cabbage. All control samples had residues at or below the limit of quantitation of the method. Cabbage treated with the triflumizole 480SC formulation had detectable residues.

^a The residue value(s) are not supported by the available storage stability data.

Fruiting vegetables, Cucurbits

The Meeting received supervised residue trials on cucurbit vegetables. Trials with cucumbers were conducted in both indoor and outdoor environments.

Cucumbers (Outdoor)

A total of six supervised trials on cucumbers were conducted in the USA in 1997. Trials were conducted in North Carolina (one), South Carolina (one), Florida (one), Indiana (two), and Texas (one). Trials were reported in Maselli 1999.

At each trial, plots received five foliar applications of the triflumizole 50WS formulation containing 500 g ai/kg. All applications were made at a rate of approximately 0.26 to 0.30 kg ai/ha per application. Applications were made on a 7-day to 11-day schedule until cucumbers were ready to be harvested. The cucumbers were harvested 0 day after the last treatment (PHI=0).

Two samples of cucumbers were collected from one treated plot and one sample was collected from one untreated plot. Specimens were stored frozen and shipped frozen to PTRL West, Inc., Richmond, California. Samples were processed with dry ice in either a Hobart or WestBend food processor and were stored frozen until analysis (< 30 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/NPD. The LOQ was 0.05 mg eq/kg, and the LOD was not determined. Average recovery of all fortifications was $82.0 \pm 9.8\%$ (n=18) for cucumbers. All control samples had residues below the limit of quantitation of the method. Cucumbers treated with the triflumizole 50WS formulation had detectable residues.

Cucumbers (Indoor)

A total of four supervised trials on cucumbers were conducted in USA from 2009 to 2010. Trials were conducted in Texas (one), Florida (one), Colorado (one), and Maryland (one). Trials were reported in Homa 2012.

At each trial, plots received five foliar applications of the triflumizole 480SC formulation containing 431 g ai/L. All applications were made at a rate of approximately 0.26 to 0.30 kg ai/ha per application. Applications were made on a 6- to 8-day schedule until cucumbers were ready to be harvested. The cucumbers were harvested 0 day after the last treatment (PHI=0), except for the trial in Colorado which had PHIs of 0, 3, 7, 12, and 15 days.

Two samples of cucumbers were collected from one treated plot and one untreated plot. Specimens were stored frozen and shipped frozen to the Western Region Laboratory at the University of California, Davis (UCD), Davis, California. Samples were processed with dry ice in a Hobart food chopper and were stored frozen until analysis (< 15 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/MSD in selective ion monitoring (SIM) mode. Average recovery of all fortifications was $76 \pm 8\%$ (n=9) for cucumbers. All control samples had residues below the limit of quantitation of the method. Cucumbers treated with the triflumizole 480SC formulation had detectable residues.

A total of four supervised trials on cucumbers were conducted in Japan from 1982 to 1990. Trials were conducted in Ibaragi (one), Osaka (two), and Chiba (one). Trials were reported in Gomyo 1993.

Two plots received five foliar applications of the triflumizole 15EC formulation containing 150 g ai/L, and two plots received five foliar applications of the triflumizole 30WP formulation containing 300 g ai/kg. All applications were made at a rate of approximately 0.06 to 0.30 kg ai/ha per application. Applications were made on a 6-day to 9-day schedule until cucumbers were ready to be harvested. The cucumbers were harvested 1, 3, and 7 days after the last treatment (PHI=1, 3, and 7 days).

One sample of cucumber was collected from one treated plot and one untreated plot. Specimens were stored frozen until analysis by Environmental Toxicology Laboratory of Nippon Soda Co., Odawara, Japan. Storage time was less than 30 months.

The method for analysis was high performance liquid chromatography with UV detection and results are reported as combined residues of triflumizole and FM-6-1. The LOQ was 0.02 mg eq/kg. All control samples had residues at or below the limit of quantitation of the method. Cucumbers treated with the triflumizole 15EC formulation and the triflumizole 30WP formulation had detectable residues.

A total of eight supervised trials on cucumbers were conducted in the Netherlands in 1993. Trials were conducted in Harmelen (one), Vleuten (one), Houten (one), Maarssen (one), Zevenhuizen (one), Moerkapelle (one), Bleiswijk (one), and Bergschenhoek (one). Trials were reported in Geuijen 1994.

For each trial, plots received three to four foliar applications of the triflumizole 15EC formulation containing 150 g ai/L. All applications were made at a rate of approximately 0.228 to 0.533 kg ai/ha per application. Applications were made on a 7-day schedule until cucumbers were ready to be harvested. The cucumbers were harvested 3 days after the last treatment (PHI=3), except for the trials located in Vleuten and Zevenhuizen, which had PHIs of 0, 1, 3, and 7 days.

One sample each of cucumber was collected from two treated plots and one untreated plot. Specimens were received by the analysis department, TNO Nutrition Research Institute, AJ Zeist, Netherlands, on the day they were harvested. Samples were homogenized using a Stephan cutter. Processed samples were stored refrigerated until analysis.

The method for analysis was high performance liquid chromatography with UV detection. The LOQ was approximately 0.1 mg eq/kg, and the LOD was 0.02 mg eq/kg. A total of 7 control samples had residues at or above the limit of quantitation of the method, and these are not considered significant. Cucumbers treated with the triflumizole 15EC formulation had detectable residues.

^b 0.10 mg eq/kg was used to calculate the average residue.

^c Based on harvest and communication dates specified in the study report.

Muskmelons

A total of six supervised trials on muskmelons were conducted in the USA in 1997. Trials were conducted in North Carolina (one), Indiana (one), Texas (one) and California (three). Trials were reported by Gaydos, Maselli, and Puhl 1999.

At each trial, plots received five foliar applications of the triflumizole 50WS formulation containing 500 g ai/kg (nominal). All applications were made at a rate of approximately 0.26 to 0.32 kg ai/ha per application. Applications were made on a 7-day to 10-day schedule until muskmelons were ready to be harvested. The muskmelons were harvested 0 day after the last treatment (PHI=0).

Two samples of muskmelons were collected from each treated plot and one sample was collected from each untreated plot. Specimens were stored frozen and shipped frozen to PTRL West, Inc., Richmond, California. Whole melon samples were sectioned and composited to obtain a representative sample for the field. Samples (pulp + peel) were processed with dry ice in a Hobart cutter/mixer and were stored frozen until analysis (< approximately 7 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/NPD. The LOQ was 0.05 mg eq/kg. Average recovery of all fortifications was $93.5 \pm 19.0\%$ (n=6) for muskmelons. All control samples had residues below the limit of quantitation of the method. Muskmelons treated with the triflumizole 50WS formulation had detectable residues.

Squash, Summer

A total of five supervised trials on summer squash were conducted in the USA in 1997. Trials were conducted in Pennsylvania (one), South Carolina (one), Florida (one), Indiana (one), and California (one). Trials were reported in Gaydosch 1999.

At each trial, plots received five foliar applications of the triflumizole 50WS formulation containing 522 g ai/kg. All applications were made at a rate of approximately 0.28 to 0.29 kg ai/ha per application. Applications were made on a 7-day to 10-day schedule until squash was ready to be harvested. The squash was harvested 0 days after the last treatment (PHI=0).

Two samples of squash were collected from one treated plot and one sample was collected from one untreated plot. Specimens were stored frozen and shipped frozen to PTRL West, Inc., Richmond, California. Samples were processed with dry ice in a Hobart or WestBend food processor and stored frozen until analysis (< 9 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/NPD. The LOQ was 0.05 mg eq/kg. Average verification recoveries for triflumizole in two verification sets were $79.0 \pm 8.0\%$ (n=6) and $77.2 \pm 3.7\%$ (n=6), while verification recoveries for FM-6-1 averaged $74.3 \pm 11.6\%$ (n=6) and $81.1 \pm 8.2\%$ (n=6). All control samples had residues at or below the limit of quantitation of the method. Squash treated with the triflumizole 50WS formulation had detectable residues.

*Fruiting vegetables, Other than Cucurbits**Tomatoes*

A total of four supervised trials on tomato were conducted in USA in 2010. Trials were conducted in greenhouses in California (1), Maryland (1), Texas (1), and Wisconsin (1). Trials were reported by Barney 2012.

At each trial, plots received four or five foliar applications of the triflumizole 480SC formulation containing 431 g ai/L. All applications were made at a rate of approximately 0.26 to 0.29 kg ai/ha per application. Applications were made on a 6-day to 14-day schedule until tomatoes were ready to be harvested. The tomatoes were harvested 0 day after the last treatment (PHI=0), except for the trial located in California, which had PHIs of 0, 1, 4, 8, 10, and 15 days.

Two samples of tomatoes were collected from one treated plot and one untreated plot. Specimens were stored frozen and shipped frozen to USDA-ARS laboratory, Beltsville, MD. After reassignment of the analytical laboratory, samples were shipped frozen to IR-4 Western Region Laboratory, Davis, CA. Samples were processed with dry ice in a Hobart or Robot Coupe food chopper and stored frozen until analysis (< 19 months).

The analytical method assayed triflumizole and its aniline-containing metabolites. Total triflumizole residues are quantified using a gas chromatograph equipped with a mass selective detector (MSD) in selective ion monitoring (SIM) mode. The LOQ was 0.50 mg eq/kg. Average recovery of all fortifications was $85.3 \pm 9.6\%$ for tomatoes (n=13). All control samples had residues below the limit of quantitation of the method. Tomatoes treated with the triflumizole 480SC formulation had detectable residues.

A total of four supervised trials on tomatoes were conducted in the Netherlands in 1995 and 1996. Trials were conducted in greenhouses in Haps (one), Siebengewald (one), and Wellerlooi (two). Trials were reported by van de Ruit 1997.

At each trial, plots received three foliar applications of the triflumizole EC formulation containing 158 g ai/L. All applications were made at a rate of approximately 0.310 to 0.322 kg ai/ha per application. Applications were made on a 7-day schedule until tomatoes were ready to be harvested. The tomatoes were harvested 3 days after the last treatment (PHI=3), except for the trial located in Haps which was a decline trial with PHIs of 0, 1, 3, and 7 days.

One sample of tomato was collected from one treated plot and one untreated plot, except for the trial located in Haps (PHI=0) and the trial located in Siebengewald, in which duplicate samples were collected. Specimens were stored frozen and shipped frozen to BCO Analytical Services B.V.,

Bergschot, Breda, Netherlands. Samples were homogenized in a blender and stored frozen until analysis (< 19 months).

The analytical method assayed residues of triflumizole and FM-6-1, with quantitation by HPLC/UV. The results are reported as combined residues. The LOQ was 0.01 mg eq/kg. Average recovery of all fortifications was $93.3 \pm 5.6\%$ (n=6) for tomatoes. All control samples had residues below the limit of quantitation of the method. Tomatoes treated with the triflumizole EC formulation had detectable residues.

A total of four supervised trials on tomatoes were conducted in Belgium in 1995 and 1996. Trials were conducted in greenhouses in Onze-Lieve-Vrouw-Waver (one), St. Katelijne-Waver (two), and Duffel (one). Trials were reported in van de Ruit 1997.

At each trial, plots received three foliar applications of the triflumizole EC formulation containing 158 g ai/L. All applications were made at a rate of approximately 0.308 to 0.319 kg ai/ha per application. Applications were made on a 7-day schedule until tomatoes were ready to be harvested. The tomatoes were harvested 3 days after the last treatment (PHI=3), except for the trial located in Onze-Lieve-Vrouw-Waver which was a decline trial with PHIs of 0, 1, 3, and 7 days.

One sample of tomato was collected from one treated plot and one untreated plot, except for the trial located in Duffel in which three samples were collected from the treated plot and two samples were collected from the untreated plot. Specimens were stored frozen and shipped frozen to BCO Analytical Services B.V., Bergschot, Breda, Netherlands. Samples were homogenized in a blender and stored frozen until analysis (< 19 months).

The analytical method assayed residues of triflumizole and FM-6-1, with quantitation by HPLC/UV. Results are reported as combined residues. The LOQ was 0.01 mg eq/kg. Average recovery of all fortifications was $93.3 \pm 5.6\%$ (n=6) for tomatoes. All control samples had residues below the limit of quantitation of the method. Tomatoes treated with the triflumizole EC formulation had detectable residues.

^a 0.50 mg eq/kg was used to calculate the average residue.

Leafy vegetables (Including brassica leafy vegetables)

The critical GAP in the USA is 2–3 applications at 0.28 kg ai/ha at a 14-day interval. The maximum seasonal use rate is 0.63 kg ai/ha. The PHIs are 0 days for leafy vegetables and 1 day for Brassica leafy vegetables.

Lettuce

A total of 17 supervised trials on head and leaf lettuce were conducted in USA from 2003 to 2006. Trials were conducted in Texas (one), Maryland (one), New Jersey (two), California (eight), New Mexico (two), Georgia (two), and Colorado (one). Once New Jersey trial and the Colorado trial were conducted in a greenhouse. Trials were reported by Gaydosh 2004b and Barney 2007e.

The trial reported by Gaydosh 2004b received five foliar applications of the triflumizole 50WS formulation containing 501 g ai/kg. Trials reported by Barney 2007e received four foliar applications of triflumizole 480SC formulation containing 453 g ai/kg. All applications were made at a rate of approximately 0.27 to 0.59 kg ai/ha per application. Applications were made on a 6-day to 9-day schedule until lettuce was ready to be harvested. The lettuce was harvested 0 days after the last treatment (PHI=0), except for the AWD-03906 trial, which was a decline trial with PHIs of 1, 3, and 7 days, and the 05-NM05 and 05-CA27 trials, which was a decline trial with PHIs of 0, 2–3, 7–8, and 14 days.

Two to three samples of lettuce each were collected from one treated plot and one untreated plot. Specimens were stored frozen and shipped frozen to Morse Laboratories, Inc., Sacramento, California, or to Cornell Analytical Laboratories, Geneva, New York. Samples were processed with dry ice in a Hobart grinder or Hobart FP 30011 stored frozen until analysis (< approximately 2 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/MSD. The LOQ was 0.05 mg eq/kg. Average recovery of all fortifications was $74 \pm 4\%$ (n=12) for Gaydosh 2004b and $90 \pm 19\%$ (n=8) for Barney 2007e. All control samples had residues below the limit of quantitation of the method. Lettuce treated with the triflumizole 50WS formulation and the triflumizole 480SC formulation had detectable residues.

Mustard greens

A total of ten supervised trials on mustard greens were conducted in the USA from 2004 to 2005. Trials were conducted in New Jersey (one), Maryland (one), Wisconsin (one), Georgia (one), Texas (one), Florida (one), North Carolina (one), Tennessee (one), and California (two). Trials were reported by Barney 2006.

At each trial, plots received four foliar applications of the triflumizole 50WS formulation containing 500 g ai/kg. All applications were made at a rate of approximately 0.27 to 0.29 kg ai/ha per application. Applications were made on a 6- to 10-day schedule until mustard greens were ready to be harvested. The mustard greens were harvested 1 day after the last treatment (PHI=1), except for the New Jersey trial, which was a decline trial with PHIs of 0, 1, 4, and 6 days.

Two samples of mustard greens were collected from one treated plot and one untreated plot. Specimens were stored frozen and shipped to Morse Laboratories, Inc., Sacramento, California. Samples were processed with dry ice in a Hobart food grinder and stored frozen until analysis (< 7 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/MSD. The LOQ was 0.05 mg eq/kg. Average recovery of all fortifications was $84.6 \pm 6.4\%$ (n=9) for mustard greens. All control samples had residues below the limit of quantitation of the method. Mustard greens treated with the triflumizole 50WS formulation had detectable residues.

Swiss chard

A total of three supervised trials on Swiss chard were conducted in the USA in 2005. Trials were conducted in Maryland (one), Texas (one), and Oregon (one). Trials were reported by Barney 2007g.

At each trial, plots received four foliar applications of the triflumizole 480SC formulation containing 453 g ai/L. All applications were made at a rate of approximately 0.28 to 0.29 kg ai/ha per application. Applications were made on a 6-day to 8-day schedule until Swiss chard was ready to be harvested. The Swiss chard was harvested 0 day after the last treatment (PHI=0).

Two samples of Swiss chard each were collected from one treated plot and one untreated plot. Specimens were stored frozen and shipped frozen to Cornell Analytical Laboratories, Geneva, New York. Samples were processed with dry ice in a Hobart chopper and stored frozen until analysis (< 7 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/MSD. The LOQ was 0.066 mg eq/kg, and the LOD was 0.022 mg eq/kg. Average recovery of all fortifications was $93 \pm 16\%$ (n=19) for Swiss chard. All control samples had residues at or below the limit of quantitation of the method. Swiss chard treated with the triflumizole 480SC formulation had detectable residues.

Turnip greens

One supervised trial on turnip greens was conducted in the USA in 2003. The trial was conducted in Texas and was reported by Gaydosh 2004c.

The treated plot received five foliar applications of the triflumizole 50WS formulation containing 501 g ai/kg. All applications were made at a rate of approximately 0.27 to 0.30 kg ai/ha per application. Applications were made on a 7-day schedule until turnip greens were ready to be harvested. The turnip greens were harvested 1, 3, and 7 days after the last treatment.

Specimens were stored frozen and shipped frozen to Morse Laboratories, Inc., Sacramento, California. Samples were processed with dry ice in a Hobart food grinder and stored frozen until analysis (< 4 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/MSD. The LOQ was 0.05 mg eq/kg, and the LOD was not determined. Average recovery of all fortifications was $91 \pm 12\%$ ($n=5$). All control samples had residues at or below the limit of quantitation of the method. Turnip greens treated with the triflumizole 50WS formulation had detectable residues.

Tree nuts

Hazelnuts

A total of three supervised trials on hazelnuts (filberts) were conducted in the USA in 2001. Trials were conducted in Oregon. Trials were reported by Thompson 2002.

At each trial, plots received six foliar applications of the triflumizole 50WS formulation containing 500 g ai/kg. All applications were made at a rate of approximately 0.80 to 0.87 kg ai/ha per application. Applications were made on a 13-day to 111-day schedule until hazelnuts were ready to be harvested. The hazelnuts were harvested approximately 18 days after the last treatment.

Two samples of hazelnuts each were collected from one treated plot and one untreated plot. Specimens were stored frozen and shipped frozen to Morse Laboratories, Inc., Sacramento, California. Nutmeat samples were processed with dry ice in a Hobart food grinder and stored frozen until analysis (< 4 months).

The analytical method assayed triflumizole and its aniline-containing metabolites, with quantitation by GC/MSD. The LOQ was 0.05 mg eq/kg for triflumizole and for FA-1-1, and the estimated LOD was 0.01 mg eq/kg for triflumizole and 0.02 mg eq/kg for FA-1-1. Average recovery of all fortifications was $91 \pm 8\%$ ($n=9$) for triflumizole and $88 \pm 9\%$ ($n=9$) for FA-1-1. All control samples had residues below the limit of quantitation of the method. Hazelnuts treated with the triflumizole 50WS formulation had no detectable residues above the LOQ.

^a Trials were conducted in the same orchard complex. One trial was on young, vigorous trees with large nuts, the second was on older, less vigorous trees with smaller nuts, and the third was in a different orchard block with different soil type and trees of an intermediate age.

Dried Herbs

Hops

A total of eight supervised trials on hops were conducted in the USA from 2002 to 2011, from three separate residue studies (#10798/RP-02011, 2006-008, and #10798). Trials were conducted in Idaho, Oregon, and Washington. Trials were reported by Corley 2012, Barney 2007b, and Barney 2007a.

Trials reported in Corley 2012 received three foliar applications of the triflumizole 480SC formulation containing 424.7 g ai/L. Trials reported by Barney 2007b received four foliar applications of the triflumizole 50WS formulation containing 503 g ai/kg. One of two trials reported by Barney 2007a received four foliar applications of the triflumizole 50WS formulation containing 509 g ai/kg, and the second trial received four foliar applications of the triflumizole 480SC formulation containing 430 g ai/L. All applications were made at a rate of approximately 0.42 to 0.58 kg ai/ha per application. Applications were made on a 10-day to 14-day schedule until hops were ready to be harvested. The hops were harvested 7 and 13–14 days after the last treatment (PHI=7, 13–14), except for the OR40 and WA 36 trials, which only had PHIs of 7, and the ID18 and WA35 trials, which was a decline trial with PHIs of 0, 3, 7–8, 14, and 21 days.

Samples of hops were collected from one treated plot and one untreated plot, except for the trial reported in Barney 2007a, which had two treated plots. Specimens were dried in a hop kiln (time not specified; ≤ 3 –6 days based on transport dates) stored frozen and shipped frozen to IR-4 Western Region Laboratory, Davis, California, or Morse Laboratories, Inc., Sacramento, California. Samples were processed with a Geno/Grinder or with dry ice in a Rietz disintegrator. Samples were stored frozen from harvest until analysis (< 5 months Corley or < 27 months Barney).

For sample analysis, residue data from Corley 2012 were obtained using two separate analytical procedures, with one measuring triflumizole and FM-6-1 separately by LC-MS/MS, while the second method determined the total triflumizole equivalents by GC-MS (i.e., triflumizole and aniline-containing metabolites that were converted to FA-1-1, and expressed as triflumizole equivalents). The method used (Barney 2007a and Barney 2007b) also determined the total triflumizole by GC-MS. The LOQs were 0.050 mg eq/kg (Corley 2012), 0.01 mg eq/kg (Barney 2007b), or 0.02 mg eq/kg (Barney 2007a). Average recovery of all fortifications was $90.0 \pm 18.1\%$ ($n=37$) for Corley 2012 or $97.6 \pm 5.1\%$ ($n=18$) for Corley 2012, $81.5 \pm 13.0\%$ ($n=6$) for Barney 2007b and $79.2 \pm 6.4\%$ ($n=6$) for Barney 2007a. All control samples had residues at or below the limit of quantitation of the method. Hops treated with the 480SC formulation and the 50WS formulation had detectable residues.

FATE OF RESIDUES IN STORAGE AND PROCESSING

In Processing

The Meeting received data depicting the effects of processing on residue levels in apple and grape processed commodities. For apples, processing factors have been calculated for juice, sauce, and wet and dry pomace. For grapes, processing factors have been calculated for juice, raisins (and related commodities), stems, and wet and dry pomace.

Apples

A processing study on apples was conducted from samples taken in three field trials located in commercial apple growing areas of the United States (Ball 1986c). In those trials, the treated plots each received four applications of triflumizole 50W at a rate of 0.56 kg ai/ha (0.5 lb ai/acre), which represents 1–2× the recommended label rate, or 1.12 kg ai/ha (1.0 lb ai/acre), which represents 2–4× the recommended label rate. Samples were collected 14 days after the last treatment. One sample was taken at each treated plot for processing into juice, sauce, wet pomace, and dry pomace. Processed commodities were produced by grinding and pressing, using a procedure that simulated commercial practice. Processed samples and a retained whole apple sample were shipped frozen to the laboratory, where the samples remained frozen until being assayed for total triflumizole via GC analysis.

The method was validated prior to analysis with a limit of quantitation of 0.02 mg eq/kg in all matrices. The performance of the method was also demonstrated during analysis of the samples by analysing fortified control matrices concurrently with experimental samples. The recoveries were 62% for whole unwashed apples, 125% for apple juice, 85% for apple sauce, 106% for wet pomace, and 96% for dry pomace. The overall mean concurrent recovery for all matrices was $95 \pm 25\%$ (n=5).

The results of the processing study are summarized in Table . Results indicate that residues did not concentrate in apple juice, sauce, or wet pomace, but was concentrated in dry apple pomace during processing.

Table 60 Processing factors for residues of triflumizole in apple processed fractions

	0.34	0.13	0.38	
	Average		1.67	

Grapes

A processing study on grapes was conducted from samples taken in nine field trials located in commercial grape growing areas of the United States (Ball 1986b and Ball 1988c). Each field trial site consisted of control and treated plots. The treated plots each received four applications of triflumizole 50W at a rate of 0.28 kg ai/ha (0.25 lb ai/acre), which represents 1–2× the recommended label rate, except for the trials located in Portland, New York which received three applications.

Samples were collected 7 days after the last treatment. One sample was taken at each treated plot for processing into wet pomace, dry pomace, raisins (washed and unwashed), stems, and juice. Two samples were taken at the plot treated with triflumizole 50W at a rate of 0.56 kg ai/ha for processing into raisin waste. Samples were processed by grinding and pressing, using a procedure that simulated commercial practice. Processed samples and a retained whole grape sample were shipped frozen to the laboratory, where the samples remained frozen until analysis.

Combined residues of triflumizole and its aniline-containing metabolites were analysed in the different grape matrices using a validated analytical method with residue determinations made by HPLC (Ball 1986b) or GC (Ball 1988c). The method was validated prior to sample analysis. The performance of the method was also demonstrated during analysis of the samples by analysing fortified control matrices concurrently with experimental samples. The overall mean recoveries were 80–84% for whole grapes, 92–101% for wet pomace, 78–98.2% for dry pomace, 94% for raisins, 64% for stems, and 116% for juice. The overall mean concurrent recovery for all matrices was $88 \pm 14\%$ (n=11).

The results of the processing study are summarized in Table . Results indicate that residues in raisins (washed and unwashed), grape juice and raisin waste are reduced, but those in wet and dry grape pomace and grape stems were concentrated during processing.

RESIDUES IN ANIMAL COMMODITIES

Farm animal feeding studies

The Meeting received a lactating dairy cow feeding study (Parkins, 1988). The only crop with potential impact to the poultry dietary burden is cabbage; this crop represents 5% of the poultry diet in the EU only, which is of minimal impact. Therefore, a poultry feeding study has not been submitted.

Lactating dairy cows

Six dairy cows were dosed, for 28 consecutive days, orally via gelatin capsules containing technical triflumizole. The cows were randomly divided into two groups of three, each group receiving one of the following feeding levels: 10 ppm (low dose) and 50 ppm (high dose) of triflumizole in the diet. An additional two cows served as control animals. Samples of milk were taken each morning and evening. At the end of the experiment, the animals were sacrificed and samples of muscle, fat, entire liver and both kidneys were taken for analysis.

Samples from the low-dose group and the high-dose group were analysed for residues containing the 2-amino-3-trifluoro-methyl-4-chloroaniline (FA-1-1) moiety using gas chromatography with a nitrogen-phosphorus detector (GC-NPD). The limit of determination was 0.01 mg eq/kg. The total residues in milk and cattle tissues were reported as triflumizole (MW: 346) equivalents by converting the analysed FA-1-1 (MW: 195) level using a molecular weight conversion factor of 1.77. The reported LOQ in terms of triflumizole is 0.02 mg eq/kg.

For the high-dose group, the metabolite 2-amino-3-trifluoro-methyl-5-chlorophenol (FA-1-5) was also analysed using HPLC with electrochemical detection. Recoveries from milk fortified with either 0.01 mg eq/kg or 0.05 mg eq/kg FA-1-1 averaged 86.3% and 86.8%, respectively; for FA-1-5, concurrent recoveries in milk were 98%, 95% and 97% for spiked levels of 0.1, 0.2, and 0.3 mg eq/kg, respectively. For tissues, the average recoveries of FA-1-1 were 86% for fat, 93% for kidney, 73% for liver, and 85% for muscle. In the fortified samples with FA-1-5, the concurrent recovery in kidney and liver averaged 70%.

During the 28-day feeding period, residues analysed as FA-1-1 in milk samples from the low-dose group were < 0.01 mg eq/L. Residues analysed as FA-1-1 in milk from the high-dose group ranged from 0.01 mg eq/L to 0.06 mg eq/L. On average, residues were fairly consistent in milk after Day 2 of dosing (Table). Residues of FA-1-5 in milk (high-dose group) were < 0.01 mg/L.

Table 62 Total residues in milk (high-dose group)

Time (days)	Triflumizole-Equivalent Residues (mg/L) ^a	FA-1-5
0	< 0.02, < 0.02, < 0.02 [< 0.02]	< 0.01

28	0.04, 0.04, 0.11 [0.06]	< 0.01

^a Bracketed values are mean

In tissues, average residues (as triflumizole-equivalents) in the low-dose group were < 0.02 mg eq/kg in muscle, 0.06 mg eq/kg in fat, 0.31 mg eq/kg in kidney, and 0.48 mg eq/kg in liver. In the high-dose group, average tissue residues were 0.09 mg eq/kg in muscle, 0.33 mg eq/kg in fat,

1.55 mg eq/kg in kidney, and 4.25 mg eq/kg in liver (Table 63). No residues of FA-1-5 were found in kidney or liver (LOD=0.03 mg eq/kg).

Table 63 Summary of feeding study results with triflumizole in dairy cattle

^a Values in brackets are mean ± std. dev.; values in braces are average matrix:feed ratios. For milk, the range of residues from Day 2 to Day 28 is shown.

APPRAISAL

Residue and analytical aspects of triflumizole were considered for the first time by the present Meeting. The residue evaluation was scheduled for the 2013 JMPR by the Forty-fourth Session of the CCPR.

Triflumizole is a broad-spectrum foliar fungicide that controls a variety of fungal diseases in fruits and vegetables. It acts as a protectant and as an eradicant by preventing disease symptoms after infection has occurred. Triflumizole has anti-sporulant activity which reduces spores after lesions become visible. Triflumizole belongs to the demethylation inhibitor (DMI) group of fungicides classified as Group 3 by the Fungicide Resistance Action Committee (FRAC). Triflumizole has protective and curative action, and acts as an inhibitor of chitin biosynthesis. The product is mixed with water and applied as a foliar spray using ground equipment equipped for conventional spraying on crops. The Meeting received information on identity, animal and plant metabolism, environmental fates in soil, rotational crops, analytical methods, storage stability, use patterns, supervised trials, dairy cattle feeding studies, and fates of residues in processing.

(E)-4-chloro- α,α,α -trifluoro-N-(1-imidazol-1-yl-2-propoxyethylidene)-o-toluidine

In this appraisal, the following abbreviated names were used for metabolites.

Identifier	Chemical Structure

Identifier	Chemical Structure
FA-1-1	
FA-1-glucuronide	
FA-1-5 (Free and sulphate conjugate)	
FD-2-1	
FD-7-1	
FD-9-1	
FM-5-1	
FM-6-1

XXVI	

Animal metabolism

The Meeting received animal metabolism studies with triflumizole in rats, lactating goat and laying hens. The metabolism and distribution of triflumizole in animals were investigated using triflumizole universally labelled in the phenyl ring.

In the metabolism studies, rats were dosed at 10 mg/kg bw per day (single and multiple dose studies) or at 300 mg/kg bw per day (single dose study). Metabolite identification in tissues was not provided. The metabolite profile indicates that triflumizole is extensively metabolized in rats: less than 2% of the radiolabel recovered from urine or faeces was identified as parent compound. A few differences in metabolite pattern were observed between males and females after repeated low and single high doses, but not after a single low dose. The major urinary metabolites are the sulphate conjugates of N-(4-chloro-2-trifluoromethylphenyl)-2-hydroxy-acetamidine (FM-8-1) and 2-amino-5-chloro-3-trifluoromethylphenol (FA-1-5). In faeces, N-(4-chloro-2-trifluoromethylphenyl)-2-hydroxy-acetamide (FD-2-1) is a major metabolite. Differences between dose regimens exist with respect to other major metabolites. 2-(4-Chloro-2- trifluoromethylphenylimino)- 2-imidazol- 1-yl-ethanol (FM-2-1) is the major metabolite after a single oral low dose, 4-Chloro-2-trifluoromethylphenylamine (FA-1-1) is a major metabolite after single and repeated low dosing, whereas N-(4-chloro-2-trifluoromethylphenyl)-2-propoxy-acetamide (FD-1-1) is the major metabolite after a single high dose. The presence of the metabolite N-(4-chloro-2-trifluoromethylphenyl)- 2-propoxy-acetamidine (FM-6-1) was confirmed in rat faeces and urine.

Lactating goat was dosed with [^{14}C]triflumizole at a dose equivalent to approximately 280 ppm in the diet twice daily for 5 consecutive days. Gelatine capsules containing [^{14}C]triflumizole were administered orally via a balling gun. The majority of the dose was rapidly excreted in urine (56% of the TAR) and faeces (19.9% TAR).

Total radioactive residues (TRR) in the milk accounted for 0.18% TAR. Tissues contained approximately 0.65% TAR. Total material balance was 76.7% TAR, with an additional 5–12% TAR estimated to be in the bladder, digestive tract and carcass; $^{14}\text{CO}_2$ was not monitored.

Levels of radiolabel material reached a plateau in milk within approximately 24 hours and account for approximately 0.16% TAR. TRR was highest in liver and kidney (11.3 and 3.4 mg eq/kg, respectively) and approximately an order of magnitude lower in muscle (0.3 mg eq/kg) and fat (0.66 mg eq/kg). The residue in liver accounted for 0.4% TAR.

Triflumizole was not detected in any matrix. Major residues in liver were FA-1-1 (79.2% TRR, of which 54.8% TRR was bound) and FA-1-5-sulphate (12.4% TRR). In milk, major residues were FA-1-5-sulphate (29.1% TRR), FA-1-5-glucuronide (11.8% TRR), FD-2-1 (10.4% TRR), and FM-8-1-sulphate (12.6% TRR). No other individual compounds accounted for more than 10% of the TRR. The study noted that residues in other matrices were not identified due to low radioactivity; however, it is unclear why further characterization/identification was not done in muscle and liver given the level of residues in those tissues (0.3 and 0.66 mg eq/kg, respectively).

Laying hens were orally dosed with [^{14}C]triflumizole at a dose equivalent to 39 (3 hens) or 53 (2 hens) ppm in the diet twice daily for 5 consecutive days. The majority of the dose was rapidly eliminated in the excreta. Average radioactive residues in the excreta and cage wash accounted for 85.3% of the total administered dose.

Total ^{14}C residues in eggs did not plateau during the dosing period. Egg yolk and white were assayed separately for the eggs from hens treated at 53 ppm. Initially, TRR levels were greater in egg white than in the yolk; however, by Day 3 of dosing residues in yolk were much greater than in the egg white. On Day 5, residues in whole eggs from hens treated at 39 ppm ranged from 0.215 to 0.431 mg eq/kg. Residues ranged from 0.899 to 2.312 mg eq/kg in egg yolk and from 0.074 to 0.408 mg eq/kg in egg white. Residues in tissues from hens treated at the lower rate were consistently lower than those from hens treated at the higher rate. At the lower rate, residue ranges (mg eq/kg) were 0.989–1.232 in liver, 0.537–0.677 in kidney, 0.050–0.067 in fat, 0.017–0.047 in leg muscle, and 0.026–0.049 in breast muscle. At the higher rate, residues (mg eq/kg) were 0.781 and 1.115 in kidney, 0.312 and 0.358 in fat, 0.066 and 0.073 in leg muscle, and 0.054 and 0.087 in breast muscle; liver samples were used for metabolite identification and were not assayed for total radioactivity.

Major residues identified in egg white/yolk consisted of triflumizole (13.4/3.7% TRR), FD-6-1 or FD-4-1 (12.6/3.0% TRR), and FA-1-1 (35.3/22.1% TRR). Volatility of FA-1-1 resulted in some evaporative losses of that analyte. Unextracted residues accounted for 17.2 and 39.8% TRR in egg white and yolk, respectively. All other identified or characterized residues were less than approximately 4% TRR. Analysis of the liver samples indicated that the only metabolite was FA-1-1 or a compound convertible to FA-1-1 during proteolytic digestion.

In animal metabolism studies, triflumizole was metabolized to several compounds. The majority of the dosed radioactivity was excreted and radioactive residues in tissues were generally low. Triflumizole was identified as a residue in egg whites only. Metabolite FA-1-1 was the most prominent component in liver and egg. Sulphur- and glucuronide-conjugated FA-1-5 was the most prominent residue in milk.

Plant metabolism

The Meeting received plant metabolism studies performed on apple, pear, grape, and cucumber with triflumizole universally labelled in the phenyl ring.

In the apple metabolism study, trees were grown in a greenhouse and treated by spotting clusters of leaves with the test substance (approximately 0.127 mg/4-leaf cluster). Branches were harvested at 0, 1, 3, 7, 14, 21, 31, 60, and 90 DAT; fruits were not harvested.

Over the 90-day time span, the overall residue decreased from 51.65 mg eq/kg to 3.03 mg eq/kg, with an initial half-life of approximately 4 days, and was associated primarily with the treated leaves. Radioactive residue in the surface wash of treated leaves accounted for the majority of the residue until 14-DAT sampling. By the 14-DAT sampling, over half of the radioactivity in treated leaves was accounted for as extracted residues or associated with the post-extraction solids (PES). Radioactivity in untreated leaves above the treatment location remained relatively constant throughout the study, ranging from 0.04–0.07 mg eq/kg. Residues in untreated leaves below the treatment location showed a small increase in levels with time, with a maximum of 0.24 mg eq/kg at the 21-DAT sampling. In treated leaves, the only major (> 10% TRR) identified compounds that appeared consistently in the residue profile were triflumizole (0.02–0.12 mg eq/kg) and FM-6-1 (1.2–31% TRR, 0.01–0.02 mg eq/kg); FD-2-1 accounted for 12.6% TRR (< 0.01 mg eq/kg) at the 90-DAT sampling. As overall residues of radiocarbon declined with increasing time after treatment FD-2-1, unidentified metabolites and the contribution from PES became more prominent in the residue profile in terms of %TRR.

In the pear metabolism study, pear trees grown in a greenhouse were treated with test substance by spotting leaves (approximately 1 mg/4-leaf cluster) or the surface of pear fruits (approximately 0.166 mg/fruit) with radiolabelled test substance. Branches from leaf-treated trees

were harvested at 0, 1, 3, 7, 14, 21, 31, 60, and 90 DAT and were divided into treated leaves, untreated leaves, and fruit. Treated fruits were harvested 0, 1, 3, 7, and 14 DAT.

Data from the leaf-treatment samples showed very little movement of radioactivity away from the treated leaves. Radioactivity reached maxima of 0.98% TAR in untreated leaves and 0.18% TAR in untreated fruit. In treated leaves, the majority of the radioactivity was associated with the surface wash through the 31-DAT sampling, at which point extractable residues and PES-associated residues, combined, constitute more than half of the TRR (56% TRR, 5.6 mg eq/kg). As with the apple study, the data show a rapid decline in radiocarbon residues, with an initial half-life of approximately 4 days.

For treated fruit, the vast majority (> 95%) of the radioactive residue was confined to the peel, with very little movement into the flesh or core of the pear. For peel, residues in surface wash were the majority at the 0- and 1-DAT sampling times, after which extractable residues became the most prominent. The data also show a rapid decline in radiocarbon residues, with an initial half-life of between 1 and 3 days, and a slower rate of decline between 3 and 14 DAT.

In leaves, triflumizole and FM-6-1 were the only residues > 10% TRR. After 3 days and for the remainder of the study, FM-6-1 occurred at levels greater than triflumizole, peaking at 0.25 mg eq/kg at 3 DAT. In fruit, major residues were triflumizole (maximum = 93.56% TRR, 1.11 mg eq/kg, 0 DAT), FM-6-1 (maximum = 30.0% TRR, 0.14 mg eq/kg, 7 DAT) and FD-1-1 (10.51% TRR, 0.06 mg eq/kg, 3 DAT).

In the grape metabolism study, grape vines were grown in a greenhouse. Treatments were with triflumizole, uniformly labelled with ^{14}C in the phenyl ring, applied either to a branch of approximately 10 leaves and blossoms approximately 67 days prior to harvesting mature fruit, or to a bunch of young fruits 35 days before harvesting mature fruit. For both treatments, the rate was equivalent to 0.280 kg ai/ha. Treated branches were harvested 0, 3, 7, 14, 31, and 67 DAT and were divided into treated leaves and fruit; treated fruits were harvested 0, 3, 7, 14, and 35 DAT.

Following treatment of leaves, the % TAR decreased from 99% TAR to 15% TAR at 67 DAT. Most of the radioactivity in leaves was recovered from the surface wash, with < 2% TAR being translocated to fruits. Triflumizole was the major residue out to 31 DAT (51% TRR, 8.8 mg eq/kg). The only other major residue was FM-6-1 (11.1% TRR, 0.76 mg eq/kg at 67 DAT). Post-extraction residues in leaves gradually increased from 3.1% TRR (1.73 mg eq/kg) to 26.02% TRR (1.79 mg eq/kg) over the course of the study. Minor metabolites and those remaining at the origin increased to 39% TRR at 67 DAT, with no individual component exceeding 8% TRR.

In treated fruit over the 35-day period of the study, overall radioactivity decreased from 100% TAR (7.79 mg eq/kg) to 24.8% TAR (1.93 mg eq/kg). The majority of the radioactivity in treated fruit was recovered from the surface wash for the 0-, 3-, and 7-DAT samples; at the 14- and 35-DAT sampling points. More of the total residue was associated with extracted and bound residues. At all of the sampling times, the only major residue was triflumizole. FM-6-1 reached a maximum of 7.59% TRR (0.07 mg eq/kg) at 35 DAT, at which point triflumizole constituted 31% TRR (0.31 mg eq/kg).

The cucumber study was conducted under greenhouse conditions. Three types of treatment were made: Foliar treatment to investigate metabolism (0.13 mg/plant), fruit treatment to investigate metabolism (0.041 mg/plant), and foliar treatment to investigate translocation (0.16 mg/plant). In the case of the foliar treatment for metabolism, whole plants were harvested 1, 3, 7, 14, 21, and 45 days after treatment (DAT). For the fruit metabolism and translocation investigations, fruits were harvested 1 (metabolism only), 3, 7, and 14 DAT.

Results from all three lines of investigation demonstrated that the majority of the radioactivity (65–76% of applied) remained on the surface of the harvested material and that there was very little movement of radioactivity within the cucumber plants. Triflumizole accounted for most of the radioactivity through 14 DAT; at 21 DAT and 45 DAT, FM-6-1 residues were approximately equal to those of triflumizole and at 45 DAT, residues of F-8-1 were greater than either triflumizole or FM-6-1 on a % TRR basis. No metabolite exceeded 10% of the TRR except for FM-6-1 approximately 12% TRR, < 0.01 mg eq/kg) at the 7- and 14-DAT sampling times in the cucumber fruit study. In those samples, FM-6-1 was associated with the peel and flesh of the fruit and not the surface wash.

The metabolic profile observed in these studies was similar across all four crops. Over the time course of the studies, triflumizole and FM-6-1 account for the majority of the radioactivity. Generally triflumizole decreased rather rapidly (half-life on the order of 3 days), with the exception of grapes where metabolism was slower (half-life approximately 14 days). Loss of triflumizole was accompanied by an increase in the FM-6-1 metabolite, which was the only metabolite to consistently occur at $\geq 10\%$ TRR.

Environmental fate in soil

The Meeting received information on soil-surface photolysis, soil dissipation, aerobic soil metabolism, and confined and field rotational crop studies.

Under aerobic conditions in soil, the imidazole ring of triflumizole is opened to yield FM-5-1, FD-1-1, and FM-6-1. The resulting amide or amine moiety is then hydrolysed to form the FA-1-1 metabolite, which then becomes associated with bound residues or is oxidized to CO₂. The DT₅₀ was 16–22 days at 20 °C with indoor studies and 7.1–22 days with outdoor studies.

In the soil photolysis study, triflumizole degraded significantly. On average after 11 days of exposure, triflumizole had declined to 30.0% of the AD. This was accompanied by formation of FM-6-1, which reached a maximum of 21.8% TAR after 7 days of exposure to simulated sunlight and then dissipated to 15.6% TAR at Day 11. The metabolites FD-1-1 (3.6% TAR at Day 11), FM-8-1 (1.8% TAR, Day 11), FD-7-1 (8.6% TAR, Day 11), and CO₂ (3.5% TAR, Day 11) were also observed. Bound residues increased over the time course of the study and averaged 18.7% TAR by the end of the 11-day period.

The results of both the aerobic soil and soil photolysis study indicate that triflumizole is not likely to be persistent in the environment.

In the confined rotational crop study, radiolabelled triflumizole was applied to bare soil at approximately 1.4 kg ai/ha (1× GAP; 6 plots) or approximately 12.7 kg ai/ha (10× GAP; 2 plots) and rotational crops of lettuce, radish, and wheat were planted into each. Plant-back intervals (PBIs) were 30, 120, and 365 days for the 1× plots and 30 days for the 10× plots. Radish was sampled for roots and tops, and wheat was sampled for forage, grain, hay, and straw. The 1X plots were used to determine % TRR only and the 10× plots were used to make metabolite identifications (except for 1× samples for wheat forage).

Quantifiable levels of TRR occurred for all crop matrices at all PBIs. Highest values were for wheat straw, starting at 1.65 mg eq/kg at the 30-day PBI and declining to 0.478 mg eq/kg at the 365-day PBI. The lowest values were for lettuce (0.086 to 0.021 mg eq/kg at the 120- and 365-day PBI, respectively). For each crop matrix, the TRR declined when going from shorter to longer PBIs with the exception of lettuce which had a maximum at the 120-day PBI (0.086 mg eq/kg) and wheat grain for which the 365-day PBI TRR (0.067 mg eq/kg) was greater than the 120-day PBI TRR (0.055 mg eq/kg).

Triflumizole underwent extensive metabolism in the confined rotational crop study. Forty-nine metabolites were identified, four of which were $> 10\%$ TRR and > 0.01 mg eq/kg in at least one matrix. No triflumizole was identified in any crop and no single metabolite was consistently the predominant residue. Two of the major metabolites were identified as glucose conjugates of FM-6-1 and FM-8-1, which constituted 22.9% TRR in lettuce and 16.1% TRR in wheat forage, respectively. The other major metabolites in the confined rotational crop study (XIV and XXVI) were not significant residues in either the crop or livestock metabolism profiles.

Field rotational crop studies were conducted with lettuce, turnip, cabbage, cotton, onion, tomato and wheat. Triflumizole was applied to squash at approximately 30 days prior to harvest or to cucumbers at the vining stage. In both studies, the initial application was followed by four subsequent applications at 7 ± 1 day intervals. All applications were 0.28 kg ai/ha for a total rate of 1.4 kg ai/ha. For all commodities except wheat fodder, forage, and hay, residues of triflumizole, analysed by the common-moiety method, were < 0.01 mg/kg, or in a few cases slightly above 0.01 mg/kg, at plant-back intervals (PBIs) of 30, 60, 90, 120, 180, and 270 days (not all crops were sampled at all

intervals). In wheat animal forage, hay, and straw, quantifiable residues persisted throughout all of the plant-back intervals with no particular trend related to PBI. Residue ranges were < 0.01–0.20 mg/kg in wheat forage, < 0.01–0.144 mg/kg in wheat hay, and < 0.01–0.134 mg/kg in wheat straw.

The field rotational crop study indicates that residues are generally not expected (< 0.01 mg/kg) in food crops planted in rotation following treatment to the previous crop. When residues do occur, they are not expected to be much above 0.01 mg/kg. In contrast, readily quantifiable residues in forage/fodder, hay, and straw commodities from cereal grains are expected when such crops are planted in rotation following a treated.

Methods of analysis

The Meeting received description and validation data for analytical methods for residues of total triflumizole (all residues convertible to the FA-1-1 metabolite, expressed as triflumizole) as well as methods for specific residues (e.g., triflumizole, FM-6-1, FA-1-5). Recovery data were provided for raw and processed agricultural commodities as well as animal commodities.

Methods that analyse total triflumizole in crops involve an initial extraction with water. Hydrolysis is accomplished by refluxing in concentrated acetic acid and sodium acetate followed by distillation in the presence of sodium hydroxide into hexane. Residues are cleaned up by column chromatography, and analysed by GC-NPD, GC-MSD, or HPLC-UV.

Methods for the analysis of specific residues in crops use solvent extraction (methanol or acetonitrile), clean-up by solid-phase partitioning and liquid/liquid partitioning, and analysis by GC-NPD, GC-MSD, HPLC-UV, or LC-MS/MS.

Recoveries for the common-moiety method averaged 80.8% and recoveries for the specific-residue method averaged 86.5%. Recoveries for both methods were generally within the range of 70–120%. Limits of quantitation are reported as being of 0.01 mg/kg for most matrices, 0.02 mg/kg for hops, and 0.05 mg/kg for nutmeats.

Data describing multi-residue method testing for residues of triflumizole were not provided.

In animals, the common-moiety method uses 20% NaOH and a Bleidner extractor to digest/distil/extract residues into hexane. The terminal residue is the FA-1-1 metabolite and analysis is by GC-NPD. Recoveries for this method ranged from 78 to 92%.

In the procedure for determining residues containing FA-1-5, the sample was extracted using an acidic digestion followed by clean up and concentration using solid phase extraction (SPE) on reversed phase C18 columns. Final separation and quantification was conducted by HPLC on a C18 column and electrochemical detection. Recoveries for this method averaged 85%.

All of the submitted methods are adequate for the analysis of triflumizole residues.

Stability of residues in stored analytical samples

The Meeting received data on the stability of residues of triflumizole and its metabolites in crops (apple, grape, strawberry, cucumber, cherry, muskmelon, squash, lettuce, and wheat forage) and livestock. The test compound was added to homogenized test matrix. Samples were placed into frozen storage and analysed by the common-moiety or analyte-specific method(s) used in the supervised residue trial.

For the following commodities, stability of residues during storage was demonstrated for at least 3 months in hazelnut, 4 months in wheat forage, 6 months in animal commodities, 12 months in cherries and grapes, and 18 months in papaya.

For the following commodities, stability of residues during storage was demonstrated for no longer than 2 months in lettuce, 3 months in muskmelon and summer squash, and 6 months in apple, cucumber, and strawberry.

For the following commodities, stability of residues during storage was not demonstrated for any time period: cabbage, mustard greens, Swiss chard, and tomato.

Definition of the residue

In the lactating goat metabolism study, TRR were significantly higher in liver than in any other matrix, including milk. Triflumizole was not detected in liver or milk. In liver, free and conjugated FA-1-1 constituted nearly 80% of the residue, with FA-1-5-sulphate making up an additional 12%. In milk, sulphate and glucuronide conjugates of FA-1-5 account for 40% of the residue; the only other major residues were FD-2-1 (10.4% TRR) and FM-8-1-sulphate (12.6% TRR).

In the laying hen metabolism study, TRR were highest in liver, kidney, and egg. Liver contained only FA-1-1 (or a metabolite converted to FA-1-1 during proteolytic digestion). In egg, major residues were triflumizole (13.4% TRR in whites), FD-6-1 or FD-4-1 (12.6% TRR in white), and FA-1-1 (up to 35% TRR in white and 22% TRR in yolk). Hen kidney was not subjected to analysis for residue identification.

In the lactating cattle feeding study, samples were analysed using a common-moiety method, which would have captured all of the major residues observed in the lactating goat and laying hen metabolism studies except for FA-1-5-sulphate, which was the major metabolite in milk observed in the metabolism study. However, in the feeding study, residues of FA-1-5-sulphate were < 0.01 mg/kg in milk and < 0.03 mg/kg in liver and kidney.

Analytical methods for animal matrices are available for the analysis of residues convertible to FA-1-1 or for analysis of FA-1-5-sulphate.

The Meeting agreed that residues converted to 4-chloro-2-(trifluoromethyl)aniline (FA-1-1) and expressed as parent triflumizole are suitable for enforcement and dietary risk purposes in animal commodities.

The log P_{OW} of the residues in animal commodities will be determined by the composition and relative amounts of the metabolite residues in the various matrices. In the lactating cattle feeding study, total residues of triflumizole in fat were, on average, approximately 3.5 times greater than those in muscle.

The Meeting concluded that the residue is fat soluble.

In metabolism studies with apple (leaves only), pear, cucumber, and grape, triflumizole and FM-6-1 constitute the vast majority of the identified residues, and no other residues consistently occur at greater than 10% TRR. The FM-6-1 metabolite was observed in the rat.

The analytical method for plant matrices is a common-moiety method that quantifies all residues convertible to FA-1-1, including FM-6-1.

The Meeting agreed that residues converted to 4-chloro-2-(trifluoromethyl)aniline (FA-1-1) and expressed as parent triflumizole are suitable for enforcement and dietary risk purposes in plant commodities.

The Meeting recommended the following residue definition:

For plants and animals:

Definition of the residue (for compliance with the MRL and for estimation of dietary intake):

Residues analysed as 4-chloro-2-(trifluoromethyl)aniline and expressed as parent triflumizole.

Results from supervised residue trials on crops

The Meeting received supervised trial data for the foliar application of triflumizole on apple, pear, cherry, grape, strawberry, papaya, broccoli, cabbage, cucumber, muskmelon, squash, tomato, lettuce (head and leaf), mustard green, Swiss chard, turnip green, hazelnuts and hops. Residue trial data were made available from the USA for all crops as well as Japan (cucumber, apple and pear), Netherlands (cucumber and tomato), and Belgium (tomato).

Labels for end-use products containing triflumizole were available from the USA and the Netherlands (glasshouse use on tomato and cucumber only) describing the registered uses of triflumizole.

For most crops, the residues were determined by the common-moiety method and reflect the sum of all residues convertible to the aniline moiety, expressed as triflumizole. For the trials in Japan (cucumber), the Netherlands (cucumber and tomato) and Belgium (tomato), the reported residues are the sum of triflumizole and FM-6-1. Side-by-side data reflecting analysis by both common-moiety and residue-specific (triflumizole + FM-6-1) methods are available for hops. In those samples, residues from the common-moiety method were considerably greater than those from the residue-specific method. As the residue definition is for residues convertible to the FA-1-1 metabolite, only residues determined as total triflumizole are suitable for making residue estimates.

Pome fruits

The GAP in the USA on pome fruit is foliar application at a maximum rate of 0.56 kg ai/ha and a PHI of 14 days. Applications may be made at a 7- to 10-day interval with a maximum seasonal rate of 2.24 kg ai/ha.

Apple

Data were available from supervised trials on apple in the USA. Data were also provided from Japan; however, there is no GAP in Japan.

Eighteen supervised trials were conducted in the USA at GAP and residues were obtained by the common-moiety method. Using trials with a supported storage interval, the Meeting selected the following data for consideration (n=3): < 0.02, 0.26, 0.30 mg/kg.

The meeting agreed that the data for apples were insufficient to make a recommendation.

Pear

Data were available from supervised trials on pear in the USA. Data were also provided from Japan; however, there is no GAP in Japan.

Seven supervised trials were conducted in the USA at GAP and residues were obtained by the common-moiety method. Using trials with a supported storage interval, the Meeting selected the following datum for consideration (n=1): 0.28 mg/kg.

The Meeting agreed that the data for pear were insufficient to make a recommendation.

Cherries

The GAP in the USA on cherry is foliar application at a maximum rate of 0.56 kg ai/ha and a PHI of 1 day. Applications may be made at a 7- to 14-day interval with a maximum seasonal rate of 3.36 kg ai/ha.

Eight supervised trials were conducted in the USA at GAP and residues were obtained by the common-moiety method. The residue results are supported by the available storage stability data. The trials resulted in the following eight independent residue values: 0.59, 0.96, 1.1, 1.1, 1.2 (2), 1.3, 1.5 mg/kg.

The Meeting estimated a maximum residue level, STMR, and HR for triflumizole residues in cherries (Subgroup 003A) of 4 mg/kg, 1.2 mg/kg, and 1.5 mg/kg, respectively.

Berries and other small fruits

The GAP in the USA on grapes and strawberries is foliar application at a maximum rate of 0.28 kg ai/ha and a PHI of 7 days for grapes and 1 day for strawberry. Applications may be made at a minimum interval of 14 days, with a maximum seasonal rate of 1.12 kg ai/ha.

Grape

Nineteen supervised trials were conducted in the USA at GAP for grapes and residues were obtained by the common-moiety method. The residue results are supported by the available storage stability data. The trials resulted in the following 12 independent residue values: 0.09, 0.1, 0.15, 0.16, 0.18, 0.21, 0.31, 0.50, 0.90, 0.94, 1.4, and 2.0 mg/kg.

Based on these data, the Meeting estimated a maximum residue level, STMR, and HR for triflumizole residues in grapes of 3 mg/kg, 0.26 mg/kg, and 2.0 mg/kg, respectively.

Strawberry

Eight supervised trials were conducted in the USA. The residue data for strawberry are not supported by the available storage stability data.

The Meeting agreed not to make a recommendation for strawberry.

Papaya

The GAP in the USA on papaya is foliar application at a maximum rate of 0.35 kg ai/ha on a 14-day interval, with a PHI of 0 days. The maximum seasonal rate is 0.84 kg ai/ha.

Four supervised trials were conducted in the USA. Each treated plot received five applications at approximately 0.42 kg ai/ha on a 12- to 14-day interval for a total rate of approximately 2.1 kg ai/ha. Papaya were harvested 0 DAT.

The Meeting agreed that although application in the papaya field trials reflects an over dosing relative to GAP due to the number of applications, the retreatment interval (12 to 14 days) combined with residue decline and the rapid growth of the papaya fruit which would be occurring during the first two applications, the early applications are unlikely to have contributed significantly to the residue level at harvest. Therefore, the available trials are suitable for estimation of residue levels resulting from GAP applications. The residue data (n=4) are: 0.22, 0.53, 0.88, and 0.89 mg/kg.

Based on the trials for papaya in the USA, the Meeting estimated a maximum residue level, STMR, and HR for triflumizole residues in papaya of 2 mg/kg, 0.71 mg/kg, and 0.89 mg/kg, respectively.

Brassica (cole or cabbage) vegetables, Head cabbages, Flowerhead brassica

The GAP in the USA on Brassica vegetables is foliar application at a maximum rate of 0.28 kg ai/ha, at a 14-day interval, and a PHI of 1 day. The maximum seasonal rate is 0.63 kg ai/ha.

Broccoli

Ten supervised trials were conducted in the USA. The residue data for broccoli are not supported by the available storage stability data.

The Meeting agreed not to make a recommendation for broccoli.

Cabbage

Nine supervised trials were conducted in the USA. The residue data for cabbage are not supported by the available storage stability data.

The Meeting agreed not to make a recommendation for cabbage.

Fruiting vegetables, Cucurbits

The GAP in the USA on cucurbit vegetables is foliar application at a maximum rate of 0.28 kg ai/ha at a 7- to 14-day interval, and a PHI of 0 days. The maximum seasonal rate is 1.4 kg ai/ha.

The GAP in the Netherlands on cucumber and summer squash is foliar application at a maximum rate of 0.225 kg ai/ha and a PHI of 1 day. One to six applications may be made per season at a 7-day interval.

Cucumber-Outdoor Crops

Six supervised trials were conducted in the USA at GAP and residues were obtained by the common-moiety method. The residue results supported by the available storage stability data are as follows (n=4): 0.13 (2), 0.17, and 0.18 mg/kg.

The Meeting agreed that the data from field-grown cucumber were insufficient to make a recommendation.

Cucumber-Indoor Crops

Four supervised trials were conducted in the USA at GAP and residues were obtained by the common-moiety method. The residue results supported by the available storage stability data are as follows (n=3): 0.10, 0.11, and 0.21 mg/kg.

An additional four trials were conducted in the Netherlands according to the Netherlands GAP. The trials measured only triflumizole and FM-6-1; therefore the residues did not match the residue definition.

The Meeting agreed that the data from indoor-grown cucumber were insufficient to make a recommendation.

Residues from the indoor and outdoor trials on cucumbers from the USA matching the USA GAP are from the same population (Mann-Whitney U test). Using the combined data set (n=7): 0.10, 0.11, 0.13 (2), 0.17, 0.18 and 0.21 mg/kg, the Meeting estimated a maximum residue level, STMR, and HR for triflumizole residues in cucumber of 0.5 mg/kg, 0.13 mg/kg, and 0.21 mg/kg, respectively.

Melon

Six supervised trials were conducted on muskmelon in the USA at GAP. The residue data for muskmelon are not supported by the available storage stability data.

The Meeting agreed not to make a recommendation for muskmelon.

Summer squash

Five supervised trials were conducted in the USA at GAP and residues were obtained by the common-moiety method. The residue data for summer squash are not supported by the available storage stability data.

The Meeting chose not to make a recommendation for summer squash.

Tomato

The GAP in the USA on tomato is foliar application at a maximum rate of 0.28 kg ai/ha at a 7- to 14-day interval and a PHI of 0 days. The maximum seasonal rate is 1.4 kg ai/ha. The USA GAP is the Critical GAP.

Four supervised trials were conducted in the USA at GAP and residues were obtained by the common-moiety method. The residue data for tomato are marginally supported by the storage stability data and are as follows (n=4): < 0.5 (2), 0.59, and 0.76 mg/kg.

The Meeting agreed that the data for tomato from the USA were insufficient to make a recommendation.

The GAP in the Netherlands on tomato is foliar application at a maximum rate of 0.015 kg ai/hL and a PHI of 1 day. One to five applications may be made per season at a 7-day interval.

Four supervised trials were conducted in each of the Netherlands and Belgium. Treated plot received three applications each at 0.016 kg ai/hL on a 7-day interval and fruits were harvested 3 DAT.

The trials in the Netherlands and Belgium were conducted according to the Netherlands GAP. The Netherlands trials measured only triflumizole and FM-6-1; therefore the residues do not reflect the residue definition.

The Meeting agreed not to make a recommendation for tomato.

Leafy vegetables (including Brassica leafy vegetables)

The GAP in the USA on leafy vegetables is foliar application at a maximum rate of 0.28 kg ai/ha at a 14-day interval and a PHI of 0 days. The maximum seasonal rate is 0.63 kg ai/ha.

Lettuce

Data were available from supervised trials on lettuce in the USA.

Seventeen supervised trials were conducted in the USA on lettuce (head lettuce = seven field trials; leaf lettuce = seven field trials + two greenhouse trials; unspecified = one field trial). In 16 trials, treated plot received four applications each at approximately 0.28 kg ai/ha on a 6- to 9-day interval. The total application rate was approximately 1.12 kg ai/ha. In the remaining trial on the unspecified lettuce variety, five applications were made at approximately 0.57 kg ai/ha, for a total rate of approximately 2.85 kg ai/ha. Lettuce was harvested 0 DAT.

The Meeting agreed that in both the number and interval of applications, the residue trials for lettuce did not match the GAP for lettuce in the USA, and that the proportionality concept could not be used.

The Meeting agreed not to make a recommendation for lettuce.

Mustard greens

Ten supervised trials were conducted in the USA on mustard greens at GAP. The residue trials are not supported by the available storage stability data.

The Meeting agreed not to make a recommendation for mustard greens.

Swiss chard

Data were available from supervised trials on Swiss chard in the USA at GAP. The residue trials are not supported by the available storage stability data.

The meeting agreed not to make a recommendation for Swiss chard.

Turnip greens

The GAP in the USA for triflumizole on turnip greens is foliar application at a maximum rate of 0.28 kg ai/ha and a PHI of 1 day. Two to three applications may be made per season at a 14-day interval with a maximum seasonal rate of 0.63 kg ai/ha.

In one trial conducted in USA, where five applications of 0.27–0.3 kg ai/ha triflumizole were made on a 7-day schedule, total residues in turnip greens 1 day after the last application were 7.1 mg/kg.

The Meeting agreed that the supporting data for turnip greens did not match the GAP in USA and are of insufficient quantity. The Meeting agreed not to make a recommendation for turnip greens.

Hazelnuts/Filberts

The GAP in the USA on hazelnut is foliar application at a maximum rate of 0.21 kg ai/ha and a PHI of 18 days. Four to six applications may be made per season at a 10- to 14-day interval with a maximum seasonal rate of 0.84 kg ai/ha.

All of the field trials in the USA (n=3) were conducted at an exaggerated rate of 6.25× GAP. Per-trial average triflumizole residues (via common moiety) were < 0.05 mg/kg for all samples. The Meeting noted that all three trials were conducted in the same year and in the same orchard complex.

The Meeting noted that the trials are not independent and agreed not to make a recommendation for hazelnuts.

Hops

The GAP in the USA on hops is foliar application at a maximum rate of 0.42 kg ai/ha and a PHI of 7 days. Three applications may be made per season at a 14-day interval with a maximum seasonal rate of 1.26 kg ai/ha.

Data were available from supervised trials on hops in the USA.

Four supervised trials were conducted in the USA at GAP and residues were obtained by the common-moiety method. The residue results are supported by the available storage stability data. The trials resulted in the following 4 independent residue values for dried hops: 7.0, 7.8, 10, and 11 mg/kg.

Based on the trials for hops in the USA, the Meeting estimated a maximum residue level, STMR, and HR for triflumizole residues in hops, dried of 30 mg/kg, 8.9 mg/kg, and 11 mg/kg, respectively.

Fate of residues during processing

The Meeting received data depicting the effects of processing on residue levels in apple (juice, sauce, and wet/dry pomace) and grape (juice, raisins (and related commodities), stems, and wet/dry pomace). The estimated processing factors for grape commodities are 0.42 for juice; 0.22 for grape, dried; and 4.3 for wet pomace.

The Meeting estimated an STMR and HR for grapes of 0.41 mg/kg and 2.0 mg/kg, respectively. Application of the estimated processing factors results in an estimated STMR-P and HR-P, respectively, of 0.06 mg/kg and 0.44 mg/kg for grape, dried; an STMR-P of 0.17 mg/kg for grape juice; and an STMR-P of 1.2 mg/kg for wet grape pomace.

Residue in animal commodities*Farm animal dietary burden*

The Meeting estimated the dietary burden of triflumizole in farm animals on the basis of the diets listed in Appendix IX of the FAO Manual 2009. Calculation from highest residue, STMR (some bulk commodities) and STMR-P values provides levels in feed suitable for estimating MRLs, while calculation from STMR and STMR-P values for feed is suitable for estimating STMR values for animal commodities.

Estimated maximum and mean dietary burdens of farm animals

Dietary burden calculations for beef cattle, dairy cattle, broilers and laying poultry are provided in Appendix IX of the FAO manual. The calculations were made according to the animal diets from US-Canada, EU, Australia and Japan in the Table (Appendix IX of the FAO manual). The diets are based on residues in wet grape pomace.

Livestock dietary burden, triflumizole, ppm of dry matter diet ^a

US-Canada	EU	Australia	Japan

	Max	Mean	Max	Mean	Max	Mean	Max	Mean
Beef cattle	—	—	—	—	1.49 ^a	1.49 ^c	—	—
Dairy cattle	—	—	—	—	1.49 ^b	1.49 ^d	—	—
Poultry—broiler	—	—	—	—	—	—	—	—
Poultry—layer	—	—	—	—	—	—	—	—

^a Highest maximum beef or dairy cattle dietary burden suitable for MRL estimates for mammalian meat

^b Highest maximum dairy cattle dietary burden suitable for MRL estimates for mammalian milk

^c Highest mean beef or dairy cattle dietary burden suitable for STMR estimates for mammalian meat.

^d Highest mean dairy cattle dietary burden suitable for STMR estimates for milk.

Farm animal feeding studies

The Meeting received lactating dairy cow feeding studies, which provided information on likely residues resulting in animal commodities and milk from triflumizole residues in the animal diet.

Lactating dairy cows

Lactating dairy cows were dosed with triflumizole for 28 days at the equivalent of 10 or 50 ppm in the diet. Analysis was for residues convertible to FA-1-1 and FA-1-5 (high-dose group only). Residues for all analyses and tissues were < 0.02 for control animals.

From the high-dose group, milk samples from even-numbered treatment days (except Day 24) were analysed. Residues of FA-1-5 were < 0.01 mg/kg in all milk samples and < 0.03 mg/kg in liver and kidney, which were the only tissue analysed for this compound. Total triflumizole residues were < 0.02 mg/kg in milk on Day 0 and were then rather consistent, ranging from, on average, 0.03 to 0.06 mg/kg. In the low- and high-dose tissue samples, respectively, average residues were 0.06 to 0.33 mg/kg in fat, 0.31 to 1.55 mg/kg in kidney, 0.48 to 4.25 mg/kg in liver, < 0.02 to 0.94 in muscle, and < 0.02 to 0.04 mg/kg in milk.

Animal commodities maximum residue levels

For MRL estimation, the residue in the animal commodities is residues analysed as 4-chloro-2-(trifluoromethyl)aniline and expressed as parent triflumizole.

Residues in tissues and milk at the expected dietary burden for beef cattle in Australia are shown in the Table below. The residue in milk was relatively consistent from Day 2 through Day 28 and the mean estimated residue in milk was calculated using the residue values from Day 4 to the final day.

Triflumizole feeding study	Feed level (ppm) for milk residues	Residues (mg/kg) in milk	Feed level (ppm) for tissue residues	Residues (mg/kg) in			
				Muscle	Liver	Kidney	Fat
MRL beef or dairy cattle							
Feeding study ^a	10	< 0.02	10	< 0.02	0.496	0.460	0.115
	50	0.041	50	0.106	4.602	1.717	0.478
Dietary burden and high residue	1.49	< 0.02	1.49	< 0.02	0.07	0.69	0.03
STMR beef or dairy cattle							
Feeding study ^b	10	< 0.02	10	< 0.02	0.484	0.307	0.056
	50	0.041	50	0.094	4.248	1.552	0.330
Dietary burden and residue estimate	1.49	< 0.02	1.49	< 0.02	0.072	0.046	0.008

^a Highest residues for tissues and mean residues for milk

^b Mean residues for tissues and mean residues for milk

The Meeting estimated the following maximum residue levels: Milk = 0.02(*) mg/kg, meat = 0.03 (fat) mg/kg and edible offal = 0.1 mg/kg.

The Meeting estimated the following STMR levels: Milk = 0 mg/kg, meat = 0 mg/kg, fat = 0.008 mg/kg and edible offal = 0.072 mg/kg.

The Meeting estimated the following HR levels: Milk = 0mg/kg, meat = 0 mg/kg, fat = 0.017 mg/kg and edible offal = 0.074 mg/kg.

RECOMMENDATIONS

On the basis of the data from supervised trials, the Meeting concluded that the residue levels listed below are suitable for estimating maximum residue limits and for IEDI and IESTI assessments.

Plant and animal commodities:

Definition of the residue for plant and animal commodities (for compliance with the MRL and for estimation of dietary intake): *Residues analysed as 4-chloro-2-(trifluoromethyl)aniline and expressed as parent triflumizole.*

The residue is fat soluble

Commodity		Recommended MRL, mg/kg	STMR or STMR-P, mg/kg	HR or HR-P, mg/kg
CCN	Name	New		
FS 0013	Cherries	4	1.17	1.5
VC042 4	Cucumber	0.5	0.13	0.21
FB 0269	Grapes	4	0.41	2.0
FI 0350	Papaya	2	0.71	0.89
DH 1100	Hops, Dried	30	8.9	11

	Grape, pomace (wet)	—	1.2	
DF 0269	Dried grapes (=currants, raisins and sultanas)	Covered by grapes	0.06	0.44

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Daily Intakes (IEDIs) of triflumizole were calculated for the 13 GEMS/Food cluster diets using STMRs/STMR-Ps estimated by the current Meeting (see Annex 3 of

the 2013 JMPR Report). The ADI is 0–0.04 mg/kg bw and the calculated IEDIs were 0–2% of the maximum ADI (0.04 mg/kg bw). The Meeting concluded that the long-term intakes of residues of triflumizole, resulting from the uses considered by the current JMPR, are unlikely to present a public health concern.

Short-term intake

The International Estimated Short-Term Intakes (IESTI) of triflumizole were calculated for food commodities and their processed commodities using HRs/HR-Ps or STMRs/STMR-Ps estimated by the current Meeting (see Annex 4 of the 2013 JMPR Report). The ARfD is 0.3 mg/kg bw and the calculated IESTIs were $\leq 100\%$ of the ARfD for all commodities. The Meeting concluded that the short-term intake of residues of triflumizole, when used in ways that have been considered by the JMPR, is unlikely to present a public health concern.

TRINEXAPAC-ETHYL (271)

First draft prepared by Dr Paul Humphrey, Australian Pesticides and Veterinary Medicines Authority, Canberra, Australia

EXPLANATION

At the Forty-fourth Session of the CCPR (2012), trinexapac-ethyl was scheduled for evaluation as a new compound by 2013 JMPR.

Trinexapac-ethyl is a synthetic plant growth regulator that is derived from cyclohexanecarboxylate. It is applied as a foliar spray, post-emergence and approved for use on cereal crops such as barley, durum wheat, oats, rye, triticale and wheat, oilseed rape and sugarcane as well as grassland, amenity turf and managed turf.

The manufacturer supplied information on identity, metabolism, methods of residue analysis, freezer storage stability, registered use patterns, supervised residue trials, fate of residues in processing and farm animal feeding studies.

SPECIFICATIONS

Specifications for trinexapac-ethyl have not been developed by FAO.

IDENTITY

ISO common name:	Trinexapac-ethyl
IUPAC name:	4-(cyclopropyl-hydroxy-methylene)-3,5-dioxo-cyclohexanecarboxylic acid ethyl ester
Chemical Abstract name:	4-(cyclopropylhydroxymethylene)-3,5-dioxo-cyclohexanecarboxylic acid ethyl ester
CAS Index Name: (alternative)	
CAS No.:	95266-40-3
CIPAC No.:	Not allocated
Manufacturer's experimental name:	CGA 163935
Molecular Formula:	C ₁₃ H ₁₆ O ₅
Structural Formula:	

Molecular Weight:	252.3 g/mol

PHYSICAL AND CHEMICAL PROPERTIES***Pure Active Ingredient (except as noted)***

ME (Micro-emulsion)	Trinexapac-ethyl 250 g/L

METABOLISM AND ENVIRONMENTAL FATE

General

The studies for plant metabolism, animal metabolism and confined rotational crops were conducted with the test materials shown below, with the label position/s indicated in the following structural formulae:

[1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl[1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl[Hydroxymethylene ¹⁴C] trinexapac-acid

Table 1 summarises the names, codes, and structures of the parent and principle metabolites found in plant, livestock, rat and rotational crop studies.

Table 1 Trinexapac-ethyl and metabolites/degradates found in metabolism and environmental fate studies

Abbreviation or Code	Chemical Structure	IUPAC Name	Found in
Active substance: Trinexapac-ethyl CGA 163935		4-(cyclopropyl-hydroxy-methylene)-3,5-dioxocyclohexanecarboxylic acid ethyl ester	Wheat, Rapeseed, Rice, Hen (egg only)
CGA 179500 Trinexapac acid		4-(cyclopropyl-hydroxy-methylene)-3,5-dioxocyclohexanecarboxylic acid	Wheat, Rapeseed, Rice, Grass, Rotational wheat, Goat, Hen
CGA 113745		3-hydroxy,5-oxocyclohexanecarboxylic acid	Goat

Abbreviation or Code	Chemical Structure	IUPAC Name	Found in
CGA 275537 Tricarballic acid		3-carboxy-pentanedioic acid	Wheat, Rice, Grass
CGA 312753 Trans aconitic acid		(E)-3-carboxy-pent-2-enedioic acid	Rapeseed, Rice, Rotational wheat
CGA 312753 mono-ethyl ester		(E)-3-ethoxycarbonylpent-2-enedioic acid	Wheat
CGA 313458		2-(4-cyclopropyl-4-hydroxy-2-oxo-but-3-enyl)-succinic acid	Rapeseed, Rice
CGA 329773		4-cyclopropanecarbonyl-3,5-dihydroxy-benzoic acid	Wheat, Rice
CGA 351210		2-(cyclopropyl-hydroxymethylene)-5-hydroxymethylcyclohexane-1,3-dione	Rapeseed
– Isocitric acid lactone		5-oxo-tetrahydro-furan-2,3-dicarboxylic acid	Rapeseed (tentative identification)

Animal metabolism

Metabolism in rats

Evaluation of the metabolism studies in rats was carried out by the WHO Core Assessment Group.

Trinexapac-ethyl undergoes limited metabolism in the rat, involving predominantly ester hydrolysis of trinexapac-ethyl to trinexapac acid. The predominant urinary metabolite was trinexapac acid (up to 100% of total urinary radioactivity), with low levels of a conjugated derivative of trinexapac acid detected only in the urine of bile-duct cannulated rats (6.3% of the administered dose). In faeces, the parent compound accounted for 5–22% of total faecal radioactivity (1–2.5% of the administered dose), with the balance comprising trinexapac acid. Bile contained mainly a conjugated derivative of trinexapac acid (2.9% of the administered dose), with low levels of the parent compound also detected (0.2% of the administered dose).

Metabolism in lactating goats

Two studies were conducted on lactating goats using [1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl.

[1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl was orally administered by capsule to two lactating goats (British Saanen, 43.0–47.5 kg bw during acclimatisation and 42.0–45.5 kg bw at sacrifice) at a level of either 7.2 ppm or 694 ppm in the feed for 4 consecutive days (Cameron *et al.* 1992, CGA163935/0276).

Actual doses were 7.17 or 694.0 ppm in feed based on feed consumption of 1.39 or 1.30 kg dry matter/ day or 0.20 or 19.9 mg/kg bw/day respectively. Urine, faeces and blood were collected throughout the study. Milk was sampled twice daily, in the morning and afternoon. The mean milk yield during the dosing period was 536 or 586 mL/day. Animals were sacrificed approximately 4 hours after the last dose. Samples of liver, kidney, muscle (tenderloin, hindquarter and forequarter), fat (omental, subcutaneous and renal) and rumen contents were collected.

The low dose goat eliminated 0.02%, 16.3% and 50.0% via milk, faeces and urine of the total dose applied respectively, while the corresponding values of the high dosed goat were 0.02%, 19.0% and 62.2% at 76 hours in the study.

The tissue residues of the low dosed goat were 0.035–0.043 mg/kg trinexapac-ethyl equivalents in muscles, 0.017–0.094 mg/kg trinexapac-ethyl equivalents in fat, 0.25 mg/kg equiv. in liver and 0.50 mg/kg equiv. in kidney. In the high dosed goat the residues were correspondingly higher *i.e.* 1.90–2.49 mg/kg trinexapac-ethyl equivalents in muscles, 1.20–1.55 mg/kg equiv. in fat, 12.1 mg/kg equiv. in liver and 41.9 mg/kg equiv. in kidney. The residue in the milk of the low dosed goat reached a plateau on the second day of dosing, with 0.002 mg/kg trinexapac-ethyl equivalents (am) and 0.007 mg/kg equiv. (pm). In the milk of the high dosed goat the plateau was reached on the third day when the total of am and pm is considered.

Residue levels in the corresponding tissues of the high dose goat were generally proportional but by a factor of 48 (liver)–84 (kidney) rather than the feed concentration factor of 96. An exception was subcutaneous fat, in which high dose residues were approximately 13 times the low dose residues, although it was postulated that the low dose subcutaneous fat result was an outlier.

Table 2 Recovery of radioactivity from goats dosed with [1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl at 7.2 ppm (low dose) and 694 ppm (high dose) in the feed for 4 consecutive days

NA = Not Applicable

In a second study (Müller 1993, CGA163935/0305) the nature of the metabolites of trinexapac-ethyl from the previously described goat metabolism study was determined.

Radioactivity in faeces was almost completely extractable with acidified methanol/water (1:1 v/v). The extractability of the muscle, liver and kidney samples was high (> 89% of the total radioactive residues). Extraction from these matrices was by using acetonitrile/water for the low dosed goat and liver of the high dosed goat, or acetonitrile and acetonitrile/water (1:1 v/v) for kidney and muscle in the high dosed goat. In milk 53–85% of the radioactivity was recovered in the supernatants after precipitation of the proteins and lipids with acetonitrile.

In the fat pools the majority of the radioactivity (70–82%) was extracted with chloroform/methanol (4:1 v/v for the low dose pool and 2:1 v/v for the high dose pool). In order to separate acidic from neutral compounds the extract was then partitioned with basic phosphate buffer and re-transferred into methylene chloride after acidification. Approximately 39% of the radioactivity remained in the organic layer in the low dosed pool, whereas in the high dosed pool the radioactivity of the extract was completely transferred into the basic aqueous layer and re-transferred in the methylene chloride phase for TLC analysis. It was assumed that the poor extractability from the chloroform phase of the low dose goat was due to the low residual radioactivity in a complex matrix, rather than due to differences in the nature of the metabolites present.

Trinexapac acid was the main component of TRR in urine, faeces and bile fluid of both low and high dose goats (81.6–96.1% of extractable radioactivity). Residues in muscle and kidney were also mostly trinexapac acid (80.7–89.6% TRR). In milk, trinexapac acid accounted for 45.5–76.0 % TRR. In liver and fat trinexapac acid was 30.8–67.3% TRR although for fat this represented 87.3–96.1% of the extractable radioactivity. For liver this represented only 34.1–47.2% of the extractable radioactivity, although other distinct metabolites observed in liver did not co-chromatograph with any of the reference compounds.

Table 4 Distribution of metabolites in goat tissues and milk after multiple applications of [1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl in the feed for 4 consecutive days

ND = Not Determined

The residual radioactivity present in the rumen content 4 hours after the last dose was readily extractable (98 and 99% for the low and high dose goats respectively). The extracts contained only trinexapac acid, indicating rapid hydrolysis of trinexapac-ethyl to the corresponding carboxylic acid, under conditions present in the rumen.

In another study [1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl was orally administered by gelatin capsule to two lactating goats (*Capra hircus*, 47.0 and 51.5 kg bw) at a level of 95 and 125 ppm in the feed for 4 consecutive days based on feed consumption of 1.50 kg feed/ day (Ray 2002, CGA163935/0944).

Urine and faeces were collected daily and blood samples just prior to sacrifice. Milk was sampled twice daily. Animals were sacrificed approximately 6 hours after the last dose. Samples of liver, kidney, muscle (leg and tenderloin), fat (omental and perirenal), bile and gastrointestinal contents were collected. Muscle and fat samples were combined.

Approximately 90% of the total administered radioactivity was recovered; 2.54% in the faeces, 80.5% in urine, < 0.01% in the bile, 2.19% in the blood, 1.19% in the combined tissues, 3.37% in the GI tract and 0.05% in milk. The ¹⁴C residue levels in composite tissues ranged from 0.106 mg/kg equiv. in the fat to 5.903 mg/kg equiv. in the kidney. The ¹⁴C residue levels in composite milk ranged from 0.018 mg/kg equiv. (7–24 hour, day 1 am) to 0.078 mg/kg equiv. (0–7 hour, day 1 pm).

The extractability of the muscle, liver and kidney samples was high (> 95% of the TRRs). Extraction from these matrices was by using acetonitrile/water. The extractability of the fat samples using chloroform/methanol was 98% of the TRR. In milk 90% of the radioactivity was recovered in the supernatants after precipitation of the proteins and lipids with acetonitrile.

Parent compound was not detected in any tissue or milk. After isolation and analysis by co-chromatography and mass spectrometry, two tissue and milk metabolites were identified. Residues of trinexapac acid accounted for 66.0–96.8% TRR in milk and tissues (Table 5). CGA 113745 (formed from further hydrolysis of trinexapac acid) was a major metabolite in liver, kidney and fat (6.0–16.3% TRR) but was not detected in muscle and milk. Post-extraction solids in tissues and milk represented 4.0–9.0% TRR.

Metabolism in Poultry

Two studies were conducted in laying hens using [1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl.

In the first study [1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl was orally administered daily to laying hens (White Leghorn, 1.26–1.45 kg bw prior to the start of acclimatisation until the last day of acclimatisation and 1.30–1.51 kg bw at sacrifice) using gelatine capsules at a low dose level (two hens, 0.4 mg/kg body weight equivalent to 3.8 ppm in feed) or a high dose level (four hens, 20.3 mg/kg body weight equivalent to 180 ppm in feed) for 4 consecutive days (Cameron *et al.* 1992, CGA163935/0277).

Excreta, blood and cage washes were collected throughout the study. Eggs were collected throughout the day and in the morning before subsequent administration. Egg yield for the low dose hens was 71–86% for the acclimatisation period (100% = 1 egg per hen per day) and 25–75% for the dose period, while for the high dose hens the egg yield was 86–100% for the acclimatisation period and 50–75% for the dose period. Animals were sacrificed approximately 4 hours after the last dose. Samples of lean meat (mixture of leg, thigh and breast), skin (including attached fat), peritoneal fat, liver and kidney and gizzard and crop contents were collected.

Over the period of the experiment (76 hours), 85–89% (high and low doses respectively) of the total administered dose was eliminated in excreta. Transfer of radioactivity into eggs accounted for only 0.01% and 0.02% of the total administered dose for the low and high dosed hens, respectively. A plateau was reached on Day 2 of the dosing period. Concentrations of radioactivity in egg yolk were generally less than in egg whites. Radioactivity did not accumulate in eggs with time over the period of the experiment. Concentrations of radioactivity in egg white and egg yolk in the low-dosed hens did not exceed 0.007 and 0.002 mg/kg trinexapac-ethyl equivalents, respectively. In the high dosed hens the corresponding values were 0.33 and 0.055 mg/kg trinexapac-ethyl equivalents.

Mean radioactive residues in tissues of the low-dosed hens were 0.002 mg/kg trinexapac-ethyl equivalents in lean meat (0.12 mg/kg equiv. high dose), 0.011 mg/kg equiv. in skin (including attached fat) (0.37 mg/kg equiv.), 0.003 mg/kg equiv. in peritoneal fat (0.18 mg/kg equiv.), 0.013 mg/kg equiv. in liver (0.60 mg/kg equiv.) and 0.043 mg/kg in kidney (1.77 mg/kg equiv.).

Residue levels in tissues of the high dose hens compared with levels observed in the low dose hens were greater by a factor of 33–61, which is comparable with the feed concentration factor of 47.

In the second study (Müller 1993a, CGA163935/0306) the nature of the metabolites of trinexapac-ethyl from the previously described hen metabolism study was determined.

A high proportion (> 97%) of the radioactivity in the excreta of low and high dosed hens was extractable using acetonitrile and acetonitrile/water (1:1 v/v), more than 90% of which was trinexapac acid. All other metabolites contributed to less than 10% of the total radioactivity.

The extractability of the radioactivity in lean meat, liver and kidney samples of low and high-dose hens was high ($\geq 83\%$ of the total radioactive residues using acetonitrile/water (1:1 v/v)).

In the fat pools the majority of the radioactivity (59–64%) was extracted with chloroform/methanol (4:1 v/v). In order to separate acidic from neutral compounds the extract was then partitioned with basic phosphate buffer and re-transferred into methylene chloride after acidification. Approximately 11% of the radioactivity remained in the organic layer in the high dosed pool whereas in the low dosed pool the radioactivity of the extract was completely transferred into the basic aqueous layer and re-transferred in the methylene chloride phase for TLC analysis.

Radioactive residues in muscle (lean meat), liver, kidney and fat samples of low and high-dosed hens were predominantly trinexapac acid (44–84% of the total residues or 54–92% of the extractable radioactivity).

In skin including attached fat the extractability (chloroform/ methanol (4:1 v/v)) was only 14–30%. No additional radioactivity could be released from the non-extractable solid of the high-dose pool when heated in acetonitrile/ formic acid (99:1 v/v) under reflux for 2 hours. The extract was then partitioned with basic phosphate buffer and re-transferred into methylene chloride after acidification. In skin with attached fat, trinexapac acid was also the major metabolite accounting for 64–80% of the extractable radioactivity. However as the extractability was rather low, the contribution to the total radioactivity was only 9–24%.

The extractability (acetonitrile) in eggs from hens of both feed levels was 55–68% of the total radioactivity in the egg white and 45–49% in the yolk. In the yolk the major metabolite was again trinexapac acid amounting to 57–76% of the extractable radioactivity, while parent trinexapac-ethyl was present at only 10–25%. In egg white the major residue was parent accounting for 64–78% of the extractable TRR. Trinexapac acid was either not detected (high dose) or accounted for only 13% of the extractable TRR (low dose).

The gizzard contents of the low and high-dose hens, which were extracted with acetonitrile, contained unchanged parent compound (43–65%) and trinexapac acid (25–39%) indicating that hydrolysis already occurs partially in the digestive tract.

Table 9 Distribution of the radioactivity in the tissues of laying hens from hens after multiple applications with [1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl in the feed for 4 consecutive days

In another hen metabolism study [1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl was orally administered daily to five laying hens (White Leghorn, 50 weeks at acclimatisation, 1.45–1.61 kg bw at the start of acclimatisation and 1.47–1.62 kg bw at sacrifice) by gelatine capsule at 10 ppm (based on mean feed consumption of 0.125 kg/day, 1.27 mg/animal/day) in feed for 10 consecutive days (Powell 2006, CGA163935/1048).

Actual doses corresponded to 8.1–10.4 ppm feed, based on the quantity of diet consumed by each hen. Eggs were collected at 24 hour intervals throughout the morning before subsequent administration. Faeces samples were collected daily. Animals were sacrificed approximately 22 hours after the last dose. Samples of fat (skin and attached fat and peritoneal), muscle (breast and thigh), kidney, liver and gastrointestinal tract and contents were collected.

Between 87.5% and 90.6% of the administered dose was recovered in the excreta (mean 89.1%), indicating that the radioactivity was rapidly excreted. The total radioactive recoveries for the five hens ranged from 89.0–91.3% (mean 90.4%).

YB = Yolk broke during separation from white, sample discarded

NS = No sample collected

TRR values for edible tissues and egg yolks were below 0.01 mg/kg trinexapac-ethyl equivalents, so no further analysis was undertaken.

A composite egg white sample (two hens, days 6–10 inclusive) was extracted with acetonitrile/ water (80:20 v/v) and acetone. After removal of acetonitrile and acidification with concentrated HCl, a liquid-liquid partition with ethyl acetate separated free organosoluble metabolites from polar residues. The major metabolites identified in the organosoluble residue were parent trinexapac-ethyl and trinexapac acid which accounted for 31.0% TRR (0.005 mg/kg equiv.) and 20.2% TRR (0.003 mg/kg equiv.) respectively (Table 14). The extract also contained at least two other components, none of which was > 0.001 mg/kg. No further analytical work was carried out on the solid debris or the aqueous fractions.

Summary of animal metabolism

Animal metabolism studies were carried out with [1, 2- ^{14}C -cyclohexyl] trinexapac-ethyl (goat and hens) or [1, 2, 6- ^{14}C -cyclohexyl] trinexapac-ethyl (goats, hens and rats). No accumulation of residues was observed in any organ, tissue or animal commodity.

In the goat [1, 2- ^{14}C -cyclohexyl] trinexapac-ethyl study, parent was hydrolysed to a significant extent prior to absorption. The acid was then efficiently absorbed and excreted via urine and faeces. Of the total dose 66–81% was eliminated in milk, faeces and urine. Trinexapac acid was the main component of urine and faeces (81–96%) and accounted for 81–90% of the total residues in muscle and kidney, 46–76% of the TRRs in milk, while accounting for lower proportions in liver and fat (31–67% of the TRRs), although for fat this represented 87–96% of the extractable radioactivity. In liver this represented only 34–47% of the extractable radioactivity, although other distinct metabolites observed in liver did not co-chromatograph with any of the reference compounds.

In another study in which [1, 2, 6- ^{14}C -cyclohexyl] trinexapac-ethyl was orally administered by gelatin capsule to two lactating goats, approximately 83% was eliminated in the milk, faeces and urine. Parent compound was not detected in any tissue or milk. Residues of trinexapac acid accounted for 66.0–96.8% TRR in milk and tissues. CGA-113745 (formed from further hydrolysis of trinexapac acid) was a major metabolite in liver, kidney and fat (6.0–16.3% TRR), but was not detected in muscle and milk. The metabolite pattern in urine and bile was similar to that of tissues.

In the hen parent trinexapac-ethyl was hydrolysed to the acid in the gizzard prior to absorption. The gizzard of the low and high-dose hens contained unchanged parent compound (43–65% of extractables) and trinexapac acid (25–39% of the extractables). The acid was efficiently absorbed and excreted. Over the period of the experiment, 85–89% of the total administered dose was eliminated in excreta. A high proportion (> 97%) of the radioactivity in the excreta of low and high dosed hens was extractable, more than 90% of which was trinexapac acid. All other metabolites contributed to less than 10% of the total radioactivity. Residues in muscle (lean meat), liver, kidney and fat samples of low and high-dosed hens were predominantly trinexapac acid (44–84% of the total residues or 54–92% of the extracted radioactivity). In the skin (with subcutaneous fat) only 14–30% of the total radioactivity was extractable. Trinexapac acid was the major metabolite in the extracts (64–80% of extracted radioactivity). The major metabolite found in egg yolks was trinexapac acid (57–76% of extracted radioactivity) while parent was present at 10–25%. In egg whites the major residue was parent accounting for 64–78% of extracted radioactivity, with acid only present at up to 13%. In another study the major metabolites identified in the organosoluble residue from egg whites were parent trinexapac-ethyl and trinexapac acid which accounted for 31.0% TRR and 20.2% TRR respectively.

In the rat, residues of trinexapac-ethyl were eliminated almost completely in the urine in the form of trinexapac acid (up to 100% of total urinary radioactivity), with low levels of a conjugated derivative of trinexapac acid detected in the urine of bile-duct cannulated rats (6.3% of the administered dose). In faeces, the parent compound accounted for 5–22% of total faecal radioactivity (1–2.5% of the administered dose), with the balance comprising trinexapac acid. Bile contained mainly a conjugated derivative of trinexapac acid (2.9% of the administered dose), with low levels of the parent compound also detected (0.2% of the administered dose).

Figure 1 Proposed metabolic pathway for trinexapac-ethyl in animals

Plant metabolism

The metabolism of trinexapac-ethyl in spring wheat, spring rape, paddy rice and grass was investigated. The radiolabelled material was either [1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl or [1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl.

Rice

[1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl was applied by foliar methods to paddy rice (Koshihikari) in water at rates of 40 and 160 g ai/ha (Gross 1996, CGA163935/0482). Applications were made at the lower rate 42 days after transplantation (stem elongation and stem node formation BBCH 37–41), or at the higher rate 64 days after transplantation (early panicle emergence). For the low application rate samples of rice plants were taken one hour as well as 7 and 21 days (full panicle emergence) after treatment. At maturity (82 days after treatment) the rest of the plant material was harvested and divided into grains, husks and straw.

The total radioactive residues (TRRs) are summarized below in Table 15. Total residues at harvest were 0.085 mg/kg trinexapac-ethyl equivalents in grain, 0.168 mg/kg equiv. in husks and 0.161 mg/kg equiv. in straw, indicating translocation of radioactivity from treated plants (foliage) into new growths. At maturity the parent content was less than 0.003 mg/kg in all plant parts. Non-extractable residues at maturity accounted for 40.5%, 41.1% and 72.0% of the total radioactivity in straw, husks and grain respectively.

In foliage unchanged parent compound decreased from 66.0% of the TRR at one hour after application, to 5.5% TRR after 7 days which indicated rapid degradation of the molecule. In addition to parent, up to ten metabolite fractions were observed, the major component being trinexapac acid (17.8–26.1% of TRR). Other metabolites observed included CGA 313458 (2.2–5.1% of the TRR), CGA 275537 or tricarballic acid (0–4.0% of the TRR) and CGA 312753 or trans aconitic acid (0–2.6% of the TRR).

Extractability of residues in grain was low. Only 16.2% of the radioactivity could be extracted with methanol/ water and another 12.5% were extracted with aqueous propanol under harsh microwave conditions. The extractable radioactivity consisted mainly of trinexapac acid with 11.6% of the TRR. Absolute amounts were low, all fractions being significantly below 0.01 mg/kg, except trinexapac acid with exactly 0.01 mg/kg (Table 18).

^a E₁ = cold extract^b E₂ = microwave extract

Due to the low residues and high % of non-extractable radioactivity in grain, the matrices of the 160 g ai/ha experiment were used for further characterisation. As also observed for the 40 g ai/ha treatment, trinexapac acid was the major component. Together with the microwave fraction this metabolite accounted for 28.1% of the total residues in grain. Other metabolites observed included parent trinexapac-ethyl (0.7% of the TRR), CGA 329773 (0.7% of the TRR), CGA 313458 (1.6% of the TRR) and CGA 275537 or tricarballic acid (2.1% of the TRR) (Table 19). Partition of the aqueous residues of E₁ with diethyl ether at pH 4 gave 73% of the radioactivity in the organic phase and 27% in the water phase. The organic phase consisted mainly of trinexapac acid and the water phase the polar fractions II₁, II₂ and II_{3a}. Further enzymatic and mild chemical treatment (0.1 N NaOH) showed that fractions II₁ and II₂ in grain consisted mainly of trinexapac acid in various conjugated forms, probably as esters of sugars and/ or plant constituents.

To characterise the methanol/water insoluble radioactivity in grain the residue R₁ (before microwave extraction) was analysed by digestion with 0.5 N NaOH followed by hydrolysis of the starch at pH 1. 70.1% of the radioactivity was eluted as a weakly acidic fraction. This radioactivity showed a similar TLC pattern to that already observed for the extractable radioactivity with fraction II₁-II₂ and II₁₀ as major spots. Formation of [¹⁴C]-osazone (8% of TRR) from the neutral water eluate indicated incorporation of carbon fragments into the sugar pool of the plant (Table 20).

In husks, extractable radioactivity of 160 g ai/ha treatment consisted mainly of II₁ (20.9% of the TRR), II₂ (8.5% of the TRR), trinexapac acid (13.8% TRR), tricarballic acid (8.2% TRR) and trinexapac-ethyl (6.1% TRR) (Table 19). Partition of the aqueous residues with diethyl ether at pH 4 showed 26% of the radioactivity in the organic phase and 74% in the water phase. The organic phase consisted mainly of trinexapac acid and parent whereas the water phase consisted mainly of the polar fractions II₁, II₂ and II_{3a} as well as tricarballic acid. The polar fractions II₁ through II_{3a} consisted mainly of acid and hydrolysis product of trinexapac acid, tricarballic acid and CGA 313458 in various conjugated forms, most probably as esters of sugars and/or plant constituents.

In straw from the 160 g ai/ha treatment besides the dominant fractions II₁ (21.2% of the TRR) and II₂ (17.0% of the TRR), tricarballic acid (10.7% of the TRR) was a major metabolite followed by trinexapac acid (6.9% TRR) and CGA 313458 (7.8% of the TRR) (Table 19).

Partition of the aqueous residues of E₁ of 160 g ai/ha treatment with diethyl ether at pH 4 gave 22% of the radioactivity in the organic phase and 78% in the water phase. The organic phase consisted mainly of trinexapac acid, II₈ = CGA313458, II₉ = CGA329773 and parent whereas the water phase consisted mainly of the polar fractions II₁, II₂, and II₈ as well as tricarballic acid. Chemical hydrolysis of the water phase (0.1 N NaOH) cleaved metabolite fraction II₂ (17.0% TRR) completely in favour of tricarballic acid and trinexapac acid proving that II₂ in straw consisted of conjugate esters of the tricarballic acid and trinexapac acid. Fraction II₁ was not altered by acid or base treatment. To characterise the non-extractable radioactivity in straw of 160 g ai/ha treatment after cold methanol and microwave extraction the residue R₂ was analysed. After boiling in water, 35% of the residual radioactivity was extracted, containing mainly water-soluble polysaccharides of the cell wall material. The remaining insoluble part was solubilised with boiling 2 N NaOH. Using this procedure another 49.5% was released from the non-extractable radioactivity containing mainly hemicellulose and lignin of the cell wall material. Quantitation of the fractions originating from the non-extractable radioactivity in straw is given in Table 20.

The proposed metabolic pathways of trinexapac-ethyl in rice are mainly by hydrolysis of the ester bond to give trinexapac acid, aromatisation of the C₆ ring of trinexapac acid presumably by hydroxylation followed by elimination of water and keto-enol tautomerisation, yielding 4-cyclopropanecarbonyl-3,5-dihydroxy-benzoic acid (CGA 329773), cleavage of the C₆ ring of trinexapac acid to 2-(4-cyclopropyl-4-hydroxy-2-oxo-but-3-enyl)-succinic acid (CGA 313458) and stepwise oxidation/decarboxylation after cleavage of the C₆ ring of trinexapac acid yielding saturated and unsaturated tricarboxylated acids such as 3-carboxy-pentanedioic acid (tricarballic acid = CGA 275537) and 3-carboxy-pent-2-enedioic acid (trans aconitic acid = CGA 312753) and conjugation of trinexapac acid, CGA 313458 and CGA 275537 with sugars and/ or other plant constituents.

Spring wheat

[1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl formulated as an emulsion concentrate was applied to spring wheat (Besso) by foliar spraying at a rate of 150 g ai/ha (Krauss 1990, CGA163935/0086). Applications were made to two week old plants (greenhouse experiment) and six week old plants (one-node stage, field experiment). In the greenhouse experiment samples were taken at seven time intervals from 0.5 hours, 4 hours, 1, 2, 7, 14 and 21 days. Plants were separated into leaves and roots. In the field experiment samples were taken at 0 days (tops), 25-days (ears and leaves at ear emergence), 48 days (ears and leaves at milky stage) and 71 days (grain, husks, straw at maturity). Soil samples were also taken.

Incorporation of radioactivity into the greenhouse grown plants is summarized below. After rapid initial dissipation of radioactivity from the leaf surface during the first day, subsequent decrease was slow for the next 20 days.

^a % of radioactivity found in sub-balanced plant parts/soil system; non-extractables (NE) is residual radioactivity determined after cold solvent extraction

^b % of radioactivity recovered at interval 1

^c % of radioactivity found in plant parts/ soil, determined by the sum of extractable and non-extractable radioactivity

The characterisation of the leaf rinse radioactivity is shown in the following table. Once penetrated, trinexapac-ethyl was hydrolysed to trinexapac acid. Parent concentration dropped to less than 2% of TRR 7 days after application, whereas the acid metabolite accounted for 30–40% of TRR in the leaf extract after 1 day and the following twenty days. After the first 24 hours approximately 80% of the recovered radioactivity had penetrated the plant surface. Translocation of radioactivity from treated plant parts into newly grown parts could be demonstrated by autoradiography.

^b LD = Limit of Detection (< 0.1% of radioactivity)

The incorporation of the radioactivity into the field grown spring wheat plants is summarized in the following table. Translocation of radioactivity from aerial plant parts to ears was significant. Total radioactive residues in the ears increased from 0.256 mg/kg at ear emergence (25 days after application) to approximately 0.47 mg/kg at milky stage and maturity. This behaviour of the TRR was confirmed by autoradiography. The TRR in grain, husks and straw at maturity was 0.462, 0.440 and 0.542 mg/kg respectively. Parent was always less than the limit of detection (0.001 mg/kg).

Characterisation of the TRR in the growing plants and at maturity is shown in the following table. The portion of the organosoluble radioactivity decreased from approximately 70% in the fresh green plant parts to 20–40% in straw and grain of the extractable radioactivity. The non-extractable residues increased from a few percent of the TRR in the fresh green plant parts to 25–50% of the TRR in grain and husks and 62% of the TRR in the straw at maturity.

Apart from the samples taken shortly after application, no parent compound could be detected in any plant part at later intervals. However the trinexapac acid was present in varying amounts in all plant parts. In the 25 and 48 day ears its relative amount was higher (28 and 25% of TRR respectively) than in the leaves (13 and 3% of TRR respectively). Likewise its content in grain (24% of TRR) was higher than in husks (10.0% of TRR) or in straw (4.5% of TRR).

Table 24 Extractability and residues of parent and trinexapac acid in whole tops, ears, grain, husks, straw and soil after foliar application of [1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl (field long term experiment)

^c LD = Limit of Detection (< 0.3% of radioactivity)

Eight significant metabolite fractions were characterised originating from the extracts of the field samples (see Table 25). The major metabolite fraction I₅ was identified as trinexapac acid.

The metabolite pattern in leaves, ears and husks was qualitatively similar, showing the presence of the metabolite fractions I₁, I₂, I₄ and I₅. In grain, metabolites I₁ and I₂ were not found. The water soluble metabolite fractions II₁ and II₃ were cellulase resistant. The upper soil layer at plant maturity contained trinexapac acid at 0.3% of the total radioactivity. Non-extractable radioactivity ranged from 26–92% of total residues under the extraction conditions used.

NA = Not analysed

A stem-injection experiment was conducted on six week old plants grown under greenhouse conditions and an incubation experiment (45 days at room temperature) of a cell suspension of treated leaves. The injection occurred with approximately 40–50 µg of [1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl per plant. All injected plants were harvested at maturity, 69 days after treatment (Krauss 1993, CGA 163935/0303).

In addition to the analytical methods used in the previous report silicagel column chromatography run was applied as flash chromatography under pressure, for fractionation of samples the column was eluted with a step gradient using ethylene chloride/ methanol mixtures and for isolation, purification and analysis different HPLC systems were applied. For the analysis of the non-extractable radioactivity in grain, husks and straw, various procedures were used. After extraction at high temperature and purification by partitioning and filtration, the water phase was dialysed in membrane bags. Further techniques for the characterisation and identification of the metabolites were high voltage electrophoresis and chemical derivatisation (methylation and acetylation).

Trinexapac acid was the dominant metabolite observed in grain (27.9% of the TRR). Other important metabolites observed included II₄, CGA 275537 (II₂) and II₃ which after methylation was identified as 4-cyclopropanecarbonyl-3, 5 dihydroxy-benzoic acid (CGA 329773). Approximately 85% of the TRR was characterised in grain and 51% could be identified.

The major metabolite observed in husks was trinexapac acid (16.7% of the TRR). Other metabolites observed included CGA 275537 (II₂). Approximately 86% of the TRR was characterised in husks and 37% could be identified.

In straw, the major fraction observed in the methylene chloride extract was trinexapac acid. Metabolite fraction I₂ which contained the mono ethyl ester of the aconitic acid was also present in the organic phase. After purification of the fraction which was generated from the water phase by partition with ethyl acetate, three major fractions were obtained which corresponded to the metabolite fractions II₃, trinexapac acid and II₄. Heating a suspension of non-extractables in a propanol/water mixture released a further 47% of TRR. From these fractions the metabolite fractions I₂, I₄ and trinexapac acid could be identified. Approximately 94% of the TRR was characterised in straw and 31% could be identified. The major metabolite observed in straw was trinexapac acid (12.8% of the TRR).

Only 6.9% of the total residues in the 0–5 cm soil layer could be extracted by methanol/water extraction followed by soxhlet extraction as previously reported (Table 25), with trinexapac acid only approximately 0.3% of the total residues. Analysis of the non-extractable radioactivity was performed by microwave extraction. The major part of the soil non-extractables (55% of the total residues) was released and partitioned with ethyl acetate. Trinexapac (2.2% of the total residues) and some minor fractions were in the combined organic phase.

The proposed transformation of trinexapac-ethyl in spring wheat is mainly by hydrolysis of the ester bond to give trinexapac acid. Conjugation of trinexapac acid with sugar occurs to a small extent in grain. Aromatisation of the C₆ ring of trinexapac acid presumably by hydroxylation followed by elimination of water and keto-enol tautomerisation, yielding CGA 329773 also occurs. Cleavage of

the C₆ ring of trinexapac-ethyl was postulated as an alternative pathway. Stepwise oxidation/decarboxylation after cleavage of the 6-membered ring yielded saturated and unsaturated tricarboxylic acids such as tricarballic acid (CGA 275537) and the mono ethyl ester of aconitic acid (CGA 312753).

Rape

[1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl was applied to spring rape (*Tobin Canola*) under greenhouse conditions in plastic containers filled with soil (Nicollier 1991, CGA163935/0209). One treatment was made to 37 day old spring rapeseed (stem elongation) at an application rate of 400 g ai/ha. Plants were sampled at 30 minutes (whole plants), 14 days (green and flowering parts) and 65 days (maturity - stalks, pods and seeds) after application. Soil samples were also taken.

The TRRs are summarized in Table 27. TRRs of 5.74 mg/kg trinexapac-ethyl equivalents, 1.43 mg/kg equiv. and 3.14 mg/kg equiv were found in the pods, seeds and stalks respectively. No parent compound was detected (< 0.002 mg/kg) in any plant part at harvest. After processing into oil and meal only 2.4% of the radioactivity was present in the oil (TRRs 0.11 and 2.11 mg/kg equiv. respectively).

Residues in soil at maturity reached 0.064 mg/kg for the 0–5 cm layer, 0.012 mg/kg for the 5–10 cm layer and 0.012 mg/kg for the 10–20 cm layer. Parent compound was below the limit of detection (0.002 mg/kg). Non-extractable residues accounted for 93.2, 97.3 and 99.0% of the total radioactivity in the 0–5 cm, 5–10 cm and 10–20 cm soil layers respectively.

Partitioning behaviour (pH 4) of the extractable residues in pods and stalks showed that the major part of the radioactivity was located in the water phase (57.9% in pods and 67.4 % in stalks) with 39.4% (pods) and 29.0% (stalks) located in the organic phase.

At harvest no parent compound was detected in pods, seeds and stalks. Approximately 16 metabolite fractions were found in plant, seeds processed parts and soil extracts. The major metabolite observed was trinexapac acid representing 26.9, 16.2 and 8.9% of the total radioactivity in meal, pods and stalks respectively (Table 28). Aqueous fractions obtained after partition were treated with cellulase which released aglycones indicating the presence of sugar conjugates. The major metabolite fractions that were released as aglycones were II₇ and II₁–II₂. The aglycones released were chromatographed and revealed the presence of trinexapac acid (I₅) and I₄. Non-extractable radioactivity accounted for 93.2% of the radioactivity in the 0–5 cm soil extract, with one minor metabolite, I₇, being observed only in soil.

The metabolite pattern observed in spring rape compared with that obtained in spring wheat, revealed the presence of crop specific metabolite fractions.

ND = Not Detected

In a subsequent study (Nicollier 1993, CGA163935/0308) with application of the radio-labelled trinexapac-ethyl and sampling of specimens as described above, additional analytical techniques were employed.

Metabolites identified are summarized below in Table 29. Forty to 46% of the TRR was identified in stalks, pods, seed meal and whole seeds while 89% of the TRR was identified in oil. In all plant parts 65–100% TRR was characterised.

In stalks organo-soluble radioactivity contained CGA 351210 and trinexapac acid while water soluble radioactivity (from a water/ methanol gradient) yielded six fractions which included trans aconitic acid (CGA 312753) and CGA 313458. Metabolite II_{3b} was tentatively identified as isocitric acid lactone while metabolite II₉ was postulated to be CGA 329773. The major fraction of the water

phase was enzymatically hydrolysed with cellulase. Two aglycones were released, one co-chromatographed with metabolite I_{4b} (CGA 351210) and the second one with metabolite I₅ (trinexapac acid).

In pods organo-soluble radioactivity again contained CGA 351210 and trinexapac acid while water soluble radioactivity (from a water/ methanol gradient) yielded four fractions which included trans aconitic acid (CGA 312753). After enzymatic hydrolysis with cellulase two aglycones, metabolites I_{4b} (CGA 351210) and I₅ (trinexapac acid) were released.

In seeds residues in oil were extracted with hexane. The two major metabolite fractions co-chromatographed were metabolite I_{4b} (CGA 351210) and metabolite I₅ (trinexapac acid). Of the oil radioactivity, 69.5% (or 1.7% of the TRR in the seed) remained attached to the lipid fraction. The meal fraction was extracted with 80% methanol. The major fractions again were metabolites I_{4b} (CGA 351210) and I₅ (trinexapac acid). Water soluble radioactivity (from a water/ methanol gradient) yielded four fractions which included trans aconitic acid (CGA 312753). After enzymatic hydrolysis with cellulase, metabolites I_{4b} (CGA 351210) and trinexapac acid were released. About 48% of the non-extractable radioactivity in meal could be solved in alkaline propanol after heating in a microwave. The major fraction of this organic phase was again trinexapac acid.

Table 29 Summary of identified components in plants parts and processed fractions at harvest after treatment with [1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl (400 g ai/ha treatment)

The proposed transformation of trinexapac-ethyl in rape seed is mainly by hydrolysis of the ester bond to give trinexapac acid. The sum of free and sugar conjugated trinexapac acid accounted for 30.6%, 3.5%, 18.5% and 9.7% of total radioactivity in meal, oil, pods and stalks respectively. Reduction of trinexapac acid to 2-(cyclopropyl-hydroxymethylene)-5-hydroxymethylcyclohexane-1,3-dione (CGA 351210) and subsequent conjugation with sugar occurs. Additional oxidation of trinexapac acid gives 2-(4-cyclopropyl-4-hydroxy-2-oxo-but-3-enyl)-succinic acid (CGA 313458) while cleavage of the C₆ ring of trinexapac-ethyl followed by stepwise oxidation/decarboxylation after cleavage of the 6-membered ring yielded isocitric acid and dehydration to trans aconitic acid (CGA 312753).

The observed metabolic pathway for rapeseed is comparable with those of wheat, grass and rice with the exception of one rape specific metabolite (CGA 351210) formed by the reduction of trinexapac acid.

Grass

[1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl was applied by foliar methods to tall fescue grass at rates of 560.4 g ai/ha (Ray and May-Hertl 2003, CGA163935/0862). One foliar broadcast spray was made 46 days prior to swath the grass for harvest of mature grass seed. Pre-forage samples were taken 22-days after application and hay samples were collected 46 days after application. The hay samples were dried and separated into straw, seed and seed screenings. Forage regrowth was collected 105 days after application. Soil samples were also taken at each of the harvest intervals listed above.

The TRRs and extractable and non-extractable radioactivity are summarized in Table 30. TRRs of 5.45 mg/kg trinexapac-ethyl equivalents, 7.13 mg/kg equiv. and 4.78 mg/kg equiv. were found in seeds, seed screenings and straw respectively. TRRs of 2.03 mg/kg equiv. and 0.054 mg/kg equiv. were observed for the 22 and 105 day forage samples respectively. Radioactivity extracted from 22 day forage, straw, seeds and seed screenings using acetonitrile/ water (4:1 v/v) or from 105 day regrowth forage using chloroform/methanol (4:1 v/v), ranged from 45% (seed screenings and seeds) to 75.5% (22 day forage).

In-depth isolation procedures of extractable and non-extractable material, followed by analysis of purified metabolites enabled identification of five metabolites which are summarized below in Table 31. Degradation of parent compound was rapid as none was detected in any plant part at harvest. Eleven metabolite fractions were found, of which five major metabolites were present in all plant samples. In the various plant matrices, the two main metabolites observed were trinexapac acid representing 10.2–22.4% of the TRR and CGA 275537 (tricarballic acid) representing 9.3–17.0% of the TRR. Radioactive residues left after solvent extraction (PES) ranged from 10.2–34.8% TRR.

^a PES values obtained by subtracting total metabolites identified from the original PES values.

NA = Not Applicable

The proposed transformation of trinexapac-ethyl in grass was mainly determined by exhaustive analyses of the straw and 22 day forage samples. The major biotransformation is by hydrolysis of the ester bond to give trinexapac acid. Trinexapac acid undergoes hydrolytic ring opening and a Baeyer-Villiger like oxidation of the cyclopropylketone moiety to yield open chain metabolite A. Subsequent retro Claisen condensation provides tricarballic acid (CGA 275537). An observed minor pathway starting from trinexapac-ethyl involves reductive elimination of one ring carbonyl group and Baeyer-Villiger like oxidation of the cyclopropyl-ketone moiety to yield metabolite B. An additional reductive elimination followed by aromatisation provides metabolite C (terephthalic acid).

Summary of plant metabolism

Rice, wheat, rape and grass (foliar treatment) metabolism studies were carried out with [1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl or [1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl. Metabolic pathways in rice, wheat, rape and grass were comparable in all four crops.

Between 85–94%, 23–79%, 65–100% and 66–75% of TRR was characterised in the various plant parts of wheat, rice, oilseed rape and grass respectively depending on the plant part and the sampling interval after application. The portion of identified metabolites was 31–51%, 10.4–60.3%, 39.6–89.0% and 33.3–64.6% of TRR in wheat, rice, oilseed rape and grass, respectively.

Seven metabolites were identified. Trinexapac acid was the major metabolite which was present in all species and all plants parts at harvest. Parent compound was completely degraded and was not detectable (< 0.001 / < 0.002 mg/kg) in any plant part of wheat, rapeseed and grass at harvest time. In rice only traces (0.001 and 0.003 mg/kg) were observed in straw and husks respectively. Further degradation of trinexapac acid proceeded *via* stepwise oxidation/ decarboxylation after cleavage of the 6-membered ring yielding saturated and unsaturated tricarboxylated acids such as tricarballic acid (CGA 275537) and trans aconitic acid (CGA 312753), the latter compound an intermediate in the citric acid cycle (Krebs cycle). From the intermediates of the citric acid cycle and their breakdown products, sugars, fatty acids and certain amino acids were formed by de-novo synthesis. Consequently high non-extractable residues are formed (for example 72.0% in rice grains). High unresolvable radioactivity in TLC-analysis after extraction may also be in part attributed to radio-labelled matrix products or breakdown products thereof. In wheat, the ring cleavage occurred also on the parent molecule yielding the mono-ethyl ester of the aconitic acid. Further minor steps were aromatisation of the 6 membered ring of trinexapac acid and keto-enol tautomerism to 4-cyclopropanecarbonyl-3,5-dihydroxybenzoic acid (CGA 329773) and in rape reduction of trinexapac acid to 2-(cyclopropylhydroxy-methylene)-5-hydroxymethyl-cyclohexane-1,3-dione (CGA 351210) and subsequent conjugation with sugar.

Sugar conjugates of trinexapac acid were hydrolysed in some crop parts to yield free acid. Trinexapac acid sugar conjugates accounted for an increase in trinexapac acid of 11.6% TRR in rice grain and 10% and 14% TRR in grass forage and straw, respectively. Levels of sugar conjugates of trinexapac acid were not significant in oilseed rape, rice straw or wheat grain and were not investigated in wheat straw or husk.

Although not all metabolites were found in every plant species, all observed degradation and transformation steps (oxidation, decarboxylation, ring cleavage and conjugation) occurred in all crops. Therefore, the metabolic profiles revealed comparable pathways in all crops.

Figure 2 Proposed metabolic pathways for trinexapac-ethyl in plants

Confined Rotational Crop Studies

The metabolism of trinexapac-ethyl was investigated in three representative succeeding crops—lettuce (representative of leafy vegetables), radish (root and tuber vegetables) and wheat (cereals) (Quistad and Kovatchev 2010, CGA163935_50024). The study was performed with the test substance, [1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl, applied to bare sandy loam soil, at a rate of 350 g ai/ha, followed by soil aging intervals of 30, 120 and 270 days. Crops were planted at each of the above intervals after application, to determine whether trinexapac-ethyl residues or degradates appear in follow crops. In addition radishes were sown at 309 days after soil treatment because the 270 plant back interval (PBI) crop did not produce root bulbs, due to the high summer temperatures during the cultivation interval.

Table 32 Schedule for planting/ seeding and harvest

Representative Crop Type	Crop	Planting/ Sowing [Days after Treatment]	Harvest [Days after Treatment]	Plant parts
Leafy Vegetable	Lettuce	30	86	Heads (immature)
			113	Heads (mature)
		120	183	Heads (immature)
			198	Heads (mature)
		270	290	Heads (immature)
			309	Heads (mature)
		30	83	Foliage, Roots
			183	Foliage, Roots
Root Vegetable	Radish	120	183	Foliage, Roots
		309	350	Foliage, Roots
		30	83	Forage
			168	Hay
Cereal	Wheat	120	231	Straw, Grain
			168	Forage
			209	Hay
			251	Straw, Grain
		270	296	Forage
			315	Hay
			352	Straw, Grain

Lettuce heads were harvested at immaturity (20–63 days after transplantation) and maturity (39–83 days after transplantation). Radish foliage and roots were harvested at maturity (41–63 days after sowing). Wheat was sampled as forage (26–53 days after sowing), as hay (45–138 days after sowing) and as straw and grain at maturity (82–201 days after sowing).

Total radioactive residues detected in rotational crops following soil application of [^{14}C] cyclohexyl trinexapac-ethyl were found to be:

- 0.011 mg/kg trinexapac-ethyl equivalents in lettuce head samples at immaturity (86 days after application) and 0.017 mg/kg equiv. in lettuce heads sampled at 100% maturity (113 days after application); for lettuce planted at 30 days PBI; 0.004 mg/kg equiv. and 0.007 mg/kg equiv. in immature lettuce heads of plants with 120 and 270 days PBI and 0.004 mg/kg equiv. and 0.001 mg/kg equiv. in mature lettuce heads of plants with 120 and 270 days PBI
- 0.005 mg/kg equiv., 0.007 mg/kg equiv. and 0.001 mg/kg equiv. for radish foliage of radish sown at 30, 120 and 309 days PBI respectively; 0.002 mg/kg equiv., 0.002 mg/kg equiv. and 0.001 mg/kg equiv. for radish roots sown at 30, 120 and 309 days PBI respectively
- 0.010 mg/kg equiv. in wheat forage sampled at 83 days after application and 0.011 mg/kg equiv. in wheat hay sampled 168 days after application, for plants with 30 days PBI; 0.004 mg/kg equiv. and 0.002 mg/kg equiv. for wheat forage of plants with 120 and 270 days PBI; 0.009 mg/kg equiv. and 0.008 mg/kg equiv. for wheat hay of plants with 120 and 270 days PBI, 0.003 mg/kg equiv., 0.004 mg/kg equiv. and 0.004 mg/kg equiv. for wheat straw samples and 0.005 mg/kg equiv., 0.008 mg/kg equiv. and 0.003 mg/kg equiv. for wheat grain samples of plants with 30, 120 and 270 days PBI respectively.

RACs were initially extracted with acetonitrile: water (1:1, 2 $\times$) followed by acetonitrile (1 $\times$). The combined acetonitrile: water extract supernatants were analysed by HPLC and/ or TLC. Post extraction solids were further extracted with other solvents if their total radioactive residues (TRR) were > 10%. The TRR of the final PES was determined by combustion.

The TRRs detected in rotational crops following soil application of [^{14}C] cyclohexyl trinexapac-ethyl at 350 g ai/ha are shown in Table 33.

Table 33 TRR values determined for trinexapac-ethyl confined accumulation in rotational crops

Crop	RAC	30 Days After Treatment (mg/kg trinexapac-ethyl equiv.)	120 Days After Treatment (mg/kg trinexapac-ethyl equiv.)	270 Days After Treatment (mg/kg trinexapac-ethyl equiv.)
Lettuce	Immature	0.011 ^a	0.004	0.007
	Mature	0.017 ^a	0.004	0.001
Radish ^b	Foliage	0.005	0.007	0.001
	Roots	0.002	0.002	0.001
	Forage	0.010 ^a	0.004	0.002
Wheat	Hay	0.011 ^a	0.009	0.008
	Straw	0.003	0.004	0.004
	Grain	0.005	0.008	0.003

^a Sum of fractions (combined acetonitrile/water extracts + further PES extracts + PES). Other TRR values were determined by combustion

^b 270 day PBI radish did not produce a root bulb, so re-sown at 309 days after treatment within the same plot

Radish RACs were not extracted with acetonitrile for analysis of residue distribution and extractable radioactivity because the TRRs were < 0.01 mg/kg. For lettuce only RACs with TRR ≥ 0.010 mg/kg were extracted (RACs with 30 days PBI). For wheat, only forage and hay specimens from plants of 30 and 120 days PBI were extracted. The extractability of radioactivity in lettuce and wheat RACs with acetonitrile was generally low at < 50% TRR. Residues of parent trinexapac-ethyl were not detectable by HPLC-UV (LOQ = 0.001 mg/kg). Residues of trinexapac acid from hydrolysis of parent and CGA 312753, formed by cleavage of the cyclohexanedione ring of trinexapac acid, were only detectable in wheat hay and forage in the range of 0.001–0.002 mg/kg.

The distribution of residual trinexapac-ethyl and extractable radioactivity in rotational crops (lettuce and wheat) is shown in Table 34.

Table 34 Summary of identified components in rotational lettuce and wheat following cultivation in soil treated with [1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl after plant back intervals of 30, 120 and 270 days.

ND = Not detectable

NA = Not Applicable (RACS were not extracted due to low TRR detected by combustion)

The uptake of residues by the rotational crops lettuce, radish and wheat planted or sown after several intervals after application of trinexapac-ethyl to bare ground was very low. No accumulation was observed. Residues of trinexapac-ethyl in the rotational crop RACs were below the LOQ (< 0.001 mg/kg). The residues of trinexapac acid and CGA 312753 were very close to or below the LOQ (< 0.001–0.002 mg/kg). The very limited uptake of radioactive material in succeeding crops clearly indicates the lack of systemic behaviour of trinexapac-ethyl. It was concluded that residues in rotational crops are negligible.

Field Accumulation in Rotational Crops

Field rotational crop studies for trinexapac-ethyl were conducted in both the USA and Switzerland.

USA Study—application to wheat (rotational crops—wheat, radish, spinach)

In a study conducted in the USA in the 2004–2005 growing season, a 250 g/L EC formulation of trinexapac-ethyl was applied once as a broadcast spray to wheat at 203 g ai/ha (Ediger 2006b, CGA163935/1054). Radish, wheat and spinach were planted after 3 different plant back intervals (14, 30 and 45 days).

Table 35 Schedule for planting/ seeding and harvest

Representative Crop Type	Crop [Varieties]	Planting/ Sowing [Days after Treatment]	Harvest [Days after Treatment]	Plant parts
	Spinach (Tyee, Melody)	14	60–73	Leaves
Leafy Vegetable		30	75–90	Leaves
		45	91–107	Leaves
		14	55–75	Tops
			55–75	Roots
Root Vegetable	Radish	30	73–90	Tops
	(Champion, Cherry Belle)		73–90	Roots
		45	79–106	Tops
			79–106	Roots
			73–75	Forage (fall)
			235–274	Forage (spring)
		14	266–287	Hay
			300–310	Straw
			300–310	Grain
			90	Forage (fall)
			250–274	Forage (spring)
Cereal	Spring and Winter Wheat	30	281–287	Hay
	(Barrie, Caledonia, Kaskaskia)		310–315	Straw
			310–315	Grain
			106–107	Forage (fall)
			266–303	Forage (spring)
		45	297–345	Hay
			331–368	Straw

Representative Crop Type	Crop [Varieties]	Planting/ Sowing [Days after Treatment]	Harvest [Days after Treatment]	Plant parts
			331–368	Grain

Spinach leaves were harvested 45–62 days after sowing. Radish tops and roots were harvested 34–61 days after sowing. Wheat was sampled as fall forage (59–62 days after sowing), spring forage (220–260 days after sowing), hay (253–300 days after sowing), straw (280–323 days after sowing) and grain (280–323 days after sowing).

Samples were stored frozen for a maximum of 23 months. Trinexapac residues in rotational crop samples were quantitated as trinexapac acid by LC/MS/MS (Method 110-01). The LOQ is 0.05 mg/kg for trinexapac acid. Concurrent method recovery data were collected in rotational crop matrices at spiking levels of 0.05 and 0.50 mg/kg and were acceptable.

The maximum residues observed in specimens from treated crops were all < 0.05 mg/kg except for one Day-14 PBI wheat straw sample at 0.07 mg/kg.

Table 36 Residues of trinexapac acid in rotational crops (spinach, radish and wheat) following application of trinexapac-ethyl to the target crop (wheat) at 203 g ai/ha

Crop	Matrix	Days After Treatment	Trinexapac Acid (mg/kg)

^a For statistical calculations 0.05 was substituted for < 0.05

DAT = Days After Treatment

NA = Not Applicable

Two control straw samples had residues of 0.05 (confirmed as 0.06) and 0.07 (confirmed as 0.07) mg/kg

The results showed that rotational crops sown 14, 30 and 45 days after application of trinexapac-ethyl to the target crop, are very unlikely to contain residues of trinexapac-ethyl as its main metabolite trinexapac acid, above the LOQ of 0.05 mg/kg.

European study—application to bare soil (rotational crops—lettuce, winter wheat, sugar beet and corn)

A trial was conducted in Switzerland during 1989 to investigate residues of trinexapac-ethyl in succeeding crops, grown in soil previously treated with [^{14}C] cyclohexyl trinexapac-ethyl (Krauss 1992, CGA163935/0265). A 250 g/L EC formulation of trinexapac-ethyl was applied once to bare soil at a rate of 150 g ai/ha. Treated plots (1 m² each) were planted after four different time intervals (69, 119, 299 and 338 days after treatment). The crops investigated were lettuce, winter wheat, sugar beet and maize (corn).

The schedule for seeding/planting and harvesting is shown in Table 37.

Table 37 Schedule for planting/ seeding and harvest

Representative Crop Type	Crop [Varieties]	Planting/ Sowing [Days after Treatment]	Harvest [Days after Treatment]	Plant parts
Leafy Vegetable	Lettuce	69	99	Heads (50% Maturity)
	(Sorraya)		119	Heads (Maturity)
			343	Tops, Roots
Root Vegetable	Sugar Beet	299	407	Tops, Roots
	(KWS)		496	Tops, Roots
			173	Whole tops (fall, cutting) (25% maturity)
Cereal	Winter Wheat	119	299	Whole tops (50% maturity)
	(Zenta)		343	Whole tops (75% maturity)
			407	Stalks, husks, grain (100% maturity)
			369	Whole tops (25% maturity)
	Maize	338	407	Whole tops (50% maturity)
	(Blizzard)		496	Stalks, husks, grain (100% maturity)

Plant samples and soil cores (0–5 cm, 5–10 cm, 10–20 cm and 20–30 cm layers) were collected. Lettuce was harvested at one-half maturity (30 days after transplantation) and maturity (50 days after transplantation). Winter wheat was sampled as a fall cutting, one quarter maturity (54 days after sowing), one half maturity (180 days after sowing), three quarters maturity (224 days after sowing), and at maturity (288 days after sowing). The sugar beets and maize were harvested at one-quarter maturity (44 and 31 days after sowing respectively), one-half maturity (108 and 69 days after sowing, respectively) and at maturity (197 and 159 days after sowing respectively).

The following tables show the distribution of radioactivity in rotational crops (lettuce, winter wheat, sugar beet and maize) and the distribution of residue trinexapac-ethyl in soil.

Total radioactive residues in rotational crops following soil application of [¹⁴C] cyclohexyl were found to be:

- 0.001 mg/kg in lettuce head samples at 50% maturity (99 days after application) and 100% maturity (119 days after application)
- 0.001 mg/kg in winter wheat whole top samples at fall cutting (173 days after application), < 0.001 mg/kg in whole tops at 50% maturity (299 days after application) and 75% maturity (343 days after application). Harvest stalks, husks and grain taken 407 days after application contained 0.002 mg/kg, 0.001 mg/kg and < 0.001 mg/kg respectively
- 0.001 mg/kg in sugar beet root samples at 25% maturity (343 days after application), < 0.001 mg/kg in sugar beet tops at 25% maturity and tops and roots taken at 50% maturity (407 days after application). and at maturity (496 days after application)

- 0.001 mg/kg in maize whole tops samples at 25% maturity (369 days after application) and < 0.001 mg/kg in whole tops taken at 50% maturity (407 days after application). Harvest stalks, cobs, and grain taken 496 days after application contained < 0.001 mg/kg.

The uptake of residues by the rotational crops lettuce, winter wheat, sugar beet and maize planted or sown after several intervals after application of trinexapac-ethyl to bareground was therefore very low (< 0.001–0.002 mg/kg). No accumulation was observed. Due to the residues in the rotational crop RACs being < 0.01 mg/kg, no characterisation was possible. The very limited uptake of radioactive material in succeeding crops clearly indicates the lack of systemic behavior of trinexapac-ethyl. It was concluded that the residues situation in rotational crops is negligible.

Greater than 90% of the TRR after application of trinexapac-ethyl to bare ground remained in the top 10 cm of soil during the entire cultivation of the succeeding crops. In soil significant residues (TRR) were only observed in the top soil layer (0–5cm) in the range of 0.065–0.076 mg/kg at planting or sowing and at 0.028–0.080 mg/kg at harvest. In layers below, the TRR did not exceed 0.019 mg/kg and was in most cases < 0.010 mg/kg. Extractables in the top soil layer amounted to 7.1–14.9% of TRR after cold extraction using 50% aqueous methanol. An additional 1.4–2.5% of TRR was extractable after a hot Soxhlet extraction with methanol. 78.9–98.7% of TRR in the top soil layer were non-extractables.

The confined and field rotational crop studies suggest that residues of trinexapac-ethyl are unlikely to occur in succeeding crops.

RESIDUE ANALYSIS

Analytical methods

Details of analytical methods including validation data were supplied for the determination of trinexapac acid or trinexapac-ethyl in plant and animal matrices, soil, water and air and are considered satisfactory. A summary of all analytical methods for plants and animals is given in Table 42.

Table 42 Summary of analytical methods developed for plant and animal matrices

Plant commodities

Method 110-01

Method 110-01 for the determination of trinexapac as trinexapac acid in plant matrices by means of high performance liquid chromatography with mass spectrometry (HPLC/MS) was reported by Lin (2002, CGA163935/0962). The method includes a reflux extraction procedure which is buffered to pH 7 and therefore does not hydrolyse sugar conjugates. Residues are quantified against a trinexapac acid external standard to give residues of “free” trinexapac acid.

Samples are extracted by refluxing for 1 hour with acetonitrile/ sodium phosphate buffer (70:30, v/v) at pH 7. The sample is passed through a pre-conditioned C₁₈ SPE cartridge for purification and evaporated to an aqueous solution (rotary evaporator). The aqueous solution is acidified and is then passed through a second SPE cartridge (C₈). The cartridge is rinsed with acetonitrile/ 0.05% H₃PO₄ aqueous solution (10:90, v/v) and the analyte is eluted from the column with acetonitrile/ 0.05% H₃PO₄ aqueous solution (30:70, v/v). The eluate is evaporated again to an aqueous solution, acidified and is liquid/liquid partitioned twice against a methyl tertiary butyl ether (MTBE)/hexane (63:35, v/v) with the addition of salt. The organic layers are collected and evaporated to dryness and re-dissolved in ethyl acetate. The ethyl acetate sample is passed through a pre-conditioned silica SPE column and rinsed with methanol/ ethyl acetate (15:85, v/v). The analyte is eluted from the cartridge with methanol/acetonitrile/ ethyl acetate (40:30:30, v/v/v). The eluate is evaporated to near dryness and dissolved in acetonitrile/water (10:90, v/v). The sample is injected onto a reverse phase C₈ column HPLC/MS/MS system for analysis of trinexapac acid using 0.1% acetic acid/acetonitrile (60:40, v/v) as the mobile phase. Detection in the positive ionisation mode was used (mass monitored 225).

Samples of grass (forage, hay/ straw, seed and seed screenings) were spiked with trinexapac acid at levels of 0.05, 1 and 5 mg/kg and then extracted and analysed using Method 110-01. Recoveries were found to be within acceptable ranges. In all matrices tested, the individual recovery values were in the acceptable range of 70–120%. The relative standard deviations (RSD, %) for all commodities and all spiking levels were at or below 20%. The mean recovery data are summarized in Table 43. The LOQ was reported as 0.05 mg/kg in all matrices.

Table 43 Method recoveries for method 110-01: trinexapac acid in field grown grass matrices

Matrix	Spiking level [mg/kg]	Recoveries for trinexapac acid			
		No.	Range [%]	Mean [%]	RSD [%]
	0.05	3	72–107	87	20
Forage	1	1	75	–	–
	5	3	76–94	86	11
	0.05	3	72–99	86	16
Hay/straw	1	1	86	–	–
	5	3	90–94	92	2
	0.05	2	84, 95	90	–
Seed	1	1	98	–	–
	5	3	77–92	87	10
	0.05	3	72–87	80	10
Seed screenings	1	1	104	–	–
	5	3	75–102	92	16

The extraction efficiency of Method 110-01 was tested. Grass matrices (forage, straw, seed and seed screenings) samples from the metabolism study were analysed in triplicate.

Table 44 Extractability of residues of [¹⁴C] trinexapac in grass matrices according to Method 110-01

Matrix	TRR (mg/kg) ^a Determined in Study 623-00	LSC Values (mg/kg) ^b Determined in this Study	Method 110-01 Extraction Efficiency ^c	Trinexapac acid residues (mg/kg) ^d Determined by Method 110-01	Accountability (%) ^e
Forage	2.03	1.6	80%	0.12 (4.8%)	5.9%
Straw	4.78	3.6	75%	0.75 (4.3%)	15.7%
Seed	5.45	3.2	58%	0.36 (38.9%)	6.6%
Seed screenings	7.13	4.2	59%	0.61 (16.6)	8.6%

^a TRRs were determined by combustion analyses of radiolabelled samples in Study 623-00 (Ray and May-Hertl 2003, CGA163935/0862)

^b Liquid scintillation counting (LSC) of the radiolabelled extracts in this study (averaged from triplicate samples)

^c Extractability or extraction efficiency = (LSC results ÷ TRR values) × 100%

^d Residues concentrations averaged from triplicate analysis (RSD)

^e Accountability = (Residues found by this method ÷ TRR) × 100%

It was found that the extraction efficiencies determined by Method 110-01 ranged from 58–80% for various grass matrices. Concentrations of trinexapac acid were determined by the method. Accountability ranged from 5.9% in forage to 15.7% in straw.

An independent laboratory validation report for Method 110-01 for the determination of residues of trinexapac acid (Cobin and Pyles 2002, CGA163935/0961) in plants (grass forage, hay, straw and seed) has been submitted. Minor modifications, principally concerning the silica SPE column, were suggested. Grass forage, straw and seed screenings were successfully validated during the first trial and grass hay during the second trial.

Table 45 Recovery results of method 110-01: trinexapac in plant matrices

Matrix	Spiking level [mg/kg]	Recoveries for trinexapac acid			
		No.	Range [%]	Mean [%]	RSD [%]

Method GRM020.01A

A validated method (GRM020.01A) has been reported for the determination of trinexapac acid in plant matrices using HPLC-MS/MS (Lin 2008, CGA179500_50010). It is a modified version of Method 110-01. This method includes a strong acid hydrolysis procedure to release “conjugated” residues of trinexapac acid from plant matrices. Residues are quantitated against a trinexapac acid external standard to give the sum of “free” and “conjugated” trinexapac acid. Other modifications included reducing the steps for sample clean-up procedures and using HPLC/MS/MS for final determination.

Samples are refluxed for 5 hours with acetonitrile/ 1 N hydrochloric acid (80:20, v/v). An aliquot of the extract supernatant is mixed with water and passed through a C₈ SPE cartridge (pre-conditioned with acetonitrile then 0.5% formic acid). The C₈ SPE cartridge is rinsed with water then water/ acetonitrile (80:20, v/v). The analyte is eluted from the cartridge with formic acid aqueous solution/ acetonitrile (80:20, v/v). The eluent is injected onto a reverse phase ODS-2 column HPLC-MS/MS system for analysis of trinexapac acid. MS/MS detection in the negative ionization mode is used to monitor the ion transition 223→135 (quantitation) for trinexapac. The 223→179 transition can be used for the confirmatory analysis of trinexapac residues.

Samples of field grown grass commodities (forage, straw, seed screenings and seed) were spiked with trinexapac acid at levels of 0.01–1 mg/kg. Samples were extracted and analysed with Method GRM020.01A (HPLC-MS/MS). In the matrices tested the mean recoveries were within 70–120% (Table 47). The relative standard deviations (RSD, %) for all commodities and all spiking levels were below 20%. The LOQ was defined by the lowest spiking level successfully tested, which was 0.01 mg/kg for trinexapac acid in all matrices.

Table 47 Method recoveries for GRM020.01A: trinexapac acid in grass matrices

Matrix	Spiking level [mg/kg]	Recoveries for trinexapac acid			
		No.	Range [%]	Mean [%]	RSD [%]

	0.2	1	100	–	–
Seed	0.01	5	95–97	96	1
	0.1	5	84–100	92	7

The extraction efficiency (radio-validation) of Method GRM020.01A was tested. Grass matrices (forage, straw and seed screenings) samples from the metabolism study were analysed in triplicate.

Table 48 Extractability of residues of [¹⁴C] trinexapac in grass matrices according to Method GRM020.01A

Matrix	TRR (mg/kg) ^a Determined in Study 623-00	LSC Values (mg/kg) ^b Determined in this Study	Method GRM020.01A Extraction Efficiency ^c	Trinexapac acid residues (mg/kg) ^d Determined in Study 623-00	Trinexapac acid residues (mg/kg) ^e Determined by GRM020.01A
Forage	2.03	2.28	112%	0.329	0.40
Straw	4.78	4.85	101%	1.068	1.3
Seed screenings	7.13	6.37	89%	0.906	2.0

^a TRRs were determined by combustion analyses of radiolabelled samples in Study 623-00 (Ray and May-Hertl 2003, CGA163935/0862)

^b Liquid scintillation counting (LSC) of the radiolabelled extracts in this study

^c Extractability or extraction efficiency = (LSC results ÷ TRR values) × 100%

^d Data reported in Study 623-00 (Ref.)

^e Averaged from triplicate analysis of radiolabelled samples (duplicate for seed screenings) by Analytical Method GRM020.01A LC-MS/MS analysis

It was found that the extraction efficiency and residue concentrations determined by Method GRM020.01A were in general agreement with those reported in the metabolism study. The radio-validation data confirms that the method is capable of accurately quantifying incurred residues of trinexapac acid as the sum of free and conjugated residues.

An independent laboratory validation report for Method GRM020.01A for the determination of residues of trinexapac acid in plants (wheat grain, forage and straw) has been submitted (Thomas 2010, CGA179500_50000).

For trinexapac, the transition 223→135 was used for quantitation, and 223→179 was used for confirmation. Recoveries at fortification levels of 0.01 (LOQ) and 0.1 mg/kg were provided for the quantitation transition and were found to be acceptable (Table 49). All individual recoveries were between 70–120% with a relative standard deviation < 20% for each fortification level / matrix combination. The LOQ was defined by the lowest spiking level successfully tested, which was 0.01 mg/kg for trinexapac in all matrices.

Table 49 Recovery results of method GRM020.01A: trinexapac acid in plant matrices

Matrix	Spiking level [mg/kg]	Recoveries for trinexapac acid			
		No.	Range [%]	Mean [%]	RSD [%]
Wheat Grain	0.01	5	86–109	95	10
	0.10	5	95–106	100	4

Method REM 137.02

A validated method (REM 137.02) has been reported for the determination of trinexapac acid in plant matrices using HPLC-UV (Forrer 1991, CGA163935/0082).

In the case of wheat and barley, trinexapac acid is extracted by shaking a homogenised subsample with a pH 7 methanol/aqueous phosphate buffer (30:70, v/v) to analyse for free trinexapac acid. In the case of rapeseed, trinexapac acid is extracted by shaking a homogenised subsample with a pH 7 acetonitrile/aqueous phosphate buffer (80:20, v/v) to analyse for free trinexapac acid. An extract aliquot is transferred to a pre-conditioned (methanol/water 50:50, v/v) solid phase extraction cartridge

(SAX). After washing with methanol/water (30:70, v/v) and water, trinexapac acid is eluted with sulphuric acid (0.1 N) and partitioned into dichloromethane. The organic phase is evaporated to dryness. Additional clean-up and final determination are achieved using a three-column HPLC switching system with UV-detection. The LOQ of this method was given as 0.02 mg/kg trinexapac acid. Recovery data are summarized in Table 52.

Table 52 Method recoveries for method REM 137.02: trinexapac acid in plant matrices

Matrix	Spiking level [mg/kg]	Recoveries for trinexapac acid			
		No.	Range [%]	Mean [%]	RSD [%]
Wheat Grain	0.04	1	94	—	—
	0.2	1	80	—	—
Wheat Straw	0.04	1	104	—	—
	0.2	1	99	—	—
Barley Grain	0.04	3	96–101	98	3
	0.2	3	89–98	95	5
Barley Straw	0.04	3	96–110	102	7
	0.2	3	89–97	94	5
Rape Seed	0.04	1	105	—	—
	0.2	1	98	—	—

In a validation study for Method 137.02 (Sack 1999, CGA163935/0588) for the final determination the HPLC system was changed from the original 3-column LC system to the 2-column system which follows the same reversed phase principles as the 3-column system. The LOQ was defined by the lowest spiking level successfully tested, which was 0.02 mg/kg for trinexapac acid in all matrices.

Samples of wheat and rape seed matrices were spiked with trinexapac acid at levels of 0.02–0.2 mg/kg. Samples were extracted and analysed with Method REM 137.02 (HPLC-UV). In the matrices tested mean recoveries were within 70–120%. The recovery data are summarized in Table 53. Relative standard deviations (RSD, %) for all commodities and all spiking levels were below 20%. Reproducibility was demonstrated by the successful validation with wheat grain and rapeseed carried out in a second laboratory, fulfilling the requirement for an enforcement method.

Table 53 Method recoveries for method REM 137.02: trinexapac acid in plant matrices

^a Results from the second laboratory

Method REM 137.11

Details of a method (REM 137.11) for the determination of trinexapac acid in rape seed oil using HPLC-UV have been reported in the rape seed processing studies (e.g. Sack 1995, CGA163935/0417).

Trinexapac acid is extracted from rape seed oil four times by vigorously shaking with methanol. The combined methanol phases are diluted with pH 7 phosphate buffer. This aqueous

sample is pre-cleaned using a C18 SPE column. After acidification of the sample passed through the first column, trinexapac acid is extracted by means of a second C18 SPE column. Final determination is performed using a two column HPLC with UV-detection. Samples of rape seed oil were spiked with trinexapac acid at levels of 0.02 and 0.1 mg/kg (recoveries 88% and 87% respectively).

Method REM 137.13

A validated method (REM 137.13) has been reported for the determination of free trinexapac acid in plant matrices using HPLC-MS/MS (Campbell and Crook 2004, CGA163935/0990). The method was developed from Method 137.02 with the replacement of the HPLC-UV two column switching method by solid phase extraction (SPE) followed by single column HPLC-MS/MS.

Samples are extracted by homogenisation with pH 7 methanol/ water/ phosphate buffer (30:56:14, v/v/v) to analyse for free trinexapac acid. Extracts are centrifuged and aliquots are subsequently diluted with ultra-pure water. A SPE procedure is then carried out to facilitate sample clean up. Final determination is by high performance liquid chromatography with triple quadrupole mass spectrometric detection (LC-MS/MS).

Samples of broad bean seed, broad bean whole plant and broad bean remainder were spiked with trinexapac acid at levels of 0.02–4 mg/kg (whole plant), 0.02–0.2 mg/kg (remainder) and 0.02–10.0 mg/kg (seed) (Table 54). Samples were extracted and analysed using Method REM 137.13. In the matrices tested the mean recoveries were within 70–120%. The relative standard deviations (RSD, %) for all commodities and all spiking levels were $\leq 20\%$. MS/MS detection in the negative ionisation mode is used to monitor the ion transition 223 $\rightarrow$ 83 for trinexapac.

Table 54 Method recoveries for method REM 137.13: trinexapac acid in bean matrices

Matrix	Spiking level [mg/kg]	Recoveries for trinexapac acid			
		No.	Range [%]	Mean [%]	RSD [%]
Broad Bean (Whole Plant)	0.02	5	91–104	97	5
	4	5	93–102	96	4
Broad Bean (Remainder)	0.02	5	64–96	78	20
	0.2	5	69–111	91	17
Broad Bean (Seed)	0.02	5	75–98	89	10
	10.0	5	87–96	91	4

An independent laboratory validation report for Method REM 137.13 for the determination of residues of trinexapac acid (Benazeraf 2004, CGA163935/0988) in plants has been submitted.

Samples of apple, potato, wheat grain and oilseed rape were spiked with trinexapac acid at levels of 0.01–0.1 mg/kg (apple), 0.01–0.1 mg/kg (potato), 0.01–0.3 (wheat grain) and 0.01–1 mg/kg (oilseed rape). Samples were extracted and analysed using Method REM 137.13. In the matrices tested the mean recoveries were within 70–120% and the relative standard deviations (RSD, %) for all commodities and all spiking levels were $\leq 20\%$ (Table 55).

Table 55 Recovery results of method REM 137.13: trinexapac acid in plant matrices

Matrix	Spiking level [mg/kg]	Recoveries for trinexapac acid			
		No.	Range [%]	Mean [%]	RSD [%]
Apple	0.01	5	63–100	84	18
	0.1	5	72–98	90	12
Potato	0.01	5	97–111	103	6
	0.1	5	88–104	98	7
Wheat Grain	0.01	5	72–96	84	12
	0.3	5	79–103	92	9
Oilseed Rape	0.01	5	74–90	85	8
	1	5	79–87	83	5

The LOQ was defined by the lowest spiking level successfully tested, which was 0.01 mg/kg each for trinexapac in all matrices.

Method REM 137.01

Method REM 137.01 has been reported for the determination of trinexapac-ethyl in wheat and barley grains and straw using HPLC-UV (Forrer 1989, CGA163935/0033).

Samples are extracted by homogenisation with pH 7 methanol/ aqueous phosphate buffer (30:70, v/v) to analyse for trinexapac-ethyl. Extracts are acidified and the compound re-extracted into dichloromethane. A SPE procedure is then carried out to facilitate sample clean up. Final determination is by a three column high performance liquid chromatography switching system with UV-detection.

Samples of wheat grain and straw were spiked with trinexapac-ethyl at levels of 0.04 and 0.2 mg/kg (Table 56). Samples were extracted and analysed using Method REM 137.01. In the matrices tested the mean recoveries were within 70–120%. The relative standard deviations (RSD, %) for all commodities and all spiking levels were $\leq 21\%$. Supplementary data (wheat and barley grain and straw) for confirmation of the validity of Method REM 137.01, using a simplified chromatographic system with only the first two columns, was presented in the same study. Method REM 137.01 was also validated in this study for quantitation of residues of trinexapac-ethyl in soil.

Table 56 Method recoveries for method REM 137.01: trinexapac-ethyl in cereal matrices

Matrix	Spiking level [mg/kg]	Recoveries for trinexapac-ethyl			
		No.	Range [%]	Mean [%]	RSD [%]
Wheat grain	0.04	6	60–111	87	21
	0.2	9	71–104	87	12
Wheat straw	0.04	2	100, 103	102	–

	0.2	4	86–101	94	7

^a Supplementary data supplied with Forrer 1989, CGA163935/0033 using a simplified chromatographic system

Method REM 137.05

A validated method (REM 137.05) has been reported for the determination of trinexapac-ethyl in rape seed using HPLC-MS/MS (Forrer 1991a, CGA163935/0142).

Trinexapac-ethyl is extracted by shaking a homogenised sub-sample with a pH 7 mixture of acetonitrile and aqueous phosphate buffer. An aliquot of the extract is washed with hexane, acidified and the compound is re-extracted into dichloromethane or into tert-butyl methyl ether/ethyl acetate. Additional clean-up and final determination are achieved by a three column HPLC switching system with UV-detection. Samples of rape seed were spiked with trinexapac-ethyl at levels of 0.04 – 0.2 mg/kg. Samples were extracted and analysed with REM 137.05 (HPLC-UV). Mean recoveries were within 70–120% (Table 57). The relative standard deviations (RSD, %) for all commodities and all spiking levels were below 20%. The limit of quantitation for trinexapac-ethyl residues in crop commodities using Method REM 137.05 was established at 0.02 mg/kg.

Table 57 Method recoveries for method REM 137.05: trinexapac-ethyl in rape seed

Matrix	Spiking level [mg/kg]	Recoveries for trinexapac acid			
		No.	Range [%]	Mean [%]	RSD [%]
Rape Seed	0.04	2	80, 91	86	-
	0.2	7	78-103	91	10
Rape Seed ^a	0.04	6	72-84	78	6
	0.2	6	62-82	75	10

^a Recoveries were generated with Method REM 137.01 using a simplified chromatographic system. Instead of the three column HPLC (as described for Method REM 137.05) the first two columns only were used.

Animal commodities

Method REM 137.12

Method REM 137.12 was developed for the determination of trinexapac acid in animal matrices (Sack 1995, CGA163935/0440). This HPLC-UV method was superseded by Method REM 137.14 (LC-MS/MS).

Method REM 137.12 involves the extraction of trinexapac acid from tissues (meat, liver or kidney) using a mixture of water/ methanol/ sodium hydroxide by shaking at room temperature. The extract is centrifuged and an aliquot is acidified. This aliquot is cleaned-up by means of solid phase extraction (SPE) using a C18 column followed by a second clean-up step on a strong anion exchange (SAX) SPE column. For milk, sub-specimens are diluted with water. After addition of sodium hydroxide an aliquot is taken and passed through a C18 SPE column. The entire pre-cleaned aliquot passed through the column is collected and acidified with phosphoric acid. Trinexapac acid is then extracted on a second C18 SPE column. For eggs, a homogenised sub-specimen (liquid part of egg only) is suspended in a mixture of water and methanol and dissolved by addition of sodium hydroxide. An aliquot of this clear solution is cleaned up/ extracted according to the same principles as applied for milk. The final extracts in all cases are analysed using HPLC-UV.

Samples of bovine meat, liver and kidney, milk and eggs were spiked with trinexapac acid at levels of 0.02–0.20 mg/kg (tissues), 0.01–0.10 mg/kg (milk) and 0.02–0.20 mg/kg (eggs). Samples were extracted and analysed using Method REM 137.12. In all the matrices tested the mean recoveries were within 70–120%. The mean recovery data are summarized in Table 58. The relative standard deviations (RSD, %) for all commodities and all spiking levels were < 20%.

The LOQ was defined by the lowest spiking level successfully tested, which was 0.01 mg/kg in milk and 0.02 mg/kg each in animal tissues and eggs.

Table 58 Recovery results of method REM 137.12: trinexapac acid in animal matrices

Matrix	Spiking level [mg/kg]	Recoveries for trinexapac acid			
		No.	Range [%]	Mean [%]	RSD [%]
Meat	0.02	8	78–88	84	5
	0.20	8	86–95	92	3
Liver	0.02	4	86–94	89	4
	0.20	4	70–86	79	9
Kidney	0.02	4	77–85	82	5

	0.10	8	92–101	97	3
Eggs	0.02	8	78–86	82	4
	0.20	8	78–84	81	2

An independent laboratory validation report for Method REM 137.12 for the determination of residues of trinexapac acid in animal matrices (milk and meat) has been submitted (Gasser 2001, CGA163935/0740).

Samples of meat and milk were spiked with trinexapac acid at levels of 0.01–0.10 mg/kg (milk) and 0.02–0.20 mg/kg (meat). Samples were extracted and analysed using Method REM 137.12. In both matrices tested the mean recoveries were within 70–120% and the relative standard deviations (RSD, %) for both commodities and both spiking levels were $\leq 20\%$ (Table 59). The LOQ was defined by the lowest spiking level successfully tested, which was 0.01 mg/kg in milk and 0.02 mg/kg in meat.

Table 59 Recovery results of method REM 137.12: trinexapac acid in animal matrices

Method REM 137.14

Method REM 137.14 was developed for the determination of trinexapac acid in animal matrices using quantification of residues by LC-MS/MS (Kwiatkowski 2004, CGA179500/0039). It supersedes the previously developed HPLC-UV Method REM 137.12.

Animal tissue and egg matrices are extracted by shaking with water/ methanol (80:20, v/v) containing 0.33% 1M sodium hydroxide solution. Milk is extracted by shaking with water/ methanol (98:2, v/v) containing 0.2% 1M sodium hydroxide solution. Extracts are centrifuged and aliquots are diluted with ultra-pure water. After a solid phase extraction procedure is carried out, final determination is by high performance liquid chromatography with triple quadrupole mass

spectrometric detection (LC-MS/MS). MS/MS detection in the negative ionisation mode is used to monitor ion transitions 223.0→83.0 and 223.0→178.6 (confirmatory transition) for trinexapac acid.

Samples of bovine muscle, kidney, liver, fat and eggs were spiked with trinexapac acid at levels of 0.01 and 0.10 mg/kg. Samples of milk were spiked with trinexapac acid at levels of 0.005 and 0.05 mg/kg. Samples were extracted and analysed with Method REM 137.14. In all matrices tested, the mean recovery values were between 70% and 120% and the relative standard deviations (% RSD) for all commodities and all spiking levels for five tests at each spiking level were ≤ 20%. Mean recovery data for the quantitation transition are given in Table 61.

The LOQ was defined by the lowest spiking level successfully tested which was 0.01 mg/kg for egg, muscle, kidney, liver and fat, and 0.005 mg/kg for milk.

Table 61 Recovery results of method REM 137.14: trinexapac acid in animal matrices

Matrix	Spiking level [mg/kg]	Recoveries for trinexapac acid			
		No.	Range [%]	Mean [%]	RSD [%]

	0.05	5	89–99	94	5
Eggs	0.01	5	67–119	96	20
	0.1	5	79–97	90	8

An independent laboratory validation report for Method REM 137.14 has been submitted (Benazeraf 2004, CGA163935/0989).

Samples of bovine muscle were spiked with trinexapac acid at levels of 0.01 and 0.10 mg/kg and samples of milk were spiked with trinexapac acid at levels of 0.005 and 0.05 mg/kg. Samples were extracted and analysed with Method REM 137.14 (HPLC-MS/MS). In all matrices tested, the mean recovery values were between 70% and 120% and the relative standard deviations (% RSD) for all commodities and all spiking levels for five tests at each spiking level were < 20%. Mean recovery data for the quantitation transition are given in Table 62.

Table 62 Recovery results of method REM 137.14: trinexapac acid in animal matrices

Matrix	Spiking level [mg/kg]	Recoveries for trinexapac acid			
		No.	Range [%]	Mean [%]	RSD [%]

Stability of pesticide residues in stored analytical samples

Plant Matrices

A freezer storage stability study was carried out on wheat grain, straw and rapeseed fortified with trinexapac acid at approximately 0.5 mg/kg and stored at $\leq -18^{\circ}\text{C}$ (Sack 1998, CGA163935/0562). Samples were analysed using Method REM 137.02 with minor modifications concerning final determination by HPLC. Concurrent recoveries were determined together with the analytical samples. The results are summarized below in Table 65 and indicate that trinexapac acid is stable in frozen storage for at least 24 months in wheat grain and rapeseed although in the case of wheat straw, the amount of trinexapac acid that could be recovered after storage for approximately 2 years dropped to an average of 69% (75% if corrected for average concurrent recovery).

^a Average fortification levels 0.55 mg/kg wheat grain and 0.45 mg/kg wheat straw and rapeseed

A freezer storage stability study was carried out on wheat processed fractions (germ, bran and flour) fortified with trinexapac acid at 0.1 mg/kg and stored at $-20 \pm 5^{\circ}\text{C}$ (Brown 2011, CGA179500_50012).

Samples were analysed using Method GRM020.01A with minor method modifications. Recoveries were run concurrently with the analytical samples. The results are summarized below in Table 66 and indicate that trinexapac acid is stable in frozen storage for at least 12 months in wheat processed fractions.

Table 66 Storage stability of trinexapac acid in plant matrices

In the [1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl grass metabolism study the storage stability was determined by comparison of the metabolite profiles of extracts of straw, seed screenings and 105 day regrowth forage at the beginning of the analytical phase and at the end of the study, approximately thirteen months later. The qualitative and quantitative metabolite profiles did not change throughout this period. It was concluded that the results of the study were not considered to be affected by the length and conditions of storage.

Animal Matrices

The stability of trinexapac acid in extracts of animal matrices was tested at the same time as the dairy cattle and laying hen feeding studies (Sack 2000, CGA179500/0030 and Simmons 2010, CGA179500_50008 respectively).

In the dairy cattle feeding study, no significant degradation of residues of trinexapac acid was observed in frozen samples of muscle (average recovery 82% corrected for concurrent recoveries), milk (89%), liver (85%), kidney (85%), fat (96%) and blood (102%) stored at $\leq -18^{\circ}\text{C}$ over the storage period from the arrival of specimens until analysis (83-121 days).

Table 67 Storage stability of trinexapac acid in dairy cattle matrices

Matrix	Spiking Level [mg/kg]	Days Stored	Concurrent Recoveries [%]	Recoveries [%]	
				Found ^a	Average ^a
Muscle	0.20	91	83, 81	86, 86, 77, 76, 87	82
Liver	0.20	94	85, 96	84, 83, 85, 87, 86	85
Kidney	0.20	95	89, 88	87, 86, 87, 81, 82	85

Milk	0.05	121	108, 109	89, 86, 90, 88, 93	89
Blood	0.10	83	99, 109	102, 99, 104, 104, 101	102

^a Recoveries found (and averages) are corrected for concurrent recoveries

In the laying hen feeding study, no significant degradation of residues of trinexapac acid was observed in frozen samples of eggs, chicken fat, chicken liver, chicken kidney and chicken muscle (average recoveries > 70%) stored at $\leq -18^{\circ}\text{C}$ over the storage period from the sample collection until analysis (31–82 days).

Table 68 Storage stability of trinexapac acid in poultry matrices

Matrix	Spiking Level [mg/kg]	Days Stored	Concurrent Recoveries [%]	Stability Recoveries [%]	
				Found	Average
Eggs	0.1	82	85, 84	73, 87	80
Fat	0.1	56	100, 104	93, 99	96
Liver	0.1	57	85, 85	83, 84	84
Kidney	0.1	54	94, 88	92, 97	95
Muscle	0.1	31	100, 101	97, 104	101

The stability of trinexapac acid in extracts of animal matrices was tested with the validation of Method REM 137.14 (Kwiatkowski 2004, CGA179500/0039). The stability of trinexapac acid in extracts of eggs (7 days storage), muscle (8 days storage), kidney (4 days storage), liver (5 days storage) and fat (3 days storage) was assessed by retaining water: methanol (80:20 v/v) containing 0.33% 1M sodium hydroxide and for milk (6 days storage) in water: methanol (98:2 v/v) containing 0.2% 1M sodium hydroxide extraction solutions at $< 7^{\circ}\text{C}$. Overall mean recoveries for trinexapac acid between 70–120% with an overall RSD of $\leq 20\%$ for each matrix tested, indicated that the compound is stable when stored in the extract solution for the period indicated.

The stability of trinexapac acid in the final solution of acetonitrile: water (30:70 v/v) for all matrices was also assessed. Milk, eggs, muscle, kidney, liver and fat aliquots in the final solution were retained, stored at $< 7^{\circ}\text{C}$ and re-analysed after 2 days (kidney and muscle), 3 days (eggs and fat), 4 days (liver) and 5 days (milk) following the original analysis and quantified against freshly calibrated solutions. The compound was shown to be stable when stored in the final solutions for those periods.

In the [1,2- ^{14}C -cyclohexyl] trinexapac-ethyl hen metabolism study the storage stability was determined by comparison of the quantitative metabolite pattern of hen excreta at the beginning of the storage period, with that obtained from the identical sample at the beginning of the analytical work approximately 2 weeks later. The extractability and quantitative metabolite patterns did not change throughout this period. It was concluded that the results of the study were not considered to be affected by the length and conditions of storage. In the hen metabolism study using [1, 2, 6- ^{14}C -cyclohexyl] trinexapac-ethyl, the extract of the egg white sample (taken as a representative of all the commodities) was analysed by TLC twice, approximately 6 months apart. The generated profiles were similar and therefore it was concluded that storage stability was confirmed.

In the [1,2- ^{14}C -cyclohexyl] trinexapac-ethyl goat metabolism study the storage stability was determined by comparison of the quantitative metabolite pattern of goat urine prior to storage and at the beginning of the experimental phase of the study, approximately nine months later. The quantitative metabolite patterns did not change throughout this period. It was concluded that the results of the study were not considered to be affected by the length and conditions of storage.

USE PATTERNS

Information on registered uses made available to this meeting is shown in Table 69.

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received information on supervised trials for the uses of trinexapac on cereals (barley and wheat), oilseeds (oilseed rape) and grasses for sugar and syrup production (sugarcane).

Trials were well documented with laboratory and field reports. The former included method validation including recoveries with spiking at residue levels similar to those occurring in samples from the supervised trials. Dates of analyses or duration of sample storage were also provided. Trials were carried out in appropriately sized plots and sample sizes were within acceptable weights. Applications were generally made using backpack sprayers although occasionally tractor mounted sprayers were used. Samples were collected and stored frozen immediately or soon after sampling. Although trials included control plots, no control data are recorded in the Tables because no residues in control samples exceeded the LOQ. Residues are unadjusted for recoveries.

Residues, application rates and spray concentrations have generally been rounded to two significant figures. Residues from the trials conducted according to maximum GAP have been used for the estimation of maximum residue levels and dietary intake assessment. If a higher residue level was observed at a longer PHI than the GAP, the higher value has been used in MRL setting and dietary intake assessment. When residues were not detected they are shown as below the LOQ (e.g. < 0.01 mg/kg) and the LOQ value was utilised for maximum residue level estimation and dietary intake assessment.

For replicate samples (from the same plot), the mean value was used for maximum residue level estimation and dietary intake assessment. For two or more analyses of the same sample, the mean value was used for maximum residue level estimation and dietary intake assessment, with the individual results given in brackets. For multiple trials on a crop from the same location, the result from the trial yielding the highest residue was utilised for maximum residue level estimation and dietary intake assessment. In this case the trials are separated by a dotted line.

In some studies (barley, wheat, sugarcane) residues have been determined as total trinexapac (includes free trinexapac acid and conjugates of trinexapac acid) while in other studies (wheat, sugarcane and rape seed) residues have been determined as trinexapac (free trinexapac acid only). In both cases trinexapac means trinexapac acid. Residues of trinexapac-ethyl were considered to be 0 mg/kg in rape seed. Residues according to maximum GAP have been underlined.

Group	Commodity	Country	Table No.

The results of these supervised trials are shown in the following tables:

Cereal Grains

Supervised trials were carried out on barley (12 trials—Table 70) in the USA during the 2008 and 2009 growing seasons (Mäyer 2010a, CGA163935_50026). A foliar application of a 250 g/L EC formulation was made at 127–134 g ai/ha at Feekes Growth Stage 7 (BBCH 32) or at 45 days before harvest, or (for generating processing samples) at 129 and 644 or 648 g ai/ha at 45 days before harvest. Applications were made to plots using spray volumes of 68–288 L/ha with ground equipment, except for one trial which simulated aerial application (Trial C08WI081703). Additional samples were collected at one site (Trial C30IA081702—Bagley, Iowa) to examine the residue decline. Residues of total trinexapac were quantitated as trinexapac acid by LC/MS/MS method GRM020.01A. Acceptable concurrent recovery data were obtained.

Residues in barley hay and straw are shown in Table 76. Processed fraction samples for analysis were generated from trials C13ND081704 and C13ND081705 (Table 82).

Supervised trials were carried out on wheat in the USA during the 2008 growing seasons (Mäyer 2010, CGA163935_50036) and the 2004 and 2005 growing seasons (Ediger 2006, 451534). The Mäyer study quantified total trinexapac residues.

Wheat (Total residues of trinexapac acid)

Supervised trials were carried out on wheat (20 trials—Table 71) in the USA during the 2008 growing season (Mäyer 2010, CGA163935_50026). A foliar application of a 250 g/L EC formulation was made at 127–134 g ai/ha at approximately Feekes Growth Stage 7 or at 45 days before harvest, or (for generating processing samples) at 129 or 130 and 646 or 649 g ai/ha at 45 days before harvest. Applications were made to plots using spray volumes of 97–252 L/ha with ground equipment, except for two trials which simulated aerial application (Trials C19KS078462 and C16SD078471). At three sites additional samples were collected to examine the residue decline. Residues of total trinexapac were quantitated as trinexapac acid by LC/MS/MS method GRM020.01A. Acceptable concurrent recovery data were obtained.

Residues in wheat forage are shown in Table 77 and in hay and straw in Table 78. Processed fraction samples for analysis were generated from trials C13ND078468 and W01TX078473 (Table 83).

Wheat (Free trinexapac acid)

Supervised trials were carried out on wheat (20 trials—Table 72) in the USA during the 2004 and 2005 growing seasons (Ediger 2006, 451534). A foliar application of a 250 g/L EC formulation was made at 123–130 g ai/ha (and at 384 or 391 and 643 g ai/ha at two sites) at approximately Feekes Growth Stage 7 or at 45 days before harvest, or (for generating processing samples) at 127 or 130 and 643 g ai/ha at 45 days before harvest. Applications were made to plots using spray volumes of 92–187 L/ha with ground equipment, except for three trials which simulated aerial application (Trials 4A-FR-04-5421, NN-FR-04-5424 and NM-FR-04-5429). At three sites additional samples were collected to examine the residue decline. Residues of trinexapac were quantitated as trinexapac acid using method 110-01. Acceptable concurrent recovery data were obtained.

Residues in wheat forage are shown in Table 79 and in hay and straw in Table 80. Processed fraction samples for analysis were generated from trials NN-FR-04-5418 and SC-FR-04-5430 (Table 84).

Feekes 10.5 = Head emergence complete

Grasses for sugar or syrup production

Supervised trials were carried out on sugarcane in the USA during the 2008 and 2004 growing seasons (Mäyer 2010b, CGA163935_50038 and Ediger 2006a, 451598 respectively). The Mäyer study quantified total trinexapac residues.

Sugarcane (Total residues of trinexapac acid)

Supervised trials were carried out on sugarcane (eight trials—Table 73) in the USA during the 2008 growing season (Mäyer 2010b, CGA163935_50038). A foliar application of a 250 g/L EC formulation was made at 350–382 g ai/ha at 28 days before harvest, or (for generating processing samples) at 361 or 382 and 1779 or 1856 g ai/ha at 28 days before harvest. Applications were made to plots using spray volumes of 94–982 L/ha with ground equipment, except for one trial which simulated aerial application (Trial E19H1078497). At two sites (E19FL078491 and E18LA078494) additional samples were collected to examine the residue decline. Residues of total trinexapac were quantitated as trinexapac acid by LC/MS/MS method GRM020.01A. Acceptable concurrent recovery data were obtained.

Processed fraction samples for analysis were generated from trials E19FL078492 and E18LA078495 (Table 85).

Sugarcane (Free trinexapac acid)

Supervised trials were carried out on sugarcane (eight trials—Table 74) in the USA during the 2004 growing season (Ediger 2006a, 451598). A foliar application of a 250 g/L EC formulation was made at 345–365 g ai/ha (and at 1764 g ai/ha at one site) at 28 days before harvest of mature cane, or (for generating processing samples) at 345 and 1739 g ai/ha at 28 days before harvest of mature cane. Applications were made to plots using spray volumes of 102–948 L/ha with ground equipment, except

for one trial which simulated aerial application (Trial SD-FR-04-5505). At two sites additional samples were collected to examine the residue decline. Residues of trinexapac were quantitated as trinexapac acid using method 110-01. Acceptable concurrent recovery data were obtained.

Processed fraction samples for analysis were generated from trial VN-FR-04-5501 (Table 86).

FATE OF RESIDUES IN STORAGE AND PROCESSING

Residues after processing

Processing studies are necessary according to the uses and the residues of trinexapac-ethyl on raw agricultural commodities. The fate of trinexapac-ethyl residues during processing of raw agricultural commodities was investigated in a number of major registered crops (barley, wheat, sugarcane and oilseed rape).

The high temperature hydrolysis of residues of trinexapac-ethyl and trinexapac acid under varying conditions were studied (CadAlbert and Buckel 2001, CGA163935/0733 and Mound and Clark 2004, CGA179500/0036 respectively). The labelled compounds used are depicted below.

[1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl

¹⁴C-cyclohexyl labelled trinexapac-acid

Trinexapac-ethyl

[1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl was added to aqueous buffer solutions and subjected to hydrolysis at pH 4, 5 and 6 at high temperature at concentrations of 5 mg/L (0.01 M citrate, acetate and phosphate buffers respectively). The conditions were selected to simulate hydrolysis under processing conditions and included:

- The effect of pasteurisation (pH 4 and pasteurised at 90 °C for 20 minutes)
- The effect of baking, boiling and brewing (pH 5 and baked at 100 °C for 60 minutes)
- The effect of sterilisation (pH 6 and autoclaving at 120 °C for 20 minutes).

The pH ranged from 4.22 (beginning of the trial), 4.30 (end of the trial) for the pH 4 samples, 5.04 (beginning of the trial), 5.07 (end of the trial) for the pH 5 samples and from 6.15 (beginning of the trial), 6.25 (end of the trial) for the pH 6 samples. No major loss of radioactivity material occurred. For all three processing conditions, 99% (mean) of the applied radioactivity remained after the test. Subsamples of the test solutions were analysed by HPLC and TLC. The amount of radioactive material in the samples at the end of the test mainly corresponded to parent compound (93–94% of the applied radioactivity in all samples). Minor compounds were present up to 3.3% of the applied radioactivity, however as they were present at the start of the incubation, these were considered to be impurities.

In summary, the data show that trinexapac-ethyl was not degraded during the simulation of pasteurisation (pH 4, 90 °C, 20 minutes), baking, boiling and brewing (pH 5, 100 °C, 60 minutes) and sterilisation (pH 6, 120 °C, 20 minutes).

Trinexapac acid

¹⁴C-cyclohexyl labelled trinexapac acid was added to aqueous acetate buffer solutions and subjected to hydrolysis at pH 4, 5 and 6 at high temperature, at concentrations ranging from 4.30–4.87 mg/L.

The conditions were the same as described above except the pH 4 experiment, simulating the effects of pasteurisation, was run for 25 minutes.

The pH of the buffer solutions prior to the experiment were 4.01, 5.06 and 6.08. No major loss of radioactivity material occurred. For the pH 4 at 90 °C experiment, 104% (mean) of the applied radioactivity remained after the test while for the other two processing conditions, 102% (mean) of the applied radioactivity remained after the test.

The major component of the radioactive material in the samples at the end of the hydrolysis reactions corresponded to unchanged trinexapac acid; at pH 4 and 90 °C the mean value was 52.5%, at pH 5 and 100 °C the mean value was 58.5% and at pH 6 and 120 °C the mean value was 50.9%. The hydrolysis products were similar at each pH. At least two major and several minor degradates were observed. The two major components were identified as CGA313458 (at pH 4 and 90 °C the mean value was 19.7%, at pH 5 and 100 °C the mean value was 16.1% and at pH 6 and 120 °C the mean value was 21.0%) and CGA113745 (at pH 4 and 90 °C the mean value was 9.6%, at pH 5 and 100 °C the mean value was 10.5% and at pH 6 and 120 °C the mean value was 11.6%). The other degradates, comprising more than one component, represented < 11.6% in any of the hydrolysates with no individual unknown being more than 5%. Characterisation was by TLC co-chromatography and where possible by HPLC confirmation. Identification of CGA313458 was confirmed by NMR.

The proposed hydrolysis of trinexapac acid under processing conditions is as follows:

Figure 3 Hydrolysis of trinexapac acid under processing conditions

In summary, the data show that trinexapac acid undergoes limited degradation during the simulation of pasteurisation (pH 4, 90 °C, 25 minutes), during the simulation of baking, boiling and brewing (pH 5, 100 °C, 60 minutes) and during sterilisation (pH 6, 120 °C, 20 minutes).

Barley

The effect of processing (laboratory scale) on residues of trinexapac-ethyl in barley was investigated in two trials conducted in the USA in the 2008 growing season (Mayer 2010a, CGA163935_50026). Barley with incurred residues was obtained where plants were sprayed with a foliar spray at 0.129 and 648 k g ai/ha at BBCH 51 and at 0.129 and 0.644 k g ai/ha at BBCH 73. Applications were made in 141–188 L/ha using ground equipment. Barley bulk RAC samples were harvested 45 days after application.

Bulk barley grain samples were processed into processed barley commodity samples according to simulated commercial procedures into the following samples: pearled barley, flour and bran.

Barley was removed from storage and a representative RAC sample taken. Barley was oven-dried at 54–71 °C to a moisture content of 11–13.5%, then samples were cleaned by aspiration and screening. Light impurities were separated from the whole barley by aspiration. Large and small foreign particles were then separated from the barley. The cleaned barley was hulled, resulting in the fractions blocked (pearled) barley and husk. A sub-fraction of the pearled barley was then fed through a mill to break the grains. The broken grain was fed onto the sifter screens (0.14 and 0.80 mm) to obtain coarse bran, break flour and middlings. Coarse bran was sifted further to produce bran and shorts. Middlings were separated in a reduction mill to reduction flour and shorts. Break flour was combined with the reduction flour to produce barley flour. Shorts obtained after shifting bran and middlings were also combined.

Residues of total trinexapac in barley RAC and processed commodities were quantitated as trinexapac acid by LC/MS/MS using Method GRM 020.01A. Acceptable concurrent recovery data were obtained for all barley commodities.

Wheat

The effect of processing (laboratory scale) on residues of trinexapac-ethyl in wheat was investigated in two trials conducted in the USA in the 2008 growing season (Mäyer 2010, CGA163935_50036). Wheat with incurred residues was obtained where plants were sprayed with a foliar spray at 0.129 and 646 kg ai/ha at BBCH 65 (durum wheat) and at 0.130 and 0.649 kg ai/ha at BBCH 52 (winter wheat). Applications were made in 188–252 L/ha using ground equipment. Wheat bulk RAC samples were harvested 45 days after application.

Bulk wheat grain samples were processed according to simulated commercial procedures into the following samples: aspirated grain fractions, bran, flour, middlings, shorts and germ.

Drying and aspiration was used to generate aspirated grain fractions. Light impurities were separated by aspiration and screened, removing foreign particles (screenings) from the wheat. For wheat germ recovery, the cleaned wheat was moisture adjusted to 16%, passed through a disc mill, and sieved to remove bran from the germ fraction. The germ (with endosperm) was then sifted to separate the germ from the endosperm and was aspirated again.

The moisture content of the cleaned wheat grain was adjusted to 17.5%. The sample was fed through a mill to break the grains. The broken grain was fed onto the sifter screens (0.14 and 0.80 mm) to obtain coarse bran, break flour and middlings. Coarse bran was sifted further to produce bran and shorts. Middlings were separated in a reduction mill to reduction flour and shorts. Break flour was combined with the reduction flour to produce wheat flour. Shorts obtained after shifting bran and middlings were also combined.

Residues of total trinexapac in wheat RAC and processed commodities were quantitated as trinexapac acid by LC/MS/MS using Method GRM 020.01A. Acceptable concurrent recovery data were obtained for all wheat commodities.

^a Outlier, not used in calculations

In another study the effect of processing (laboratory scale) on residues of trinexapac-ethyl in wheat was investigated in two trials conducted in the USA in the 2004 or 2005 growing seasons (Ediger 2006, 451534). Wheat with incurred residues was obtained where plants were sprayed with a foliar spray at 0.127 and 0.643 k g ai/ha at BBCH 61 or 0.130 and 0.643 k g ai/ha at BBCH 45. Applications were made in 92–144 L/ha using ground equipment.

Bulk wheat grain samples were processed according to simulated commercial procedures into the following samples: aspirated grain fractions, bran, flour, middlings, shorts and germ (as described for Mäyer 2010, CGA163935_50036).

Residues of trinexapac in wheat RAC and processed commodities were quantitated as trinexapac acid using Method 110.01. Acceptable concurrent recovery data were obtained for all wheat commodities.

Sugarcane

The effect of processing (laboratory scale) on residues of trinexapac-ethyl in sugarcane was investigated in two trials conducted in the USA in the 2008 growing season (Mäyer 2010b, CGA163935_50038). Sugarcane with incurred residues was obtained where plants were sprayed with one foliar spray at 0.382 and 1.856 kg ai/ha at BBCH 91 and 0.361 and 1.779 k ai/ha at BBCH 70.

Application was made 28 days prior to the harvest of the mature cane. Applications were made in 102–223 L water /ha.

Bulk sugarcane samples were processed according to simulated commercial procedures into blackstrap molasses and refined sugar.

The sugarcane was cleaned by spraying the cane. Juice was pressed out using a cane crusher repeatedly until the majority of the juice was yielded. Juice of the first pressing was screened (sieve) to remove large particles prior to pH adjustment to 7.2–7.6 with a 20% w/w calcium-oxide solution. After pH adjustment, the juice was boiled (97–100 °C) for 3 minutes. The heated juice was then immediately centrifuged to separate mud and thin juice. Thin juice was evaporated under vacuum (rotary evaporator) until the juice contained 50–60% solids (thick juice) with the temperature maintained below 70 °C. After evaporation the thick juice was filtered using cotton. During laboratory evaporation a known amount of thick juice was evaporated to 70–80% solids and a small amount of sugar was added to “seed” crystallisation of sugar granules. The remaining thick juice was slowly added and continuously evaporated, and the solution was allowed to cool. Crystallised raw sugar and molasses were separated by centrifugation. Final black strap molasses was 60–65% solids. After molasses was removed, the remaining sugar was refined.

Equal parts of raw sugar and water were combined and mixed to dissolve the sugar. The pH of the mixture was adjusted to 5.2–5.8. After resting, mixing was resumed and the pH adjusted to 7.0–7.4. After heating to approximately 59–61 °C, filter aid was added and the solution was vacuum filtered. Upon obtaining a non-cloudy filtrate, the solution was evaporated and crystallised. Refined sugar was dried at 38–54 °C until the moisture content was approximately 3.0%.

Residues of total trinexapac in sugarcane RAC and processed commodities were quantitated as trinexapac acid by LC/MS/MS using Method GRM 020.01A. Acceptable concurrent recovery data were obtained for all sugarcane commodities.

In another study the effect of processing (laboratory scale) on residues of trinexapac-ethyl in sugarcane was investigated in one trial conducted in the USA in the 2004 growing season (Ediger 2006a, 451598). Sugarcane with incurred residues was obtained where plants were sprayed with a foliar spray at 0.345 or 1739 kg ai/ha at 28 days prior to harvest of the mature cane. Applications were made in 276–278 L/ha using ground equipment.

Bulk sugarcane samples were processed according to simulated commercial procedures into molasses and refined sugar (as described for Mäyer 2010b, CGA163935_50038, with very minor modifications).

Residues of trinexapac in sugarcane RAC and processed commodities were quantitated as trinexapac acid using Method 110.01. Acceptable concurrent recovery data were obtained for all sugarcane commodities.

Rape seed

The effect of processing (laboratory scale) on residues of trinexapac-ethyl in rape seed was investigated in two trials carried out in Germany during the 1994 growing season (Sack 1995a, CGA163935/0416 and Sack 1995, CGA163935/0417). Rapeseed with incurred residues were obtained where plants were sprayed a foliar spray at 0.375 kg ai/ha. Application was made 84–85 days prior to the harvest of the mature rape seeds. Applications were made in 300 L water /ha.

Bulk rape seed samples were processed into processed rape seed commodity samples (crude oil, press cake and refined oil) according to simulated commercial procedures.

The harvested rape seed samples were processed into crude oil and press cake by cold pressing or hot extraction simulating industrial practice as closely as possible. Crude oil was processed further into refined oil.

Residues of trinexapac acid in rapeseed RAC and press cake were quantitated by LC/MS/MS using modified Method REM 137.02, while Method REM 137.11 was used for the quantification of

trinexapac acid residues in crude and refined oil. Acceptable concurrent recovery data for rape seed commodities were obtained for each analyte.

RESIDUES IN ANIMAL COMMODITIES

Dairy cattle transfer study (Sack 2000, CGA179500/0030)

A feeding study with trinexapac acid was conducted in lactating cows (ten *Bos taurus Holstein* dairy cattle ranging from 2–6 years of age divided into three dose groups of three cows with one control animal, 514–720 kg during dosing).

The animals received nominal doses of trinexapac acid equivalent to 0, 2 (40 mg trinexapac acid, 1×), 6 (120 mg trinexapac acid, 3×) and 20 ppm in the feed (400 mg trinexapac acid, 10×) respectively (actual doses 40.4, 121.2 and 404.0 mg respectively). The doses were administered orally *via* gelatine capsules, for a period of 29–30 consecutive days.

Milk samples from each animal were collected twice daily, at approximately 6 am and pm, and combined as one pooled sample. Milk specimens were collected on day 0 (pre-dose) and days 1, 2, 3, 5, 8, 12, 15, 19, 22 and 28 of the feeding period. The cows were sacrificed within 20–24 hours after the final dosing (one cow from each treatment group on day 29 and two cows from each group, except the control group, on day 30). Besides blood, the following tissues were collected; liver, kidney, round muscle, tenderloin muscle, diaphragm, perirenal and omental fat.

Milk, tissues and blood samples were analysed for residues of trinexapac acid using Method REM 137.12.

The residues of trinexapac acid found in milk during the treatment periods are summarized in Table 89.

Table 89 Residues of trinexapac acid in milk

< 0.005 denotes less than the LOQ

^a Average of three analyses (0.010, 0.011, 0.011 mg/kg)

^b Average of two analyses (0.0061 and 0.005 mg/kg)

No quantifiable residues of trinexapac acid were found in the milk of the 0, 2 and 6 ppm dose groups. Residues in the 20 ppm dose group ranged from < 0.005–0.011 mg/kg. Residues reached a plateau after one day.

Results of the tissue and blood analysis are summarized in Table 90.

Table 90 Residues of trinexapac acid in tissues

Treatment Group	Group mean (and maximum individual) residues in tissue for trinexapac acid (mg/kg)							
	Muscle Tenderloin	Muscle Round	Diaphragm	Liver	Kidney	Perirenal Fat	Omental Fat	Blood
0 ppm	< 0.02	< 0.02	< 0.02	< 0.02	< 0.02	< 0.02	< 0.02	< 0.010
2 ppm	< 0.02 (< 0.02)	< 0.02 (< 0.02)	< 0.02 (< 0.02)	< 0.02 (< 0.02)	0.03 (0.03)	< 0.02 (< 0.02)	< 0.02 (< 0.02)	0.018 (0.023)
6 ppm	< 0.02 (< 0.02)	< 0.02 (< 0.02)	< 0.02 (< 0.02)	< 0.02 (< 0.02)	0.04 (0.05)	< 0.02 (< 0.02)	< 0.02 (< 0.02)	0.031 (0.036)
20 ppm	< 0.02 (< 0.02)	< 0.02 (< 0.02)	< 0.02 (0.02)	0.03 (0.03)	0.17 (0.29)	< 0.02 (0.02)	< 0.02 (0.02)	0.13 (0.17)

< 0.02 denotes less than the LOQ

No quantifiable residues of trinexapac acid were found in the tissues of the control cow. In the lowest and mid-range dose groups (2 and 6 ppm), no quantifiable residues were detected in muscle, liver and fat, although residues slightly above LOQ were observed in kidney (means 0.03 and 0.04 mg/kg respectively).

In the highest dose group (20 ppm), quantifiable residues were detected in one diaphragm sample (0.02 mg/kg), two liver samples (both 0.03 mg/kg) and one perirenal fat sample (0.02 mg/kg). Quantifiable residues were observed in all kidney samples (mean 0.17 mg/kg).

Quantifiable residues were observed in all blood samples from all dose groups (means 0.018, 0.031 and 0.13 mg/kg respectively).

Laying hen transfer study (Simmons 2010, CGA179500_50008)

A feeding study with trinexapac acid was conducted in laying hens (forty *Hyline Browns*, approximately 37 weeks old upon arrival, divided into 3 dose groups and a control group each of ten hens, 1.80–1.92 kg from 7 days before dosing until the end of dosing). The target doses of trinexapac acid were equivalent to 3.3, 9.9 and 33.0 ppm in the feed. Mean doses in the feed were determined to be 3.7, 10 and 37 ppm.

The doses were administered orally *via* gelatine capsules, for a period of 28 days. Ten animals were allocated per dose group divided into three subgroups of 3–4 birds. Eggs from each hen were collected on day 0 (pre-dose) and days 1, 3, 7, 10, 14, 17, 21, 24 and 28 of the feeding period. Egg production by group was at or above 89% with two exceptions (the control group on week 4 at 74% and the high dose group on week 4 at 75%). The animals were sacrificed within 6 hours after the last administration of the treated feed. Tissues collected were skin plus attached fat and peritoneal fat, liver, kidney and breast and thigh muscle.

Liver, kidney, breast and thigh muscle, skin with attached fat and peritoneal fat and eggs were analysed for residues of trinexapac acid using Method REM 137.14 with some modifications.

Residues of trinexapac acid found in eggs during the treatment period are summarized in Table 91. Residues in control samples were all < LOQ (< 0.01 mg/kg).

Table 91 Residues of trinexapac acid in eggs

Study day	Group mean (and maximum individual) residues of trinexapac acid (mg/kg)			
	0 ppm	3.7 ppm	10 ppm	37 ppm
0	< 0.01	NA	< 0.01 (< 0.01)	< 0.01 (< 0.01)

28	–	NA	< 0.01 (< 0.01)	0.013 (0.013)

< 0.01 denotes less than the LOQ

NA = Samples were not analysed, because residues of higher dose groups are < LOQ

No quantifiable residues were detected in any dose group apart from in the 37 ppm dose group at day 28 (mean residues in groups A (three hens), B (three hens) and C (four hens) were all 0.013 mg/kg).

Residues of trinexapac acid in tissues are summarized below in Table 92. Residues in control samples were all < LOQ.

Table 92 Residues of trinexapac acid in tissues

Treatment Group	Group mean (and maximum individual) residues in tissue for trinexapac acid (mg/kg)			
	Fat	Liver	Kidney	Muscle
0 ppm	< 0.01 (< 0.01)	< 0.01 (< 0.01)	< 0.01 (< 0.01)	< 0.01 (< 0.01)
3.7 ppm	NA	NA	0.06 (0.08)	NA
10 ppm	< 0.01 (< 0.01)	< 0.01 (< 0.01)	0.04 (0.05)	NA
37 ppm	0.03 (0.03)	0.02 (0.02)	0.45 (0.54)	< 0.01 (< 0.01)

< 0.01 denotes less than the LOQ

NA = Samples were not analysed, because residues of higher dose groups are < LOQ

No residues of trinexapac acid above LOQ (0.01 mg/kg) were detected in any muscle (breast and thigh muscle) sample from any treatment group. No residues of trinexapac acid above LOQ (0.01 mg/kg) were detected in any liver sample from any treatment group apart from the highest dose group (mean 0.02 mg/kg). No residues of trinexapac acid above LOQ (0.01 mg/kg) were detected in any fat sample from any treatment group apart from the highest dose group (mean 0.03 mg/kg). Mean residues of trinexapac acid in kidney were 0.06, 0.04 and 0.45 mg/kg in the lowest to highest dose groups respectively.

APPRAISAL

At the Forty-fourth Session of the CCPR (2012), trinexapac-ethyl was scheduled for evaluation as a new compound by 2013 JMPR.

Trinexapac-ethyl is a synthetic plant growth regulator that is derived from cyclohexanecarboxylate. It is applied as a foliar spray, post-emergence and is approved for use on cereal crops such as barley, durum wheat, oats, rye, triticale and wheat, oilseed rape and sugarcane as well as on grassland pastures.

The manufacturer supplied information on identity, metabolism, methods of residue analysis, freezer storage stability, registered use patterns, supervised residue trials, fates of residues in processing and farm animal feeding studies.

The IUPAC name is 4-(cyclopropyl-hydroxy-methylene)-3,5-dioxo-cyclohexanecarboxylic acid ethyl ester.

Trinexapac-ethyl

The 2013 JMPR established an ADI for trinexapac-ethyl of 0–0.3 mg/kg bw trinexapac acid equivalents.

The structures of the key metabolites discussed are shown below:

CGA 179500
Trinexapac acid

CGA 275537
Tricarballic acid

CGA 312753
Trans aconitic acid

CGA 329773

CGA 351210

CGA 312753 mono-ethyl ester

Terephthalic acid

CGA113745

Animal metabolism

The Meeting received animal metabolism studies with trinexapac-ethyl in rats, hens and goats.

Rats

Evaluation of the metabolism studies in rats was carried out by the WHO Core Assessment Group.

Trinexapac-ethyl undergoes limited metabolism in the rat, involving predominantly ester hydrolysis of trinexapac-ethyl to trinexapac acid. The predominant urinary metabolite was trinexapac acid (up to 100% of total urinary radioactivity), with low levels of a conjugated derivative of trinexapac acid detected only in the urine of bile-duct cannulated rats (6.3% of the administered dose). In faeces, the parent compound accounted for 5–22% of total faecal radioactivity (1–2.5% of the administered dose), with the balance comprising trinexapac acid. Bile contained mainly a conjugated derivative of trinexapac acid (2.9% of the administered dose), with low levels of the parent compound also detected (0.2% of the administered dose).

Goats

[1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl was orally administered via capsule to lactating goats at 7.2 ppm or 694 ppm in the feed (or 0.20 or 19.9 mg/kg bw/day respectively) for 4 consecutive days. Milk was sampled twice daily, in the morning and afternoon. Animals were sacrificed approximately 4 hours after the last dose.

The low dose goat eliminated 16% and 50% via faeces and urine of the total administered dose respectively at 76 hours in the study, while the corresponding values of the high dosed goat were 19% and 62%. In milk, 0.02% of the administered dose was recovered at both dose levels. A plateau was reached after 2 days (low dose-0.002 mg/kg equiv (am) and 0.007 mg/kg equiv. (pm)) or 3 days (high dose-0.22 mg/kg equiv (am) and 0.83 mg/kg equiv. (pm)) after administration.

The tissue residues of the low dosed goat were 0.035–0.043 mg/kg equiv. in muscles, 0.017–0.094 mg/kg equiv. in fat, 0.25 mg/kg equiv. in liver and 0.50 mg/kg equiv. in kidney. In the high dosed goat the residues were correspondingly higher, i.e., 1.90–2.49 mg/kg equiv. in muscles, 1.20–1.55 mg/kg equiv. in fat, 12.1 mg/kg equiv. in liver and 41.9 mg/kg equiv. in kidney.

Residues in muscle and kidney were mostly trinexapac acid (81–90% TRR). In milk, trinexapac acid accounted for 46–76% TRR. In liver and fat trinexapac acid was 31–67% TRR, although for fat this represented 87–96% of the extracted radioactivity. For liver this represented only 34–47% of the extracted radioactivity.

In another study [1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl was orally administered by gelatine capsule to two lactating goats at 100 ppm in the feed (or 3.1 mg/kg bw/day) for 4 consecutive days. Milk was sampled twice daily. Animals were sacrificed approximately 6 hours after the last dose.

The goats had eliminated 3% and 81% via faeces and urine of the total administered dose respectively at 78 hours in the study while 0.05% of the administered dose was recovered in milk. Residues in the Day 2 pm sample of milk were 0.076 mg/kg equiv.

The tissue residues were 0.28 mg/kg equiv. in muscles, 0.11 mg/kg equiv. in fat, 0.80 mg/kg equiv. in liver and 5.90 mg/kg equiv. in kidney.

No parent was observed in tissues or milk. Residues in liver, kidney, muscle and fat were mostly trinexapac acid (CGA179500) (66–97% TRR). In milk, trinexapac acid accounted for 85% TRR. In liver, kidney and fat the metabolite CGA113745 accounted for 6–16% TRR. This metabolite was not detected in either muscle or milk.

Hens

[1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl was orally administered daily to laying hens using gelatine capsules at a low dose level (2 hens, 0.4 mg/kg body weight equivalent to 3.8 ppm in feed) or a high dose level (4 hens, 20.3 mg/kg body weight equivalent to 180 ppm in feed) for 4 consecutive days. Eggs were collected throughout the day and in the morning before subsequent administration. Animals were sacrificed approximately 4 hours after the last dose.

Over the period of the experiment (76 hours), 85–89% (high and low doses respectively) of the total administered dose was eliminated in excreta. Transfer of radioactivity into eggs accounted for only 0.01% and 0.02% of the total administered dose for the low and high dosed hens, respectively. A plateau was reached at Day 2 of the dosing period. Concentrations of radioactivity in egg yolk were generally less than in egg whites. Concentrations of radioactivity in egg white and egg yolk in the low-dosed hens did not exceed 0.007 and 0.002 mg/kg equiv., respectively. In the high dosed hens the corresponding values were 0.33 and 0.055 mg/kg equiv.

Mean radioactive residues in tissues of the low-dosed hens were 0.002 mg/kg equiv. in lean meat (0.12 mg/kg equiv. high dose), 0.011 mg/kg equiv. in skin (including attached fat) (0.37 mg/kg equiv.), 0.003 mg/kg equiv. in peritoneal fat (0.18 mg/kg equiv.), 0.013 mg/kg equiv. in liver (0.60 mg/kg equiv.) and 0.043 mg/kg equiv. in kidney (1.77 mg/kg equiv.).

Radioactive residues in muscle (lean meat), liver, kidney and fat samples of low and high-dosed hens were predominantly trinexapac acid (44–84% TRR). In skin including attached fat in which the extractability was low, trinexapac acid was again the major metabolite accounting for 64–80% of the extracted radioactivity.

In the yolk the major metabolite was trinexapac acid accounting for 57–76% of the extracted radioactivity (0.0003–0.011 mg/kg equiv.), while parent trinexapac-ethyl was present at only 10–25% (< 0.0001–0.005 mg/kg equiv.). In egg white the major residue was parent accounting for 64–78% of the extractable TRR (0.0017–0.124 mg/kg equiv.). Trinexapac acid was either not detected (high dose) or accounted for only 13% (0.0003 mg/kg equiv.) of the extractable TRR (low dose).

In another hen metabolism study [1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl was orally administered daily to 5 laying hens by gelatine capsule at 8.1–10.4 ppm in feed for 10 consecutive days. Eggs were collected at 24 hour intervals throughout the morning before subsequent administration. Animals were sacrificed approximately 22 hours after the last dose.

Of the administered dose 89% was recovered in the excreta. Residue levels in the various tissue samples were all < 0.01 mg/kg equiv. Residue levels in egg yolk were very low, ranging from < 0.003–0.009 mg/kg equiv. Egg white residues ranged from 0.005–0.031 mg/kg equiv. The maximum residue levels of 0.009 and 0.031 mg/kg equiv. were reached by Day 8 of the dosing period. Overall retention of the radioactivity in eggs was < 0.1% of the administered dose.

TRR values for edible tissues and egg yolks were below 0.01 mg/kg equiv., so no further analysis was undertaken. The major metabolites identified in the organosoluble residue of the composite egg white sample were parent trinexapac-ethyl and trinexapac acid which accounted for 31% TRR and 20% TRR respectively.

Summary of animal metabolism

The metabolic pathways of trinexapac-ethyl observed in rats, goats and poultry are similar. Animal metabolism studies showed that parent was rapidly absorbed and almost completely hydrolysed to

trinexapac acid before excretion. No accumulation of residues was observed in any organ, tissue or animal commodity.

Plant metabolism

Paddy rice, spring wheat, spring rape and grass (foliar treatment) metabolism studies were carried out with [1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl or [1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl.

[1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl was applied by foliar methods to rice at rates of 40 and 160 g ai/ha. TRRs in samples taken at maturity (60 days after treatment at 160 g ai/ha) were 1.58 mg/kg equiv. for straw, 2.22 mg/kg equiv. for husks and 1.07 mg/kg equiv. for grain. Trinexapac acid was the only identified compound present in rice grain at greater than 10% TRR (36% TRR) and was the major identified component of rice husks (30% TRR). It was present in rice straw at 9% TRR. Tricarballic acid (CGA 275537) was present at 14% TRR in straw. Some parent compound was observed in grain, husks and straw (all < 10% TRR). Metabolite CGA 329773 was a minor metabolite in grain, husks and straw (< 3% TRR).

[1, 2-¹⁴C-cyclohexyl] trinexapac-ethyl was applied to spring wheat by foliar spraying at a rate of 150 g ai/ha. Trinexapac acid was the only identified component in wheat grain (24% TRR) and was the only identified component of both wheat husks and wheat straw observed at > 10% of the TRR (15 and 21% TRR respectively).

A stem-injection experiment was conducted on six week old wheat plants grown under greenhouse conditions. Trinexapac acid was the major identified component of wheat grain (27.9% TRR, 0.129 mg/kg equiv.) and was the only identified component of both wheat husks and wheat straw observed at > 10% of the TRR (17% (0.073 mg/kg equiv.) and 13% TRR (0.069 mg/kg equiv.) respectively). Metabolites CGA329773 and CGA275537 were present in grain at 11% (0.050 mg/kg equiv.) and 3% TRR (0.014 mg/kg equiv.) respectively and in straw at 3 and 2% TRR respectively.

[1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl was applied to spring rape under greenhouse conditions in plastic containers filled with soil. Trinexapac acid (free and conjugated) was the major metabolite observed in rape meal (31% TRR, 0.647 mg/kg equiv.), rape whole seeds (30% TRR, 0.431 mg/kg equiv.), pods (19% TRR, 1.06 mg/kg equiv.) and stalks (10% TRR, 0.304 mg/kg equiv.) and was also observed in oil (4% TRR, 0.004 mg/kg equiv.). Metabolite CGA 351210 was observed in oil at 16% TRR but at only 0.02 mg/kg equiv. This metabolite, only observed in rape, accounted for 16–28% TRR in pods and stalks (0.918 mg/kg equiv. and 0.869 mg/kg equiv. respectively).

[1, 2, 6-¹⁴C-cyclohexyl] trinexapac-ethyl was applied by foliar methods to tall fescue grass at 560 g ai/ha. TRRs of 5.45 mg/kg equiv., 7.13 mg/kg equiv. and 4.78 mg/kg equiv. were observed for seeds, seed screenings and for straw respectively. TRRs of 2.03 mg/kg equiv. and 0.054 mg/kg equiv. were observed for 22 day forage and 105 day forage respectively. In grass, trinexapac acid was the major identified component of 22 day forage (16% TRR), straw (22% TRR) and regrowth forage (10% TRR) and was also a major component of seeds (15% TRR) and seed screenings (13% TRR). Also observed in all matrices were CGA 275537 (9-17% TRR) and terephthalic acid (7–12% TRR) the latter metabolite only observed in grass.

Summary of plant metabolism

Parent compound was completely degraded and was not detectable (< 0.001/< 0.002 mg/kg) in any plant part of wheat, rapeseed and grass at harvest time. In rice only traces (0.001 and 0.003 mg/kg) were observed in straw and husks respectively.

Trinexapac acid was therefore the major metabolite which was present in all species and all plant parts at harvest. Sugar conjugates of trinexapac acid were hydrolysed in some crop parts to yield free acid which, in some cases, significantly increased the levels of trinexapac acid recovered. Trinexapac acid sugar conjugates accounted for an increase in trinexapac acid of 11.6% TRR in rice grain and 10% and 14% TRR in grass forage and straw, respectively.

Rotational Crops

Studies of residues in confined rotational crops have been submitted in which soil was treated at 350 g ai/ha, followed by soil aging at 30, 120 and 270 days. Representative succeeding crops of lettuce (leafy vegetable), radish (root vegetable) and wheat (cereal grain) were planted at the above intervals to determine whether trinexapac-ethyl residues or degradates appear in follow crops.

The uptake of residues by the rotational crops lettuce, radish and wheat planted or sown after several intervals after application of trinexapac-ethyl to bare ground was very low. No accumulation was observed. Residues of trinexapac-ethyl in the rotational crop RACs were below the LOQ (< 0.001 mg/kg). The residues of trinexapac acid and CGA 312753 (trans aconitic acid) were very close to or below the LOQ (< 0.001 – 0.002 mg/kg). The very limited uptake of radioactive material in succeeding crops clearly indicates the lack of systemic behaviour of trinexapac-ethyl. It was concluded that residues in rotational crops are negligible.

The Meeting received information on field rotational crop studies for trinexapac-ethyl which were conducted in both the USA and Switzerland.

In a study conducted in the USA in the 2004–2005 growing season, a 250 g/L EC formulation of trinexapac-ethyl was applied once as a broadcast spray to wheat at 203 g ai/ha. Radish, wheat and spinach were planted after three different plant back intervals (14, 30 and 45 days). The results showed that rotational crops sown 14, 30 and 45 days after application of trinexapac-ethyl to the target crop, are very unlikely to contain residues of trinexapac-ethyl as its main metabolite trinexapac acid, above the LOQ of 0.05 mg/kg.

A trial was conducted in Switzerland during 1989 to investigate residues of trinexapac-ethyl in succeeding crops, grown in soil previously treated with [^{14}C]cyclohexyl trinexapac-ethyl. A 250 g/L EC formulation of trinexapac-ethyl was applied once to bare soil at a rate of 150 g ai/ha. Treated plots were planted after four different time intervals (69, 119, 299 and 338 days after treatment). The crops investigated were lettuce, winter wheat, sugar beet and maize (corn).

The uptake of residues by the rotational crops lettuce, winter wheat, sugar beet and maize planted or sown after several intervals after application of trinexapac-ethyl to bare ground was therefore very low. No accumulation was observed. Residues of trinexapac-ethyl in the rotational crop RACs were below the LOQ (< 0.001 mg/kg) so no characterization was possible. The very limited uptake of radioactive material in succeeding crops clearly indicates the lack of systemic behaviour of trinexapac-ethyl. It was concluded that the residues situation in rotational crops is negligible.

The confined and field rotational crop studies suggest that residues of trinexapac acid are unlikely to occur in succeeding crops.

Methods of analysis

The Meeting received information on analytical methods suitable for the determination of residues of trinexapac acid in plant matrices and animal matrices. The methodology involves quantification of free trinexapac acid (plant and animal matrices) or quantification of both free and conjugated trinexapac acid with the inclusion of an acid hydrolysis step (plant matrices). The methods used are based on HPLC-MS/MS (LOQs of 0.01 or 0.05 mg/kg for trinexapac acid in plant matrices and 0.02 mg/kg for animal matrices (0.01 mg/kg for milk)) and HPLC-UV (LOQs of 0.02 mg/kg for trinexapac acid in plant matrices or 0.01 mg/kg in animal matrices (0.005 mg/kg for milk)).

Details of HPLC-UV methods for determining residues of parent trinexapac-ethyl have also been submitted (LOQs of 0.02 or 0.04 mg/kg).

Stability of pesticide residues in stored analytical samples

The Meeting received information on the freezer storage stability of trinexapac acid in plant and animal commodities.

Freezer storage stability studies indicate that trinexapac acid is stable for at least 24 months in wheat grain and rapeseed and up to 24 months in wheat straw and for at least 12 months in wheat

processed fractions. The stability of trinexapac acid in extracts of animal matrices was tested in the dairy cattle and laying hen feeding studies. No significant degradation of residues of trinexapac acid was observed in cattle matrices (83–121 days) or in poultry matrices (31–82 days).

The periods of storage stability studies cover the sample storage intervals of residue trials.

Definition of the residue

Animals

In the goat metabolism studies, no parent was observed in tissues and milk. Trinexapac acid accounted for 81–97% of the total residues in muscle and kidney, 31–84% of the TRRs in liver and fat and 46–85% of the TRRs in milk. In one study the metabolite CGA 113745 accounted for 6–16% TRR in liver, kidney and fat, but was not detected in either muscle or milk.

In the hen metabolism studies residues in muscle (lean meat), liver, kidney and fat samples of low and high-dosed hens were dominated by trinexapac acid (44–84% of TRR). Only in the skin (with subcutaneous fat) was the major portion of the total radioactivity (70–86%) not extractable. However trinexapac acid was the dominant metabolite in the extract (64–80% of the extractable radioactivity). The major metabolites identified in the organosoluble residue of egg whites were parent trinexapac-ethyl and trinexapac acid which accounted for 31% TRR and 20% TRR respectively.

The observed metabolic pathway of trinexapac-ethyl in livestock is comparable to that observed for the rat in which trinexapac acid is the major and only residue component of significance.

The ratio of trinexapac acid residues in muscle and fat observed in the livestock metabolism and feeding studies support the conclusion that trinexapac is not fat soluble. There is no evidence to suggest that there is significant potential for bioaccumulation in fat tissues.

It is considered that a residue definition of “Trinexapac (acid)” is appropriate for commodities of animal origin for compliance with MRLs (enforcement) and for risk assessment.

Plants

In the rice study trinexapac acid was the major identified component in rice grain (36% TRR) and rice husks (30% TRR). In the spring wheat study, trinexapac acid was the major identified component of wheat grain (28% TRR) and was the only identified component of both wheat husks and wheat straw observed at > 10% of the TRR. It was the major metabolite observed in rape meal, rape whole seeds and pods (19–31% TRR) and was also observed in oil and stalks (4–10% TRR). In grass, trinexapac acid was the major identified component of 22 day forage, straw, straw and regrowth forage (10–22% TRR) and was also a major component of seed screenings and seeds (13–15% TRR). Sugar conjugates of trinexapac acid were hydrolysed in some crop parts to yield free acid.

Trinexapac acid was present in all species and all plants parts at harvest and was generally the main component of the TRR. A definition of trinexapac acid is therefore considered suitable as the residue definition for compliance. Since conjugates of trinexapac acid were sometimes significant in edible commodities and are supposed to be of similar toxicity, the Meeting decided to include conjugates of trinexapac acid in the residue definition for risk to the acid assessment. A suitable method is available for determining residues of free and conjugated trinexapac acid.

It is therefore considered that a residue definition of “Trinexapac (acid)” is appropriate for plant commodities for compliance with MRLs (enforcement). It is considered that a residue definition of “Trinexapac and its conjugates, expressed as trinexapac acid” is appropriate for plant commodities for risk assessment.

Definition of the residue (for compliance with the MRL for plant and animal commodities and for estimation of dietary intake for animal commodities): Trinexapac (acid)

Definition of the residue (for estimation of dietary intake for plant commodities): Trinexapac and its conjugates, expressed as trinexapac acid

The residue is considered not fat soluble.

Results of supervised residue trials on crops

Supervised trials were available for the use of trinexapac on barley, wheat, oilseed rape and sugarcane.

In some studies (barley, wheat and sugarcane) residues have been determined as total trinexapac (includes free trinexapac acid and conjugates of trinexapac acid) while in other studies (wheat, sugarcane and rape seed) residues have been determined as trinexapac (free trinexapac acid only). In both cases trinexapac means trinexapac acid. For dietary intake assessment (risk assessment) residues expressed as total trinexapac acid, where available, have been considered. For maximum residue level estimation (compliance) residues expressed as trinexapac acid, where available, have been considered.

Product labels were available from Belgium, France, Germany and the United States of America.

Cereals - wheat (free trinexapac acid)

Residue trials were conducted in wheat in the USA according to the critical GAP in the USA (1 application at 0.123 kg ai/ha, 45-day PHI).

For the estimation of maximum residue levels the ranked order of residues of trinexapac acid in wheat grain from supervised trials according to the GAP in the USA was 0.10, 0.25, 0.32, 0.34, 0.35, 0.46, 0.49, 0.55, 0.55, 0.57, 0.77, 0.88, 0.91, 0.98, 0.99, 1.05, 1.35 and 1.95 mg/kg.

The Meeting estimated a maximum residue level for trinexapac acid in wheat of 3 mg/kg.

The Meeting recognized that wheat (spring wheat, winter wheat and durum wheat) and triticale, barley and oats have similar GAPs and normally show comparable residues after early treatment. As application was before flowering, the Meeting decided to extrapolate the MRL estimated for wheat grain to barley, oats and triticale.

Cereals - barley

Residue trials were conducted in barley in the USA according to the GAP in the USA (1 application at 0.123 kg ai/ha, 45-day PHI).

For dietary intake purposes the ranked order of total residues of trinexapac acid in barley grain from supervised trials according to the GAP in the USA was 0.03, 0.08, 0.44, 0.50, 0.52, 0.53, 0.60, 0.72, 0.76, 0.83, 1.0 and 1.2 mg/kg.

Cereals - wheat (total residues of trinexapac acid)

Residue trials were conducted in wheat in the USA according to the GAP in the USA (1 application at 0.123 kg ai/ha, 45-day PHI).

For dietary intake purposes the ranked order of total residues of trinexapac acid in wheat grain from supervised trials according to the GAP in the USA was 0.07, 0.15, 0.27, 0.31, 0.32, 0.40, 0.45, 0.47, 0.53, 0.77, 0.78, 0.82, 0.85, 0.99, 1.01, 1.14, 1.64 and 3.32 mg/kg.

The Meeting noted that the USA GAP is the same for barley and wheat. The Meeting noted that the populations of residues data for barley and wheat matching USA GAP resulted in similar distributions of residues for barley and wheat (e.g. medians do not differ by more than 5×). Given the similarity of the datasets (confirmed by the Mann-Whitney U test), the Meeting decided to combine the datasets for barley and wheat to give a larger dataset for estimation of dietary parameters for the purposes of determining an STMR residue level for barley grain and wheat grain.

For dietary intake purposes residues were 0.03, 0.07, 0.08, 0.15, 0.27, 0.31, 0.32, 0.40, 0.44, 0.45, 0.47, 0.50, 0.52, 0.53, 0.53, 0.60, 0.72, 0.76, 0.77, 0.78, 0.82, 0.83, 0.85, 0.99, 1.0, 1.01, 1.14, 1.2, 1.64 and 3.32 mg/kg.

The Meeting estimated an STMR of 0.57 mg/kg.

The Meeting recognized that wheat (spring wheat, winter wheat and durum wheat), triticale, barley and oats have similar GAPs and normally show comparable residues after early treatment. As application was before flowering, the Meeting decided to extrapolate the STMR estimated for barley grain and wheat grain to oats and triticale.

Grasses for sugar or syrup production - sugarcane (free trinexapac acid)

Residue trials were conducted in sugarcane in the USA according to the critical GAP in the USA (1 application at 0.347 kg ai/ha, 28-day PHI).

For the estimation of maximum residue levels the ranked order of residues of trinexapac acid in sugar cane from supervised trials according to the GAP in the USA was < 0.05, 0.06, 0.09, 0.12, 0.22, 0.23 and 0.25 mg/kg.

The Meeting estimated a maximum residue level for trinexapac acid in sugarcane of 0.5 mg/kg.

Grasses for sugar or syrup production—sugarcane (total residues of trinexapac acid)

Residue trials were conducted in sugarcane in the USA according to the critical GAP in the USA (1 application at 0.347 kg ai/ha, 28-day PHI).

For dietary intake purposes the ranked order of total residues of trinexapac acid in sugar cane from supervised trials according to the GAP in the USA was < 0.01, 0.04, 0.06, 0.08, 0.17 and 0.42 mg/kg.

The Meeting estimated an STMR value for trinexapac acid in sugarcane of 0.07 mg/kg.

Oilseeds - Rape

As conjugates of trinexapac acid were not significant in the submitted rape metabolism studies, residue levels from the submitted rape seed studies, which were determined as trinexapac only, have been considered suitable for estimation of a maximum residue level and also for estimation of dietary intake parameters.

Residue trials were conducted in winter rape (canola) in Germany according to the critical GAP in Germany for winter rape (1 application at 0.375 kg ai/ha).

For the estimation of maximum residue levels and for dietary purposes the ranked order of residues of trinexapac acid in winter rape seed from supervised trials according to GAP was 0.04, 0.10, 0.10, 0.13, 0.15, 0.15, 0.16, 0.24, 0.24, 0.26, 0.29, 0.31, 0.64, 0.64, 0.90 and 1.0 mg/kg.

The Meeting estimated maximum residue level and STMR values for trinexapac acid in rape seed of 1.5 and 0.24 mg/kg respectively.

Animal feeds

The Meeting received supervised trials data for barley hay and straw, wheat forage, hay and straw and rape seed forage.

Moisture content percentages for animal feeds have not been determined. The values from the FAO Manual on the Submission and Evaluation of Pesticides Residues Data for the feeds, have been used to convert wet weight or 'as received' residues values to dry weight residues values.

Forage - Wheat (residues of free and conjugated trinexapac acid)

Wheat forage was collected in the trials carried out in the USA according to GAP in the USA (1 application at 0.123 kg ai/ha).

For the calculation of the livestock animal dietary burden the ranked order of total residues in wheat forage samples collected 30 days after application (wet weight) at the GAP application rate was

0.02, 0.03, 0.04, 0.06, 0.07, 0.08, 0.08, 0.09, 0.10, 0.10, 0.12, 0.17, 0.17, 0.22, 0.23, 0.33, 0.38 and 0.94 mg/kg.

For the calculation of the livestock animal dietary burden the ranked order of total residues in wheat forage samples collected 30 days after application (dry weight) at the GAP application rate was 0.08, 0.12, 0.16, 0.24, 0.28, 0.32, 0.32, 0.36, 0.40, 0.40, 0.48, 0.68, 0.68, 0.88, 0.92, 1.32, 1.52 and 3.76 mg/kg.

The Meeting estimated median and highest residue values for trinexapac acid in wheat forage (dry weight) of 0.40 and 3.76 mg/kg respectively.

The Meeting recognized that wheat (spring wheat, winter wheat and durum wheat) and triticale, barley and oats have similar GAPs and normally show comparable residues after early treatment. The Meeting decided to extrapolate the dietary parameters estimated for wheat forage to barley, oats and triticale.

Hay and Straw - Barley and Wheat

Data for wheat hay and straw were collected in the trials carried out in the USA which approximate USA GAP (1 application at 0.123 kg ai/ha).

For the estimation of maximum residue levels the ranked order of residues in wheat hay samples collected 30 days after application (wet weight) at the GAP application rate was < 0.05, < 0.05, < 0.05, 0.05, 0.06, 0.07, 0.07, 0.08, 0.08, 0.09, 0.11, 0.11, 0.13, 0.15, 0.18, 0.19, 0.19 and 0.75 mg/kg.

The ranked order of residues in wheat hay samples converted to dry weight basis at the GAP application rate was < 0.06, < 0.06, < 0.06, 0.06, 0.07, 0.08, 0.08, 0.09, 0.09, 0.10, 0.13, 0.13, 0.15, 0.17, 0.20, 0.22, 0.22 and 0.85 mg/kg.

For the estimation of maximum residue levels the ranked order of residues in wheat straw samples collected 45 days after application (wet weight) at the GAP application rate was < 0.05, < 0.05, < 0.05, < 0.05, < 0.05, < 0.05, < 0.05, < 0.05, < 0.05, 0.06, 0.06, 0.07, 0.07, 0.08, 0.10, 0.11 and 0.12 mg/kg.

The ranked order of residues in wheat straw samples (dry weight) at the GAP application rate was < 0.06, < 0.06, < 0.06, < 0.06, < 0.06, < 0.06, < 0.06, < 0.06, < 0.06, < 0.06, 0.07, 0.07, 0.08, 0.08, 0.09, 0.11, 0.13 and 0.14 mg/kg.

The Meeting used the wheat hay data for the free trinexapac acid to estimate a maximum residue level in wheat straw and fodder (dry) of 0.9 mg/kg. The Meeting recognized that wheat (spring wheat, winter wheat and durum wheat), triticale, barley and oats have similar GAPs and normally show comparable residues after early treatment. It was therefore decided to apply the maximum residue level recommended for trinexapac acid on wheat straw and fodder (dry) to barley, oats and triticale.

For the calculation of the livestock animal dietary burden the ranked order of total residues in barley hay samples collected 30 days after application (wet weight) at the GAP application rate was < 0.01, 0.03, 0.05, 0.10, 0.13, 0.15, 0.17, 0.18, 0.25, 0.33, 0.40 and 0.48 mg/kg.

The ranked order of total residues in barley hay samples converted to a dry weight basis at the GAP application rate was < 0.011, 0.03, 0.06, 0.11, 0.15, 0.17, 0.19, 0.20, 0.28, 0.38, 0.45 and 0.55 mg/kg.

For the calculation of the livestock animal dietary burden the ranked order of total residues in barley straw samples collected 45 days after application (wet weight) at the GAP application rate was < 0.01, 0.02, 0.07, 0.08, 0.08, 0.09, 0.11, 0.12, 0.14, 0.17, 0.20 and 0.24 mg/kg.

The ranked order of total residues in barley straw samples converted to a dry weight basis at the GAP application rate was 0.01, 0.02, 0.08, 0.09, 0.09, 0.10, 0.12, 0.13, 0.16, 0.19, 0.22 and 0.27 mg/kg.

For the calculation of the livestock animal dietary burden the ranked order of total residues in wheat hay samples collected 30 days after application (wet weight) at the GAP application rate was 0.03, 0.04, 0.04, 0.06, 0.09, 0.11, 0.11, 0.14, 0.17, 0.19, 0.24, 0.30, 0.31, 0.41, 0.50, 0.59, 0.78 and 1.18 mg/kg.

The ranked order of total residues in wheat hay samples collected 30 days after application (dry weight) at the GAP application rate was 0.03, 0.05, 0.05, 0.07, 0.10, 0.13, 0.13, 0.16, 0.19, 0.22, 0.27, 0.34, 0.35, 0.47, 0.57, 0.67, 0.89 and 1.34 mg/kg.

For the calculation of the livestock animal dietary burden the ranked order of total residues in wheat straw samples collected 45 days after application (wet weight) at the GAP application rate was 0.01, 0.03, 0.04, 0.04, 0.06, 0.09, 0.11, 0.11, 0.15, 0.15, 0.17, 0.20, 0.23, 0.28, 0.33, 0.46, 0.59 and 0.60 mg/kg.

The ranked order of total residues in wheat straw samples collected 45 days after application (dry weight) at the GAP application rate was 0.01, 0.03, 0.05, 0.05, 0.07, 0.10, 0.13, 0.13, 0.17, 0.17, 0.19, 0.23, 0.26, 0.32, 0.38, 0.52, 0.67 and 0.68 mg/kg.

The Meeting noted that the USA GAP is the same for barley and wheat. The Meeting also noted that the populations of residues data for barley and wheat hay matching USA GAP gave higher residues than the straw and resulted in similar distributions of residues (e.g., medians do not differ by more than 5×). Given the similarity of the datasets (confirmed by the Mann-Whitney U test), the Meeting decided to combine the datasets for barley and wheat hay (dry weight) to give a larger dataset for estimation of dietary parameters for the purposes of determining median and highest residue levels for barley straw and fodder (dry) and wheat straw and fodder (dry).

For the calculation of the livestock animal dietary burden the ranked order of total residues of trinexapac acid in barley and wheat hay (dry weight) collected 30 days after application (dry weight) from supervised trials according to the GAP in the USA was < 0.011, 0.03, 0.03, 0.05, 0.05, 0.06, 0.07, 0.10, 0.11, 0.13, 0.13, 0.15, 0.16, 0.17, 0.19, 0.19, 0.20, 0.22, 0.27, 0.28, 0.34, 0.35, 0.38, 0.45, 0.47, 0.55, 0.57, 0.67, 0.89 and 1.34 mg/kg.

The Meeting used the barley and wheat hay data to estimate median and highest residue values for trinexapac acid in barley straw and fodder (dry) and wheat straw and fodder (dry) of 0.19 and 1.34 mg/kg respectively, based on the combined dataset for barley and wheat hay.

The Meeting recognized that wheat (spring wheat, winter wheat and durum wheat) and barley have similar GAPs to oats and triticale and normally show comparable residues after early treatment. The Meeting decided to extrapolate the dietary parameters estimated for wheat and barley to oats and triticale.

Rape seed forage

In four trials conducted according to GAP in Germany, residues in rape remaining plant type (forage) at PHIs from 49–68 days were < 0.04, < 0.04, < 0.04 and 0.04 mg/kg.

The Meeting agreed that four trials according to GAP were not sufficient to estimate a highest residue for trinexapac in rape forage.

Fate of residues during processing

High temperature hydrolysis of residues of trinexapac-ethyl and trinexapac acid under varying conditions have been reported. The [¹⁴C]-labelled compounds were dissolved in aqueous buffer; at pH 4 and heated for 20 or 25 minutes at 90 °C to simulate pasteurisation, at pH 5 and refluxed at 100 °C for 60 minutes to simulate baking, brewing and boiling and at pH 6 at about 120 °C in an autoclave for 20 minutes to simulate sterilisation. Trinexapac-ethyl was not degraded. Trinexapac acid underwent limited degradation and was the major component of the radioactive material at the end of the hydrolysis reactions (51–59%). It degraded into the compounds CGA113745 (10–12%) and CGA313458 (16–21%).

CGA113745 was observed as a goat metabolite in one metabolism study, while CGA313458 was observed as a rapeseed and rice metabolite. Based on a structural assessment of CGA 113745 and CGA 313458 and the estimated levels of chronic dietary intake, the Meeting concluded that these metabolites are unlikely to pose a dietary risk.

Hydrolysis of trinexapac acid under processing conditions

The Meeting also received processing studies for barley, wheat, sugarcane and rape seed. The table below summarizes STMR-P values calculated on the determined processing factors. In addition the following maximum residue levels were estimated.

Barley

Based on the total trinexapac processing factor of 1.9 for barley bran (in the absence of a trinexapac processing factor) and the barley grain MRL of 3 mg/kg, the calculated expected highest residues in barley bran are 5.7 mg/kg. The Meeting estimated an MRL for trinexapac in barley bran of 6 mg/kg.

Wheat

Based on the trinexapac processing factor of 2.3 for wheat bran and the wheat grain MRL of 3 mg/kg the calculated expected highest residues in wheat bran are 6.9 mg/kg. The Meeting estimated an MRL for trinexapac in wheat bran of 8 mg/kg.

The processing factors derived from the processing studies and the resulting recommendations for STMR-Ps (and maximum residue levels) are summarized in the table below.

Processing Factors from the Processing of Raw Agricultural Commodities (RACs) with Field-Incurred Residues from Foliar Treatment with Trinexapac-ethyl

RAC	Processed Commodity	Best Estimate Processing Factor	RAC MRL	RAC STMR	Processed Commodity STMR-P
Barley	Pearled barley	1.2	3	0.57	0.68
	Bran	1.9			1.08
	Flour	0.43			0.25
Wheat	Aspirated Grain Fractions	0.55	3	0.57	0.31

RAC	Processed Commodity	Best Estimate Processing Factor	RAC MRL	RAC STMR	Processed Commodity STMR-P
	Bran	1.9			1.08
	Flour	0.43			0.25
	Middlings	0.55			0.31
	Shorts	0.46			0.26
	Germ	1.1			0.63
Sugarcane	Molasses	5.8	0.5	0.07	0.40
	Refined sugar	0.15			0.01
Rapeseed	Press cake	1.2	1.5	0.24	0.32
	Refined oil	0.05			0.01

Except for the rapeseed study (in which processing factors were determined based on residues of trinexapac), processed commodity STMR-Ps were calculated on the basis of the total trinexapac acid processing factors.

Residues in animal commodities

Estimated maximum and mean dietary burdens of farm animals

Dietary burden calculations for beef cattle and dairy cattle and poultry are provided below. The dietary burdens were estimated using the OECD diets listed in Appendix IX of the 2009 edition of the FAO Manual.

Potential cattle feed items include: wheat, barley, oat and triticale grain, straw, forage, hay and silage, wheat milled by-products (bran), wheat aspirated grain fractions, barley bran fractions, sugarcane molasses and bagasse and rape forage and rape seed meal.

Summary of livestock dietary burden for trinexapac (ppm of dry matter diet)

	US-Canada		EU		Australia		Japan	
	max	mean	max	mean	max	mean	max	mean
Beef cattle	0.98	0.87	1.76	0.82	3.76 ^a	0.88	0.97	0.97 ^c
Dairy cattle	1.76	0.77	1.76	0.76	3.76 ^b	0.86 ^d	1.00	0.83

^a Highest maximum beef or dairy cattle dietary burden suitable for HR and MRL estimates for mammalian meat

^b Highest maximum dairy cattle dietary burden suitable for HR and MRL estimates for mammalian milk

^c Highest mean beef or dairy cattle dietary burden suitable for STMR estimates for mammalian meat

^d Highest mean dairy cattle dietary burden suitable for STMR estimates for mammalian milk

Potential poultry feed items include: wheat, barley, oat and triticale grain, straw, forage, hay and silage, wheat milled by-products (bran), wheat aspirated grain fractions, barley bran fractions, sugarcane molasses and bagasse and rape forage and rape seed meal.

Summary of poultry dietary burden for trinexapac (ppm of dry matter diet)

	US-Canada		EU		Australia		Japan	
	max	mean	max	mean	max	mean	max	mean
Poultry Broiler	0.94	0.94	0.70	0.70	0.34	0.34	0.13	0.13
Poultry Layer	0.94	0.94 ^b	1.08 ^a	0.76	0.34	0.34	0.37	0.37

^a Highest maximum poultry dietary burden suitable for HR and MRL estimates for poultry meat and eggs

^b Highest maximum poultry dietary burden suitable for STMR estimates for poultry meat and eggs

Farm Animal Dietary Burden

The Meeting received a lactating dairy cow feeding study which provided information on residues of trinexapac acid arising in tissues and milk when dairy cows were dosed for 29–30 days, at target feeding levels equivalent to 0, 2, 6 and 20 ppm trinexapac acid in the diet.

No quantifiable residues of trinexapac acid were observed in milk at the 0, 2 and 6 ppm dose groups. Residues in the 20 ppm dose group ranged from < 0.005–0.011 mg/kg. Residues reached a plateau after one day.

No quantifiable residues of trinexapac acid were observed in the tissues of the control cow. In the lowest and mid-range dose groups (2 and 6 ppm), no quantifiable residues were detected in muscle, liver and fat, although residues slightly above LOQ (0.02 mg/kg) were observed in kidney (highest (mean in brackets) were 0.03 (0.03) and 0.05 (0.04) mg/kg respectively). No quantifiable residues were detected in muscle in the 20 ppm dose group while the highest residues (mean in brackets) observed in liver, kidney and fat in the 20 ppm dose group were 0.03 (0.03), 0.29 (0.17) and 0.02 (< 0.02) mg/kg respectively.

The Meeting also received information on the residue levels arising in tissues and eggs when laying hens were dosed with trinexapac acid for 28 days, at feeding levels equivalent to 3.7, 10 and 37 ppm in the diet.

No quantifiable residues of trinexapac acid were observed in eggs at any feeding level except in the 37 ppm dose group at 28 days (highest and mean residues were 0.01 mg/kg).

No residues of trinexapac acid above LOQ (0.01 mg/kg) were detected in any muscle (breast and thigh muscle) sample from any treatment group. No residues of trinexapac acid above LOQ were detected in any liver sample from any treatment group apart from the highest dose group (highest and mean residues were 0.02 mg/kg). No residues of trinexapac acid above LOQ were detected in any fat sample from any treatment group apart from the highest dose group (highest and mean residues were 0.03 mg/kg). Highest (mean) residues of trinexapac acid in kidney were 0.08 (0.06), 0.05 (0.04) and 0.54 (0.45) mg/kg in the lowest to highest dose groups respectively.

*Animal commodity maximum residue levels**Cattle- STMR, HR and MRLs*

For highest residue level estimation, the high residues in the cattle tissues were calculated by interpolating the maximum dietary burden for beef cattle (3.76 ppm) between the relevant feeding levels (2 and 6 ppm) in the dairy cow feeding study and using the highest tissue concentrations from individual animals within those feeding groups. For highest residue level estimation, the high residues in the cattle milk were calculated by interpolating the maximum dietary burden for dairy cattle (3.76 ppm) with the lowest feeding level (2 and 6 ppm) in the dairy cow feeding study and using the highest mean milk concentrations from those feeding groups.

The STMR values for the tissues were calculated by extrapolating the mean dietary burden for beef cattle (0.97 ppm) with the 2 ppm feeding level from the dairy cow feeding study and using the mean tissue concentrations from that feeding group. The STMR values for the milk were calculated by extrapolating the mean dietary burden for dairy cattle (0.86 ppm) with the 2 ppm feeding level from the dairy cow feeding study and using the mean milk concentrations from that feeding group.

Trinexapac Feeding Study	Feed Level (ppm) for milk residues	Residues (mg/kg) in milk	Feed Level (ppm) for tissue residues	Residues (mg/kg)			
				Muscle	Liver	Kidney	Fat
HR Determination (beef or dairy cattle)							
Feeding Study	2	< 0.005	2	< 0.02	< 0.02	0.03	< 0.02
	6	< 0.005	6	< 0.02	< 0.02	0.05	< 0.02
Dietary burden and estimate of highest	3.76	< 0.005	3.76	< 0.02	< 0.02	0.04	< 0.02

residue							
STMR Determination (beef or dairy cattle)							
Feeding Study	2	< 0.005	2	< 0.02	< 0.02	0.03	< 0.02
Dietary burden and estimate of highest residue	0.86	< 0.0022	0.97	< 0.010	< 0.010	0.015	< 0.010

The Meeting estimated the following STMR values: milk 0 mg/kg; muscle 0 mg/kg; edible offal (based on kidney) 0.015 mg/kg and fat 0 mg/kg.

The Meeting estimated the following maximum residue levels: milk 0.005(*) mg/kg; meat (mammalian except marine mammals) 0.01(*) mg/kg, edible offal (based on kidney) 0.1 mg/kg and mammalian fats (except milk fats) 0.01(*) mg/kg.

Poultry - STMR, HR and MRLs

For highest residue level estimation, the high residues in the hen tissues and eggs were calculated by extrapolating the maximum dietary burden (1.08 ppm) with the lowest feeding level (3.7 ppm) in the laying hen feeding study and using the highest tissue concentrations from individual animals within that feeding group and using the highest mean egg concentration from that feeding group.

The STMR values for the tissues and eggs were calculated by extrapolating the mean dietary burden (0.94 ppm) with the lowest feeding level (3.7 ppm) from the poultry feeding study and using the mean tissue and egg concentrations from that feeding group.

Trinexapac Feeding Study	Feed Level (ppm) for egg residues	Residues (mg/kg) in egg	Feed Level (ppm) for tissue residues	Residues (mg/kg)			
				Muscle	Liver	Kidney	Fat
HR Determination (poultry broiler or layer)							
Feeding Study	3.7	< 0.01	3.7	< 0.01	< 0.01	0.08	< 0.01
Dietary burden and estimate of highest residue	1.08	< 0.003	1.08	< 0.003	< 0.003	0.023	< 0.003
STMR Determination (poultry broiler or layer)							
Feeding Study	3.7	< 0.01	3.7	< 0.01	< 0.01	0.06	< 0.01
Dietary burden and estimate of highest residue	0.94	< 0.0025	0.94	< 0.0025	< 0.0025	0.015	< 0.0025

The Meeting estimated the following STMR values: egg 0 mg/kg; muscle 0 mg/kg; edible offal (based on kidney) 0.015 mg/kg and fat 0 mg/kg.

The Meeting estimated the following maximum residue levels: eggs 0.01(*) mg/kg; poultry meat 0.01(*) mg/kg, poultry edible offal (based on kidney) 0.05 mg/kg and poultry fats 0.01(*) mg/kg.

RECOMMENDATIONS

Definition of the residue (for compliance with the MRL for plant and animal commodities and for estimation of dietary intake for animal commodities): Trinexapac (acid)

Definition of the residue (for estimation of dietary intake for plant commodities): *Trinexapac and its conjugates, expressed as trinexapac acid*.

The Meeting estimated the maximum residue levels and STMR values shown below.

Commodity		MRL, mg/kg	STMR or STMR-P, mg/kg	HR or HR-P, mg/kg

DIETARY RISK ASSESSMENT

Long-term intake

The evaluation of trinexapac has resulted in recommendations for MRLs and STMRs for raw and processed commodities. Consumption data were available for 36 food commodities and were used in the dietary intake calculation. The results are shown in Annex 3. The International Estimated Daily Intakes for the 13 GEMS/Food regional diets, based on estimated STMRs were in the range 0–1% of the maximum ADI of 0.3 mg/kg bw (Annex 3).

The Meeting concluded that the long-term intake of residues of trinexapac from uses that have been considered by the JMPR is unlikely to present a public health concern.

Short-term intake

The International Estimated Short-term Intake (IESTI) for trinexapac was not calculated, as it was not considered necessary to establish an ARfD.

The Meeting concluded that the short-term intake of residues of trinexapac from uses that have been considered by the JMPR is unlikely to present a public health concern.

Annex I. Reports and other documents resulting from previous Joint Meetings of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO CORE ASSESSMENT GROUP on Pesticide Residues

1. Principles governing consumer safety in relation to pesticide residues. Report of a meeting of a WHO Expert Committee on Pesticide Residues held jointly with the FAO Panel of Experts on the Use of Pesticides in Agriculture. FAO Plant Production and Protection Division Report, No. PL/1961/11; WHO Technical Report Series, No. 240, 1962.
2. Evaluation of the toxicity of pesticide residues in food. Report of a Joint Meeting of the FAO Committee on Pesticides in Agriculture and the WHO Expert Committee on Pesticide Residues. FAO Meeting Report, No. PL/1963/13; WHO/Food Add./23, 1964.
3. Evaluation of the toxicity of pesticide residues in food. Report of the Second Joint Meeting of the FAO Committee on Pesticides in Agriculture and the WHO Expert Committee on Pesticide Residues. FAO Meeting Report, No. PL/1965/10; WHO/Food Add./26.65, 1965.
4. Evaluation of the toxicity of pesticide residues in food. FAO Meeting Report, No. PL/1965/10/1; WHO/Food Add./27.65, 1965.
5. Evaluation of the hazards to consumers resulting from the use of fumigants in the protection of food. FAO Meeting Report, No. PL/1965/10/2; WHO/Food Add./28.65, 1965.
6. Pesticide residues in food. Joint report of the FAO Working Party on Pesticide Residues and the WHO Expert Committee on Pesticide Residues. FAO Agricultural Studies, No. 73; WHO Technical Report Series, No. 370, 1967.
7. Evaluation of some pesticide residues in food. FAO/PL:CP/15; WHO/Food Add./67.32, 1967.
8. Pesticide residues. Report of the 1967 Joint Meeting of the FAO Working Party and the WHO Expert Committee. FAO Meeting Report, No. PL:1967/M/11; WHO Technical Report Series, No. 391, 1968.
9. 1967 Evaluations of some pesticide residues in food. FAO/PL:1967/M/11/1; WHO/Food Add./68.30, 1968.
10. Pesticide residues in food. Report of the 1968 Joint Meeting of the FAO Working Party of Experts on Pesticide Residues and the WHO Expert Committee on Pesticide Residues. FAO Agricultural Studies, No. 78; WHO Technical Report Series, No. 417, 1968.
11. 1968 Evaluations of some pesticide residues in food. FAO/PL:1968/M/9/1; WHO/Food Add./69.35, 1969.
12. Pesticide residues in food. Report of the 1969 Joint Meeting of the FAO Working Party of Experts on Pesticide Residues and the WHO Expert Group on Pesticide Residues. FAO Agricultural Studies, No. 84; WHO Technical Report Series, No. 458, 1970.
13. 1969 Evaluations of some pesticide residues in food. FAO/PL:1969/M/17/1; WHO/Food Add./70.38, 1970.
14. Pesticide residues in food. Report of the 1970 Joint Meeting of the FAO Working Party of Experts on Pesticide Residues and the WHO Expert Committee on Pesticide Residues. FAO Agricultural Studies, No. 87; WHO Technical Report Series, No. 4574, 1971.
15. 1970 Evaluations of some pesticide residues in food. AGP:1970/M/12/1; WHO/Food Add./71.42, 1971.
16. Pesticide residues in food. Report of the 1971 Joint Meeting of the FAO Working Party of Experts on Pesticide Residues and the WHO Expert Committee on Pesticide Residues. FAO Agricultural Studies, No. 88; WHO Technical Report Series, No. 502, 1972.

17. 1971 Evaluations of some pesticide residues in food. AGP:1971/M/9/1; WHO Pesticide Residue Series, No. 1, 1972.
18. Pesticide residues in food. Report of the 1972 Joint Meeting of the FAO Working Party of Experts on Pesticide Residues and the WHO Expert Committee on Pesticide Residues. FAO Agricultural Studies, No. 90; WHO Technical Report Series, No. 525, 1973.
19. 1972 Evaluations of some pesticide residues in food. AGP:1972/M/9/1; WHO Pesticide Residue Series, No. 2, 1973.
20. Pesticide residues in food. Report of the 1973 Joint Meeting of the FAO Working Party of Experts on Pesticide Residues and the WHO Expert Committee on Pesticide Residues. FAO Agricultural Studies, No. 92; WHO Technical Report Series, No. 545, 1974.
21. 1973 Evaluations of some pesticide residues in food. FAO/AGP/1973/M/9/1; WHO Pesticide Residue Series, No. 3, 1974.
22. 22. Pesticide residues in food. Report of the 1974 Joint Meeting of the FAO Working Party of Experts on Pesticide Residues and the WHO Expert Committee on Pesticide Residues. FAO Agricultural Studies, No. 97; WHO Technical Report Series, No. 574, 1975.
23. 1974 Evaluations of some pesticide residues in food. FAO/AGP/1974/M/11; WHO Pesticide Residue Series, No. 4, 1975.
24. Pesticide residues in food. Report of the 1975 Joint Meeting of the FAO Working Party of Experts on Pesticide Residues and the WHO Expert Committee on Pesticide Residues. FAO Plant Production and Protection Series, No. 1; WHO Technical Report Series, No. 592, 1976.
25. 1975 Evaluations of some pesticide residues in food. AGP:1975/M/13; WHO Pesticide Residue Series, No. 5, 1976.
26. Pesticide residues in food. Report of the 1976 Joint Meeting of the FAO Panel of Experts on Pesticide Residues and the Environment and the WHO Expert Group on Pesticide Residues. FAO Food and Nutrition Series, No. 9; FAO Plant Production and Protection Series, No. 8; WHO Technical Report Series, No. 612, 1977.
27. 1976 Evaluations of some pesticide residues in food. AGP:1976/M/14, 1977.
28. Pesticide residues in food—1977. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues and Environment and the WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 10 Rev, 1978.
29. Pesticide residues in food: 1977 evaluations. FAO Plant Production and Protection Paper 10 Suppl., 1978.
30. Pesticide residues in food—1978. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues and Environment and the WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 15, 1979.
31. Pesticide residues in food: 1978 evaluations. FAO Plant Production and Protection Paper 15 Suppl., 1979.
32. Pesticide residues in food—1979. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 20, 1980.
33. Pesticide residues in food: 1979 evaluations. FAO Plant Production and Protection Paper 20 Suppl., 1980

34. Pesticide residues in food—1980. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 26, 1981.
35. Pesticide residues in food: 1980 evaluations. FAO Plant Production and Protection Paper 26 Suppl., 1981.
36. Pesticide residues in food—1981. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 37, 1982.
37. Pesticide residues in food: 1981 evaluations. FAO Plant Production and Protection Paper 42, 1982.
38. Pesticide residues in food—1982. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 46, 1982.
39. Pesticide residues in food: 1982 evaluations. FAO Plant Production and Protection Paper 49, 1983.
40. Pesticide residues in food—1983. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 56, 1985.
41. Pesticide residues in food: 1983 evaluations. FAO Plant Production and Protection Paper 61, 1985.
42. Pesticide residues in food—1984. Report of the Joint Meeting on Pesticide Residues. FAO Plant Production and Protection Paper 62, 1985.
43. Pesticide residues in food—1984 evaluations. FAO Plant Production and Protection Paper 67, 1985.
44. Pesticide residues in food—1985. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and a WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 68, 1986.
45. Pesticide residues in food—1985 evaluations. Part I. Residues. FAO Plant Production and Protection Paper 72/1, 1986.
46. Pesticide residues in food—1985 evaluations. Part II. Toxicology. FAO Plant Production and Protection Paper 72/2, 1986.
47. Pesticide residues in food—1986. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and a WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 77, 1986.
48. Pesticide residues in food—1986 evaluations. Part I. Residues. FAO Plant Production and Protection Paper 78, 1986.
49. Pesticide residues in food—1986 evaluations. Part II. Toxicology. FAO Plant Production and Protection Paper 78/2, 1987.
50. Pesticide residues in food—1987. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and a WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 84, 1987.
51. Pesticide residues in food—1987 evaluations. Part I. Residues. FAO Plant Production and Protection Paper 86/1, 1988.

52. Pesticide residues in food—1987 evaluations. Part II. Toxicology. FAO Plant Production and Protection Paper 86/2, 1988.
53. Pesticide residues in food—1988. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and a WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 92, 1988.
54. Pesticide residues in food—1988 evaluations. Part I. Residues. FAO Plant Production and Protection Paper 93/1, 1988.
55. Pesticide residues in food—1988 evaluations. Part II. Toxicology. FAO Plant Production and Protection Paper 93/2, 1989.
56. Pesticide residues in food—1989. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and a WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 99, 1989.
57. Pesticide residues in food—1989 evaluations. Part I. Residues. FAO Plant Production and Protection Paper 100, 1990.
58. Pesticide residues in food—1989 evaluations. Part II. Toxicology. FAO Plant Production and Protection Paper 100/2, 1990.
59. Pesticide residues in food—1990. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and a WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 102, Rome, 1990.
60. Pesticide residues in food—1990 evaluations. Part I. Residues. FAO Plant Production and Protection Paper 103/1, Rome, 1990.
61. Pesticide residues in food—1990 evaluations. Part II. Toxicology. World Health Organization, WHO/PCS/91.47, Geneva, 1991.
62. Pesticide residues in food—1991. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and a WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 111, Rome, 1991.
63. Pesticide residues in food—1991 evaluations. Part I. Residues. FAO Plant Production and Protection Paper 113/1, Rome, 1991.
64. Pesticide residues in food—1991 evaluations. Part II. Toxicology. World Health Organization, WHO/PCS/92.52, Geneva, 1992.
65. Pesticide residues in food—1992. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and a WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 116, Rome, 1993.
66. Pesticide residues in food—1992 evaluations. Part I. Residues. FAO Plant Production and Protection Paper 118, Rome, 1993.
67. Pesticide residues in food—1992 evaluations. Part II. Toxicology. World Health Organization, WHO/PCS/93.34, Geneva, 1993.
68. Pesticide residues in food—1993. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and a WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 122, Rome, 1994.
69. Pesticide residues in food—1993 evaluations. Part I. Residues. FAO Plant Production and Protection Paper 124, Rome, 1994.

70. Pesticide residues in food—1993 evaluations. Part II. Toxicology. World Health Organization, WHO/PCS/94.4, Geneva, 1994.
71. Pesticide residues in food—1994. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and a WHO Expert Group on Pesticide Residues. FAO Plant Production and Protection Paper 127, Rome, 1995.
72. Pesticide residues in food—1994 evaluations. Part I. Residues. FAO Plant Production and Protection Paper 131/1 and 131/2 (2 volumes), Rome, 1995.
73. Pesticide residues in food—1994 evaluations. Part II. Toxicology. World Health Organization, WHO/PCS/95.2, Geneva, 1995.
74. Pesticide residues in food—1995. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. FAO Plant Production and Protection Paper 133, Rome, 1996.
75. Pesticide residues in food—1995 evaluations. Part I. Residues. FAO Plant Production and Protection Paper 137, 1996.
76. Pesticide residues in food—1995 evaluations. Part II. Toxicological and Environmental. World Health Organization, WHO/PCS/96.48, Geneva, 1996.
77. Pesticide residues in food—1996. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. FAO Plant Production and Protection Paper, 140, 1997.
78. Pesticide residues in food—1996 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 142, 1997.
79. Pesticide residues in food—1996 evaluations. Part II. Toxicological. World Health Organization, WHO/PCS/97.1, Geneva, 1997.
80. Pesticide residues in food—1997. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. FAO Plant Production and Protection Paper, 145, 1998.
81. Pesticide residues in food—1997 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 146, 1998.
82. Pesticide residues in food—1997 evaluations. Part II. Toxicological and Environmental. World Health Organization, WHO/PCS/98.6, Geneva, 1998.
83. Pesticide residues in food—1998. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. FAO Plant Production and Protection Paper, 148, 1999.
84. Pesticide residues in food—1998 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 152/1 and 152/2 (two volumes).
85. Pesticide residues in food—1998 evaluations. Part II. Toxicological and Environmental. World Health Organization, WHO/PCS/99.18, Geneva, 1999.
86. Pesticide residues in food—1999. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. FAO Plant Production and Protection Paper, 153, 1999.
87. Pesticide residues in food—1999 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 157, 2000.

88. Pesticide residues in food—1999 evaluations. Part II. Toxicological. World Health Organization, WHO/PCS/00.4, Geneva, 2000.
89. Pesticide residues in food—2000. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. FAO Plant Production and Protection Paper, 163, 2001.

96. Pesticide residues in food—2002 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 175/1 and 175/2 (two volumes).
97. Pesticide residues in food—2002 evaluations. Part II. Toxicological. World Health Organization, WHO/PCS, 2003.
98. Pesticide residues in food—2003. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. [FAO Plant Production and Protection Paper](#), 176, 2004.
99. Pesticide residues in food—2003 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 177, 2004.
100. Pesticide residues in food—2003 evaluations. Part II. Toxicological. World Health Organization, WHO/PCS, 2004.
101. Pesticide residues in food—2004. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. [FAO Plant Production and Protection Paper](#), 178, 2004.
102. Pesticide residues in food—2004 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 182, 2005.
103. Pesticide residues in food—2004 evaluations. Part II. Toxicological. World Health Organization, WHO/PCS, 2005.
104. Pesticide residues in food—2005. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. [FAO Plant Production and Protection Paper](#), 183, 2005.
105. Pesticide residues in food—2005 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 184, 2006.

106. Pesticide residues in food—2005 evaluations. Part II. Toxicological. World Health Organization, WHO/PCS/07.1, 2006.
107. Pesticide residues in food—2006. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. FAO Plant Production and Protection Paper, 187, 2007.
108. Pesticide residues in food—2006 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 189/1 and 189/2 (two volumes), 2007.
109. Pesticide residues in food—2006 evaluations. Part II. Toxicological. World Health Organization, 2008.
110. Pesticide residues in food—2007. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. FAO Plant Production and Protection Paper, 191, 2008.
111. Pesticide residues in food—2007 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 192, 2008.
112. Pesticide residues in food—2007 evaluations. Part II. Toxicological. World Health Organization, 2009.
113. Pesticide residues in food—2008. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. FAO Plant Production and Protection Paper, 193, 2009.
114. Pesticide residues in food—2008 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 194, 2009.
115. Pesticide residues in food—2008 evaluations. Part II. Toxicological. World Health Organization, 2010.
116. Pesticide residues in food—2009. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. FAO Plant Production and Protection Paper, 196, 2010.
117. Pesticide residues in food—2009 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 198, 2010.
118. Pesticide residues in food—2009 evaluations. Part II. Toxicological. World Health Organization, 2011.
119. Pesticide residues in food—2010. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group. FAO Plant Production and Protection Paper, 200, 2011.
120. Pesticide residues in food—2010 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 206, 2011.
121. Pesticide residues in food—2010 evaluations. Part II. Toxicological. World Health Organization, 2011.
122. Pesticide residues in food—2011. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group on Pesticide Residues. FAO Plant Production and Protection Paper, 211, 2012.
123. Pesticide residues in food—2011 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 206, 2012.

124. Pesticide residues in food—2011 evaluations. Part II. Toxicological. World Health Organization, 2012.
125. Pesticide residues in food—2012. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group on Pesticide Residues. FAO Plant Production and Protection Paper, 215, 2013.
126. Pesticide residues in food—2012 evaluations. Part I. Residues. FAO Plant Production and Protection Paper, 216, 2013.
127. Pesticide residues in food—2012 evaluations. Part II. Toxicological. World Health Organization, 2013
128. Pesticide residues in food—2013. Report of the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group on Pesticide Residues. FAO Plant Production and Protection Paper, 219, 2014.

FAO TECHNICAL PAPERS

FAO PLANT PRODUCTION AND PROTECTION PAPERS

- 1 Horticulture: a select bibliography, 1976 (E)
- 2 Cotton specialists and research institutions in selected countries, 1976 (E)
- 3 Food legumes: distribution, adaptability and biology of yield, 1977 (E F S)
- 4 Soybean production in the tropics, 1977 (C E F S)
- 4 Rev.1 Soybean production in the tropics (first revision), 1982 (E)
- 5 Les systèmes pastoraux sahéliens, 1977 (F)
- 6 Pest resistance to pesticides and crop loss assessment – Vol. 1, 1977 (E F S)
- 6/2 Pest resistance to pesticides and crop loss assessment – Vol. 2, 1979 (E F S)
- 6/3 Pest resistance to pesticides and crop loss assessment – Vol. 3, 1981 (E F S)
- 7 Rodent pest biology and control – Bibliography 1970-74, 1977 (E)
- 8 Tropical pasture seed production, 1979 (E F** S**)
- 9 Food legume crops: improvement and production, 1977 (E)
- 10 Pesticide residues in food, 1977 – Report, 1978 (E F S)
- 10 Rev. Pesticide residues in food 1977 – Report, 1978 (E)
- 10 Sup. Pesticide residues in food 1977 – Evaluations, 1978 (E)
- 11 Pesticide residues in food 1965-78 – Index and summary, 1978 (E F S)
- 12 Crop calendars, 1978 (E/F/S)
- 13 The use of FAO specifications for plant protection products, 1979 (E F S)
- 14 Guidelines for integrated control of rice insect pests, 1979 (Ar C E F S)
- 15 Pesticide residues in food 1978 – Report, 1979 (E F S)
- 15 Sup. Pesticide residues in food 1978 – Evaluations, 1979 (E)
- 16 Rodenticides: analyses, specifications, formulations, 1979 (E F S)
- 17 Agrometeorological crop monitoring and forecasting, 1979 (C E F S)
- 18 Guidelines for integrated control of maize pests, 1979 (C E)
- 19 Elements of integrated control of sorghum pests, 1979 (E F S)
- 20 Pesticide residues in food 1979 – Report, 1980 (E F S)
- 20 Sup. Pesticide residues in food 1979 – Evaluations, 1980 (E)
- 21 Recommended methods for measurement of pest resistance to pesticides, 1980 (E F)
- 22 China: multiple cropping and related crop production technology, 1980 (E)
- 23 China: development of olive production, 1980 (E)
- 24/1 Improvement and production of maize, sorghum and millet – Vol. 1. General principles, 1980 (E F)
- 24/2 Improvement and production of maize, sorghum and millet – Vol. 2. Breeding, agronomy and seed production, 1980 (E F)
- 25 Prosopis tamarugo: fodder tree for arid zones, 1981 (E F S)
- 26 Pesticide residues in food 1980 – Report, 1981 (E F S)
- 26 Sup. Pesticide residues in food 1980 – Evaluations, 1981 (E)
- 27 Small-scale cash crop farming in South Asia, 1981 (E)
- 28 Second expert consultation on environmental criteria for registration of pesticides, 1981 (E F S)
- 29 Sesame: status and improvement, 1981 (E)
- 30 Palm tissue culture, 1981 (C E)
- 31 An eco-climatic classification of intertropical Africa, 1981 (E)
- 32 Weeds in tropical crops: selected abstracts, 1981 (E)
- 32 Sup.1 Weeds in tropical crops: review of abstracts, 1982 (E)
- 33 Plant collecting and herbarium development, 1981 (E)
- 34 Improvement of nutritional quality of food crops, 1981 (C E)
- 35 Date production and protection, 1982 (Ar E)
- 36 El cultivo y la utilización del tarwi – *Lupinus mutabilis* Sweet, 1982 (S)
- 37 Pesticide residues in food 1981 – Report, 1982 (E F S)
- 38 Winged bean production in the tropics, 1982 (E)
- 39 Seeds, 1982 (E/F/S)
- 40 Rodent control in agriculture, 1982 (Ar C E F S)
- 41 Rice development and rainfed rice production, 1982 (E)
- 42 Pesticide residues in food 1981 – Evaluations, 1982 (E)
- 43 Manual on mushroom cultivation, 1983 (E F)

44	Improving weed management, 1984 (E F S)	71	Technical guideline on seed potato micropropagation and multiplication, 1986 (E)
45	Pocket computers in agrometeorology, 1983 (E)	72/1	Pesticide residues in food 1985 – Evaluations – Part I: Residues, 1986 (E)

The annual Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group on Pesticide Residues was held in Geneva, Switzerland, from 17 to 26 September 2013. The FAO Panel of Experts had met in preparatory sessions from 6 to 10 September. The Meeting was held in pursuance of recommendations made by previous Meetings and accepted by the governing bodies of FAO and WHO that studies should be undertaken jointly by experts to evaluate possible hazards to humans arising from the occurrence of pesticide residues in foods. During the meeting the FAO Panel of Experts was responsible for reviewing pesticide use patterns (use of good agricultural practices), data on the chemistry and composition of the pesticides and methods of analysis for pesticide residues and for estimating the maximum residue levels that might occur as a result of the use of the pesticides according to good agricultural use practices. The WHO Core Assessment Group was responsible for reviewing toxicological and related data and for estimating, where possible and appropriate, acceptable daily intakes (ADIs) and acute reference doses (ARfDs) of the pesticides for humans. This report contains information on ADIs, ARfDs, maximum residue levels, and general principles for the evaluation of pesticides. The recommendations of the Joint Meeting, including further research and information, are proposed for use by Member governments of the respective agencies and other interested parties.
