LIST OF PARTICIPANTS

2015 Joint FAO/WHO Meeting on Pesticide Residues

GENEVA, 15–24 SEPTEMBER 2015

Professor Árpád Ambrus, 1221 Budapest Hómezö u 41, Hungary *(FAO Temporary Adviser)*

Dr Michael Doherty, Office of Pesticide Programs, Health Effects Division, Risk Assessment Branch II, United States Environmental Protection Agency, MS 7509P, Washington, DC 20460, USA *(FAO Temporary Adviser)*

Professor Eloisa Dutra Caldas, Pharmaceutical Sciences Department, College of Health Sciences, University of Brasilia, Campus Universitário Darci Ribeiro, 70910-900 Brasília/DF, Brazil *(FAO Rapporteur)*

Dr Paul Humphrey, Scientific Assessment and Chemical Review Program, Australian Pesticides and Veterinary Medicines Authority (APVMA), PO Box 6182, Kingston, ACT 2604, Australia *(FAO Temporary Adviser)*

Mr Makoto Irie, Plant Products Safety Division, Food Safety and Consumer Affairs Bureau, Ministry of Agriculture, Forestry and Fisheries, 1-2-1 Kasumigaseki, Chiyoda-ku, Tokyo 100-8950, Japan *(FAO Temporary Adviser)*

Professor Mi-Gyung Lee, Department of Food Science & Biotechnology, College of Natural Science, Andong National University, #1375 Gyeongdong-ro, Andong-si, Gyeongbuk 760-749, Republic of Korea *(FAO Temporary Adviser)*

Mr David Lunn, Principal Adviser (Residues), Plants, Food & Environment Directorate, Ministry for Primary Industries, PO Box 2526, Wellington, New Zealand *(FAO Member)*

Dr Dugald MacLachlan, Australian Government Department of Agriculture, GPO Box 858, Canberra, ACT 2601, Australia *(FAO Chairman)*

Mr Christian Sieke, Residue Assessment of Pesticides and Biocides Unit, Department of Chemicals Safety, Federal Institute for Risk Assessment, Max-Dohrn-Strasse 8-10, D-10589 Berlin, Germany *(FAO Member)*

Dr Anita Strömberg, Risk Benefit Assessment Department, National Food Agency, Box 622, 751 26 Uppsala, Sweden *(FAO Temporary Adviser)*

Ms Monique Thomas, Pest Management Regulatory Agency, Health Canada, 2720 Riverside Drive, Ottawa, Ontario, Canada K1A 0K9 *(FAO Temporary Adviser)*

Mrs Trijntje van der Velde-Koerts, Centre for Nutrition, Prevention and Health Services (VPZ), National Institute for Public Health and the Environment (RIVM), Antonie van Leeuwenhoeklaan 9, PO Box 1, 3720 BA Bilthoven, the Netherlands *(FAO Member)*

Dr Yukiko Yamada, Ministry of Agriculture, Forestry and Fisheries, 1-2-1 Kasumigaseki, Chiyoda-ku, Tokyo 100-8950, Japan *(FAO Member)*

Dr Guibiao Ye, Institute for the Control of Agrochemicals, Ministry of Agriculture, Maizidian 22, Chaoyang District, Beijing 100125, China *(FAO Temporary Adviser)*

Secretariat

Mr Kevin Bodnaruk, 26/12 Phillip Mall, West Pymble, NSW 2073, Australia *(FAO Editor)*

Ms Gracia Brisco, Food Standards Officer, Joint FAO/WHO Food Standards Programme, Food and Agriculture Organization of the United Nations, Viale delle Terme di Caracalla, 00153 Rome, Italy *(Codex Secretariat)*

Dr Ronald Eichner 13 Cruikshank Street, Wanniassa, ACT 2903, Australia *(FAO Editor)*

Ms Yong Zhen Yang, Plant Production and Protection Division, Food and Agriculture Organization of the United Nations, Viale delle Terme di Caracalla, 00153 Rome, Italy *(FAO JMPR Secretariat)*

ABBREVIATIONS

ADI	acceptable daily intake
ae	acid equivalent
ai	active ingredient
AR	applied radioactivity
ARfD	acute reference dose
asp gr fn	aspirated grain fraction
AU	Australia
BAM	2,6-dichlorobenzamide
BBCH	**B**iologischen Bundesanstalt, **B**undessortenamt und **CH**emische Industrie
bw	body weight
CAC	Codex Alimentarius Commission
CAS	Chemical Abstracts Service
CCN	Codex classification number (for compounds or commodities)
CCPR	Codex Committee on Pesticide Residues
*c*GAP	Critical GAP
CXL	Codex MRL
DALA	days after last application
DAP	days after planting
DALT	days after last treatment
DAT	days after treatment
DM	dry matter
DT_{50}	time required for 50% dissipation of the initial concentration
dw	dry weight
ECD	electron capture detector
EFSA	European Food Safety Authority
EPO	early post-emergence
equiv	equivalent
EU	European Union
FAO	Food and Agriculture Organization of the United Nations
fw	fresh weight
GA	glufosinate-ammonium
GAP	good agricultural practice
GC	gas chromatography
GC-ECD	gas chromatography with electron capture detection
GC-FID	gas chromatography with flame ionization detection

GC-FPD	gas chromatography with flame photometric detection
GC/MS	gas chromatography/mass spectrometry
GC/MSD	gas chromatography/mass selective detector
GC-NPD	gas chromatography coupled with nitrogen-phosphorus detector
GEMS/Food	Global Environment Monitoring System – Food Contamination Monitoring and Assessment Programme
GLC	gas liquid chromatography
GLP	good laboratory practice
GPC	gel permeation chromatography
HEPA	2-hydroxyethyl phosphonic acid; 2-hydroxyethephon
HPLC	high performance liquid chromatography
HR	highest residue in the edible portion of a commodity found in trials used to estimate a maximum residue level in the commodity
HR-P	highest residue in a processed commodity calculated by multiplying the HR of the raw commodity by the corresponding processing factor
IEDI	international estimated daily intake
IESTI	international estimate of short-term dietary intake
ISO	International Organization for Standardization
IUPAC	International Union of Pure and Applied Chemistry
JMPR	Joint FAO/WHO Meeting on Pesticide Residues
JP	Japan
LC	liquid chromatography
LOD	limit of detection
log P_{ow}	octanol-water partition coefficient
LOQ	limit of quantification
MOA	mode of action
MRL	maximum residue limit
MS	mass spectrometry
MS/MS	tandem mass spectrometry
ND	non-detect - below limit of detection
OECD	Organisation for Economic Co-operation and Development
OP	organophosphorus compound
PBI	plant back interval
Pf	processing factor
PH	pre-harvest
PHI	pre-harvest interval
ppm	parts per million
PRE	pre-emergence

QuEChERS	Quick, Easy, Cheap, Effective, Rugged, and Safe–Multiresidue pesticide analysis
RAC	raw agricultural commodity
RSD	relative standard deviation
RTI	re-treatment interval
SC	suspension concentrate
SL	soluble liquid
SPE	solid phase extraction
STMR	supervised trials median residue
STMR-P	supervised trials median residue in a processed commodity calculated by multiplying the STMR of the raw commodity by the corresponding processing factor
TAR	total administered radioactivity
TF	transfer factor
TFNA	4-trifluoromethylnicotinic acid
TFNA-AM	4-trifluoromethylnicotinamide
TFNA-OH	6-hydroxy-4-trifluoromethylnicotinic acid
TFNG	*N*-(4-trifluoromethylnicotinoyl) glycine
TFNG-AM	*N*-(4-trifluoromethylnicotinoyl) glycinamide
TLC	thin-layer chromatography
TRR	total radioactive residues

WHO	World Health Organization
WP	wettable powder

USE OF JMPR REPORTS AND EVALUATIONS BY REGISTRATION AUTHORITIES

Most of the summaries and evaluations contained in this report are based on unpublished proprietary data submitted for use by JMPR in making its assessments. A registration authority should not grant a registration on the basis of an evaluation unless it has first received authorization for such use from the owner of the data submitted for the JMPR review or has received the data on which the summaries are based, either from the owner of the data or from a second party that has obtained permission from the owner of the data for this purpose.

INTRODUCTION

A Joint Meeting of the Food and Agriculture Organization of the United Nations (FAO) Panel of Experts on Pesticide Residues in Food and the Environment and the World Health Organization (WHO) Core Assessment Group on Pesticide Residues (JMPR) was held at WHO Headquarters, Geneva (Switzerland), from 15 to 24 September 2015. The FAO Panel Members met in preparatory sessions on 10–14 September.

The meeting was opened by Dr Angelika Tritscher, Coordinator, Risk Assessment and Management, Department of Food Safety and Zoonoses, WHO. On behalf of WHO and FAO, Dr Tritscher welcomed and thanked the participants for providing their expertise and for devoting significant time and effort to the work of JMPR. She noted that the work of JMPR is of great importance, as it provides the scientific basis for international food safety standards as recommended by the Codex Alimentarius Commission. She emphasized that the programme is also important for other programmes within the Organizations; for example, the WHO Guidelines for Drinking-water Quality use the scientific advice provided by JMPR as the basis for the derivation of drinking-water guidelines for pesticides.

Dr Tritscher noted that further important considerations at the meeting related to methodological aspects, such as discussing the outcome of the recent workshop to review the international estimate of short-term dietary intake (IESTI) equations, in an effort to further improve and harmonize risk assessment methodology for pesticide residues. The Meeting was also asked to consider the outcome of the WHO Expert Task Force on Carcinogenicity of Diazinon, Glyphosate and Malathion, to provide recommendations to the Organizations on necessary actions in light of recent International Agency for Research on Cancer (IARC) hazard classifications. Dr Tritscher reminded the Meeting of the importance of food safety in public health; in order to raise awareness of this issue, WHO dedicated the 2015 World Health Day to food safety, with important advocacy and information material being available from the WHO website. Lastly, she reminded participants that they were invited as independent experts and not as representatives of their countries or organizations. She also reminded them of the confidential nature of the meeting, in order to allow experts to freely express their opinions.

During the meeting, the FAO Panel of Experts was responsible for reviewing residue and analytical aspects of the pesticides under consideration, including data on their metabolism, fate in the environment and use patterns, and for estimating the maximum levels of residues that might occur as a result of use of the pesticides according to good agricultural practice (GAP). Maximum residue levels, supervised trials median residue (STMR) levels and highest residue (HR) levels were estimated for commodities of plant and animal origin. The WHO Core Assessment Group was responsible for reviewing toxicological and related data in order to establish acceptable daily intakes (ADIs) and acute reference doses (ARfDs), where necessary.

The Meeting evaluated 29 pesticides, including eight new compounds and four compounds that were re-evaluated within the periodic review programme of the Codex Committee on Pesticide Residues (CCPR), for toxicity or residues, or both. The original schedule of compounds to be evaluated was amended, with dicamba and methoxyfenozide not considered for residues and fluazifop-*p*-butyl not considered for toxicity or residues owing to the submission of incomplete data sets.

The Meeting established ADIs and ARfDs, estimated maximum residue levels and recommended them for use by CCPR, and estimated STMR and HR levels as a basis for estimating dietary intake.

The Meeting also estimated the dietary intakes (both short-term and long-term) of the pesticides reviewed and, on this basis, performed dietary risk assessments in relation to their ADIs or ARfDs. Cases in which ADIs or ARfDs may be exceeded were clearly indicated in order to facilitate the decision-making process of CCPR. The rationale for methodologies for long- and short-term dietary risk assessment are described in detail in the FAO manual on the *Submission and evaluation of pesticide residues data for the estimation of maximum residue levels in food and feed* (2009).

The Meeting considered a number of current issues related to the risk assessment of chemicals, the evaluation of pesticide residues and the procedures used to recommend maximum residue levels.

ABAMECTIN (177)

First draft prepared by Professor Eloisa Dutra Caldas, University of Brasilia, Brazil

BACKGROUND INFORMATION

Abamectin belongs to the family of avermectins, which are macrocyclic lactones produced by a soil actinomycete, *Streptomyces avermitilis*. It is a broad-spectrum acaricide with additional insecticidal action on a limited number of insects. The compound acts on insects by increasing the membrane permeability to chloride ions, and it mainly stimulates the release of γ-aminobutyric acid (GABA). The affected arthropod becomes paralysed, stops feeding, and dies after a few days. It exerts contact and stomach action, with limited plant systemic activity, but exhibits translaminar movement into treated leaves. Abamectin is also used as an anthelmintic drug in veterinary medicine.

Abamectin was firstly evaluated by JMPR in 1992 (T,R). The latest review of toxicology data was conducted in 1997 and of residue data in 2000. Abamectin was scheduled at the 46th Session of the CCPR (2014) for the periodic re-evaluation of toxicology and residues by the 2015 JMPR.

For the residue evaluation, data were submitted on physical chemical properties, environmental fate, metabolism on plants and lactating goats, analytical methods, GAP, supervised trials on fruits, vegetables, nuts, beans, coffee, cotton and cereals, processing studies and a cow feeding study.

IDENTITY

Abamectin is a mixture containing ≥ 80% avermectin B_{1a} and ≤ 20% avermectin B_{1b}. The absolute stereochemistry of both avermectin homologues is known and defined at each chiral centre and stereogenic carbon-carbon double bond by their IUPAC nomenclature.

ISO Common Name:	Abamectin
Composition:	a mixture containing ≥ 80% avermectin B_{1a} and ≤ 20% avermectin B_{1b}
IUPAC nomenclature:	
Avermectin B_{1a}:	(10*E*,14*E*,16*E*)-(1*R*,4*S*,5′*S*,6*S*,6′*R*,8*R*,12*S*,13*S*,20*R*,21*R*,24*S*)-6′-[(*S*)-*sec*-butyl]-21,24-dihydroxy-5′,11,13,22-tetramethyl-2-oxo-(3,7,19-trioxatetracyclo [15.6.1.1^{4,8}.0^{20,24}]pentacosa-10,14,16,22-tetraene)-6-spiro-2′-(5′,6′-dihydro-2′*H*-pyran)-12-yl 2,6-dideoxy-4-*O*-(2,6-dideoxy-3-*O*-methyl-α-L-*arabino*-hexopyranosyl)-3-*O*-methyl-α-L-*arabino*-hexopyranoside
Avermectin B_{1b}:	(10*E*,14*E*,16*E*)-(1*R*,4*S*,5′*S*,6*S*,6′*R*,8*R*,12*S*,13*S*,20*R*,21*R*,24*S*)-21,24-dihydroxy-6′-isopropyl-5′,11,13,22-tetramethyl-2-oxo-(3,7,19-trioxatetracyclo[15.6.1.1^{4,8}.0^{20,24}] pentacosa-10,14,16,22-tetraene)-6-spiro-2′-(5′,6′-dihydro-2′*H*-pyran)-12-yl 2,6-dideoxy-4-*O*-(2,6-dideoxy-3-*O*-methyl-α-L-*arabino*-hexopyranosyl)-3-*O*-methyl-α-L-*arabino*-hexopyranoside
CA nomenclature:	
Abamectin:	Avermectin B_1
Avermectin B_{1a}:	5-O-demethyl-avermectin A_{1a}
Avermectin B_{1b}:	5-O-demethyl-25-de(1-methylpropyl)-25-(1-methylethyl)-avermectin A_{1a}
CAS registry no:

Physical and chemical properties

Abamectin technical material was of high purity (> 98%) and was used for the determination of the physical and chemical properties of the pure active substance.

Properties of abamectin (> 98% purity) and degradation in water (avermectin B_{1a})

Property	Results	Reference; Report
Appearance(physical state, colour, odour)	White powder, odour was not determined	Das, R 1999
Vapour pressure	< 3.7×10^{-6} Pa at 25 °C was calculated using the LOQ of the test substance	Widmer, H 1999;1999a
Melting point	Melting range: 161.8 °C–169.4 °C, with thermal decomposition during melting	Das, R 1999;
Partition coefficient n-octanol/water	Average log K_{OW} was 4.4 ± 0.3	McCauley, JA 1996
Solubility in water	1.21 ± 0.15 mg/L (pH = 7.57 ± 0.23) at 25 ºC	McCauley, JA 1997
Solubility in organic solvents	At 25 ºC: acetone: 72 g/L dichloromethane: 470 g/L ethyl acetate: 160 g/L hexane: 0.11 g/L methanol: 13 g/L octanol: 83 g/L toluene: 23 g/L	Stulz, J 1999
Density	Density 1.18×10^3 kg/m^3, corresponding to a relative density of 1.18. At 22 ºC.	Füldner, HH 1999
Hydrolysis in water	No hydrolysis at pH 4–9, 25 °C	Maynard, S, Ku, CC 1982;

Property	Results	Reference; Report
[^{3}H] avermectin B_{1a}	No hydrolysis at pH 4–7, 50 °C pH 9, 60 °C: 4.9 d pH 9, 50 °C: 9.9 d pH 9, 25 °C: 213 d (extrapolated) pH 9, 20 °C: 380 d (calculated with Arrhenius equation) Metabolites: 2-epi-avermectin B_{1a}: 25% of AR at 50 and 60 °C 1,18 hydrolysed avermectin B_{1a}: 17.5% of AR at 60 °C unknown: 15.6% of AR at 60 °C	Ellgehausen, H 2001
Photochemical stability in water [23–^{14}C] avermectin B_{1a}	Xenon lamp. DT_{50}: 2 d (equivalent to 1.5 sunlight days at 30–50 °N, pH 7) Metabolites: 8α-oxo-avermectin B_{1a}: 5.6% of AR [8,9-Z]-avermectin B_{1a}: 8.2% of AR, DT_{50},photo 5.8 sunlight days at 30–50 °N	Adam, D 2001
Dissociation constant	No dissociation or spectral changes were observed in the 1–12 pH range at 20 ºC	Hörmann, A 1999

The abamectin technical material of a purity of 96.7% was used for colour, physical state, vapour pressure, melting point, octanol/water partition coefficient, solubility in organic solvents, density, dissociation constant and thermal stability studies. The radio-labelled avermectin B_{1a} used for hydrolysis in water and photochemical stability in water had a radiochemical purity of ≥ 95.6%. The abamectin technical material used for aqueous solubility determination was of unknown purity.

Technical grade material.

Property	Results	Reference
Minimum purity	Min. 850 g/kg	EC COMMISSION DIRECTIVE 2008/107/EC
Melting Range	Melting range: 161.8 °C–169.4 °C, with thermal decomposition during melting	Das, R 1999; 1999a
Stability (thermal)	Decomposition starts at about 162 °C (see also ‘melting range’)	Das, R 1999; 1999a

ENVIRONMENTAL FATE AND METABOLISM

The fate and behaviour of abamectin in soils, water, plants and animals were investigated using [^{14}C] and/or [^{3}H] labelled avermectin $B_{1a.}$

	[^{14}C] avermectin B_{1a}: mixture of five single ^{14}C-labelled compounds at C3, C7, C11, C13, and C23 of the main complex. A radioactive label only at the C23 position was also used in some studies ([23-^{14}C])	[^{3}H] avermectin B_{1a}: labelled at C5 of the main complex
Used on studies with soil, citrus, cotton and celery, tomato	Used on studies with soil, celery and lactating goat

The chemical structures of the major degradation compounds arising from the environmental fate and metabolism studies are shown below.

Name	Structure	Compound found in
8α-oxo-avermectin B_{1a}		Aerobic soil Tomato Rat
8α-hydroxy-avermectin B_{1a}		Aerobic soil Celery Tomato Rat
4,8α-dihydroxy-avermectin $_{B1a}$ (also 4,8α-dihydroxy-$\Delta^{2,3}$-avermectin $_{B1a}$)		Aerobic soil
8α-oxo-4-hydroxy-avermectin $_{B1a}$ (also 8α-oxo-4-hydroxy-$\Delta^{2,3}$-avermectin B_{1a})		Aerobic soil

Name	Structure	Compound found in
8,9-Z isomer of avermectin B_{1a}		Soil photolysis Citrus Cotton Celery Tomato
2-Epi-avermectin B_{1a}		Hydrolysis product at pH 9
DT3		Hydrolysis product at pH 9
1,18-hydrolysed avermectin B_{1a}		Hydrolysis product at pH 9
Monosaccharide of avermectin B_{1a} or 4'-O-de(2,6-dideoxy-3-O-methyl-α-L-arabino-hexopyranosyl)-5-O-demethyl-avermectin A_{1a} (Unknown 1)		High temperature hydrolysis
((2S,4S,6S,8R,9S)-8-sec-Butyl-4-hydroxy-9-methyl-1,7-dioxa-spiro[5.5]undec-10-en-2-yl)-acetic acid (I_4)		Tomato
4"-oxo-avermectin B_{1a}		Tomato

Name	Structure	Compound found in
3"-O-desmethyl-avermectin B_{1a}		Tomato Goat, Rat
4"-,8α-di-oxo-avermectin B_{1a} (I_{37})		Tomato
(24-hydroxymethyl) avermectin B_{1a}		Goat, Rat

ENVIRONMENTAL FATE

Aerobic degradation in soil

The degradation of [^{14}C]avermectin B_{1a} was investigated in the laboratory under aerobic conditions in one soil (Gartenacker loam) incubated at 20 °C (Nicollier, 2001). The test substance was applied to the soil at a rate of 0.22 mg/kg, equivalent to a field rate of 0.28 kg ai/ha assuming a soil density of 1.3 g/cm^3 and uniform distribution in the upper 10 cm soil layer. Aerobic samples were incubated over 365 days with a soil moisture content of 40% of the maximum water holding capacity. Sampling intervals were immediately after application (0 days) up to 365 days. Samples were submitted to exhaustive extraction and the extracts were analysed by two dimensional TLC and by HPLC. The identity of the soil metabolites was determined by liquid chromatography/mass spectrometry (LC/MS) and nuclear magnetic resonance spectroscopy (NMR). The extracted radioactivity declined from 97.9% at day 0 to 30.6% of the applied radioactivity (AR) at the end of the study (Table 1). Non-extracted residues increased during the study and reached 33.9% AR at Day 365. Non-extracted residues from Day 168 sample were submitted to reflux under neutral and acidic conditions, releasing 5.7% AR. Fractionation of non-extracted residues showed 6–10% AR associated with the fulvic, humin and humic acid fractions. Organic volatiles were ≤ 0.1% AR. The amount of avermectin B_{1a} declined from 97.9% at Day 0 to 1.4% AR at Day 365. 8α-oxo-avermectin $B_{1a}$and 8α-hydroxy avermectin B_{1a} reached a maximum at Day 28. Two minor metabolites were identified as 4,8α-dihydroxy-avermectin B_{1a} and 8α-oxo-4-hydroxy-avermectin B_{1a} amounting at maximum to 9.3% AR. All other metabolites individually represented ≤ 4.1% AR.

Table 1 Distribution of degradation products of avermectin B_{1a} under aerobic conditions (%AR)

Incubation Time	Extracted residues	$^{14}CO_2$	Non-extracted residues	Avermectin B_{1a}	8α-oxo-avermectin B_{1a}	8α-hydroxy avermectin B_{1a}	4,8α-dihydroxy-avermectin B_{1a}	8α-oxo-4-hydroxyavermectin B_{1a}	Recovery

n.d. = Not detected

Avermectin B_{1a} was rapidly degraded under aerobic conditions with a half-life of 18 days. Avermectin B_{1a} was either hydroxylated to 8α-hydroxy avermectin B_{1a} or oxidised to 8α-oxo avermectin B_{1a}. Both of these major metabolites were further hydroxylated with half-lives of 35.4 and 32.5 days, respectively. The endpoint of the metabolic pathway under aerobic conditions was mineralisation to carbon dioxide accounting for up to 27.6% AR, accompanied by the formation of unextracted residues. Table 2 summarizes the half-lives and DT_{90} values for avermectin $B_{1a}$and metabolites.

Table 2 Half-lives and DT_{90} values for avermectin B_{1a} and soil metabolites under aerobic conditions (Nicollier, 2001)

Compound	DT_{50}(days)	DT_{90}(days)
avermectin B_{1a}	18.0	59.6
8α-oxo-avermectin B_{1a}	32.5	108.0
8α-hydroxy-avermectin B_{1a}	35.4	117.8
4,8α-dihydroxy-avermectin B_{1a}	105.2	349.4
8α-oxo-4-hydroxy-avermectin B_{1a}	83.3	276.8

The degradation of [23-^{14}C]-labelled avermectin B_{1a} was investigated in Gartenacker soil (loam/silt loam) under various conditions (Adam, 2001a). Soil samples were treated with avermectin B_{1a} at 0.1 mg/kg dry soil, corresponding to a field rate of 100 g ai/ha. Samples were incubated under aerobic conditions in the dark at a temperature of 30, 20 and 10 °C with a soil moisture content of 40% water holding capacity (WHC; Series 1, Series 2 and Series 3, respectively). In addition, one experiment was performed at 30 °C and 25% WHC (Series 4). Duplicate samples were taken for analysis at each sampling time and submitted to exhaustive extractions before analysis by TLC and HPLC.

The distribution of radioactivity and metabolites at different sampling dates are summarized in Table 3. The extracted radioactivity declined from the beginning to the end of the study, followed by an increase in the non-extracted residues. When non-extracted residues of Day 120 samples were submitted to reflux under neutral and acidic conditions, 4 to 6% AR were released for series 1, 2, 3 and 4, respectively. Subsequent fractionation of the unextracted residues showed that 3 to 12.6% AR associated with the fulvic acid, humic acid and humin fraction.

The amount of avermectin B_{1a} declined from over 90% AR on Day 0 to up to 22.6% on Day 120 (Table 3). 8α-hydroxy-avermectin B_{1a}, formed as major metabolite under all four conditions, reached its highest level on Day 28; 8α-oxo-avermectin B_{1a} was formed above 10%

AR only in series 1, 2 and 3. Two other metabolites, 4,8α-dihydroxy-avermectin B_{1a} and 8α-oxo-4-hydroxy-avermectin B_{1a}, were found in amounts up to 9.9% depending on the incubation conditions (Table 5). Up to 19 minor metabolites were formed during the course of the study, each representing ≤ 5% AR.

The degradation of [23-^{14}C]-labelled avermectin B_{1a} was investigated in Pappelacker soil (loamy sand), 18 Acres soil (sandy clay loam), and in Marsillargues soil (silty clay loam) under aerobic conditions at 20 ± 2 °C in the dark (Phaff, 2012). Soils were treated with avermectin B_{1a} at 0.125 mg/kg dry soil, incubated over 196 days under aerobic conditions in the dark with a soil moisture content of 40% water holding capacity (WHC). Samples were taken for analysis at 0 up to 196 days after treatment and submitted to exhaustive extraction procedures. The extracts were concentrated and analysed by TLC and HPLC.

The distribution of radioactivity and the metabolites at different sampling dates are summarized in Table 5. Non-extracted residues reached at least 30% AR. Day 126 samples submitted to reflux under neutral and acidic conditions released from 5.6 to 13.6% AR. Subsequent fractionation of the unextracted residues showed the up to 13.7% AR associated with fulvic acid, humic acid and humin. Avermectin B_{1a}residues declined from over 95% AR at the start of the experiment to < 7% AR at Day 196; 8α-oxo-avermectin $B_{1a}$and 8α-hydroxy-avermectin B_{1a} were the major metabolites found, in addition to 4,8α-dihydroxy-avermectin B_{1a} and 8α-oxo-4-hydroxy-avermectin B_{1a}.

The degradation of ^{3}H-labelled avermectin B_{1a} and ^{14}C-labelled avermectin B_{1a} was investigated in the laboratory under aerobic conditions in three different soils (Lufkin fine sandy loam, Houston clay and a coarse “construction grade” sand) incubated at 25 °C, at a soil moisture level of 75% of Field Capacity (Ku & Jacob, 1983). The test substance was applied to the soil at 0.1, 1.0 and 50 mg/kg. Samples were submitted to exhaustive extraction and the extracts analysed by TLC and HPLC. In order to account for the loss of radioactivity in all the aerobic soil studies a study was carried out with a biometer flask containing Lufkin fine sandy loam treated with ^{14}C-labelled avermectin B_{1a} (10 mg/kg) to determine the amount of $^{14}CO_2$ produced during the course of the study.

Avermectin B_{1a} degraded at a fairly rapid rate to at least 13 radioactive products, the major fraction being an equilibrium mixture (ratio of 1:2.5) of the 8-α hemiacetal derivative and the corresponding ring-opened hydroxy aldehyde derivative of avermectin B_{1a}, identified by NMR, MS and FTIR. Minor products, which individually never exceeded 2–3% AR, were found in addition to the metabolites listed in Table 7. The mineralisation of ^{14}C-labelled avermectin B_{1a} to carbon dioxide reached a maximum of 3.2% during a 21 week study.

In experiments with [^{3}H]avermectin B_{1a} there were substantial quantities of volatile radioactive material (approximately 27.6–45.5% of the dose through the experiments) condensed in the water which was used to maintain the level of relative humidity. Since none of this radioactive material partitioned into dichloromethane it is concluded that it represents tritiated water rather than volatile organic materials. As the specific activity of ^{3}H-labelled avermectin B_{1a} was unchanged after 28 days of exposure it can be concluded that there was no apparent tritium exchange upon ageing of [^{3}H]avermectin B_{1a} in treated soil. The apparent release of tritium resulted from metabolic oxidation at the C5 position of the parent molecule or a degradate.

Unextracted residues increased with time, reaching a maximum of 12.2 to 35.0% AR. In most cases, there was a progressive increase in % AR which could not be accounted for in the radio-balance assessment, reaching values below 52% AR at the end of incubation. Since this loss was also observed among samples held in containers in which condensed volatile radioactive material was measured, it was assumed that the trapping of these volatiles was inefficient. Table 8 shows the half-lives estimated for avermectin B_{1a} in the various soils.

Soil photolysis

[^{14}C]avermectin B_{1a} was applied at a rate of 0.09 kg/ha onto the surface of a moist (75% FC) 2 mm soil layer and irradiated with a xenon arc light source in a wavelength range of 300–400 nm and at a light intensity of 84.7 ± 3.8 Wm^{-2}(Phaff, 2001). The mean temperature of the soil layers was kept at 24.5 ± 0.1 °C. The total irradiation time was 336 hours of xenon light (28 days incubation) equivalent to 47 days of natural summer sunlight (NSS) at latitudes 30 to 50 °N. Irradiation was performed in cycles of 12 hours xenon light and 12 hours darkness. Dark control samples were incubated for 28 days. Replicate samples were taken at 0 to 28 days, extracted and analysed by TLC and HPLC.

The overall recovery of radioactivity ranged between 96.9 and 102.8% AR for the irradiated samples (Table 9) and between 101.8 and 104.8% AR for the dark controls. At the end of the irradiation period, avermectin B_{1a} accounted for 19.5%AR in the irradiated soil (Table 9) and 86% AR in the control. In addition to the parent compound, six minor photoproducts were formed in the irradiated samples, two identified as 8α-oxo-avermectin B_{1a} and 8α-hydroxy-avermectin B_{1a} (Table 9). All other degradation products were below 5.3%. In the dark control samples four degradation products were observed, two of them were identified as 8α-oxo-avermectin B_{1a} and 8α-hydroxy-avermectin B_{1a} (≤ 5%). Under irradiation, non-extracted radioactivity increased from 0.3% at Day 0 up to 25.9% at the end of the study, and volatiles in the form of $^{14}CO_2$ amounted to 7.6%.

A soil photolysis study was conducted using [^{3}H]avermectin B_{1a} applied to a clay loam soil kept outdoors at latitude 40.5 ºN during the summer (Ku & Jacob, 1983a). Soil TLC plates (20 cm × 20 cm) were prepared by spreading a slurry of air dried soil (40 g) and methanol (30 mL) and air dried at room temperature before use. Approximately 50 µL of a solution of [^{3}H]avermectin B_{1a} (0.85 mg/mL methanol) was applied to several pre-scored soil thin layer plates (6.5 cm^2). The treated plates were exposed to sunlight and sampled at 0 to 31 hours. At each sampling time, a square of the soil thin film was carefully scrapped off the plates, transferred to a glass column, eluted with ethyl acetate followed by methanol and the eluents analysed by HPLC. Soil residues were air-dried and combusted for radio assay. Total recovery [%] of [^{3}H]avermectin B_{1a} from the soil thin layer extracts is presented in Table 11.

Table 11 Photodegradation of [^{3}H]avermectin B_{1a} in soil thin layer plates exposed to sunlight

Exposure Time [hr]	% [^{3}H]avermectin B_{1a} remaining		
	Ethyl acetate extract	Methanol extract	Total
0	93.1	5.7	98.8
1	84.7	6.4	91.1
2	82.7	6.2	88.9
4	78.0	6.9	84.9
8	70.5	8.6	79.1
16	56.8	6.4	63.2
31	27.3	5.3	32.6

A plot of the logarithm of the remaining [^{3}H]avermectin B_{1a} against time gives a straight line, indicating first order kinetics. The calculated half-life (DT_{50}) from this plot is approximately 21 hours. The metabolic pathway of avermectin $B1_a$ in soil is proposed in Figure 1.

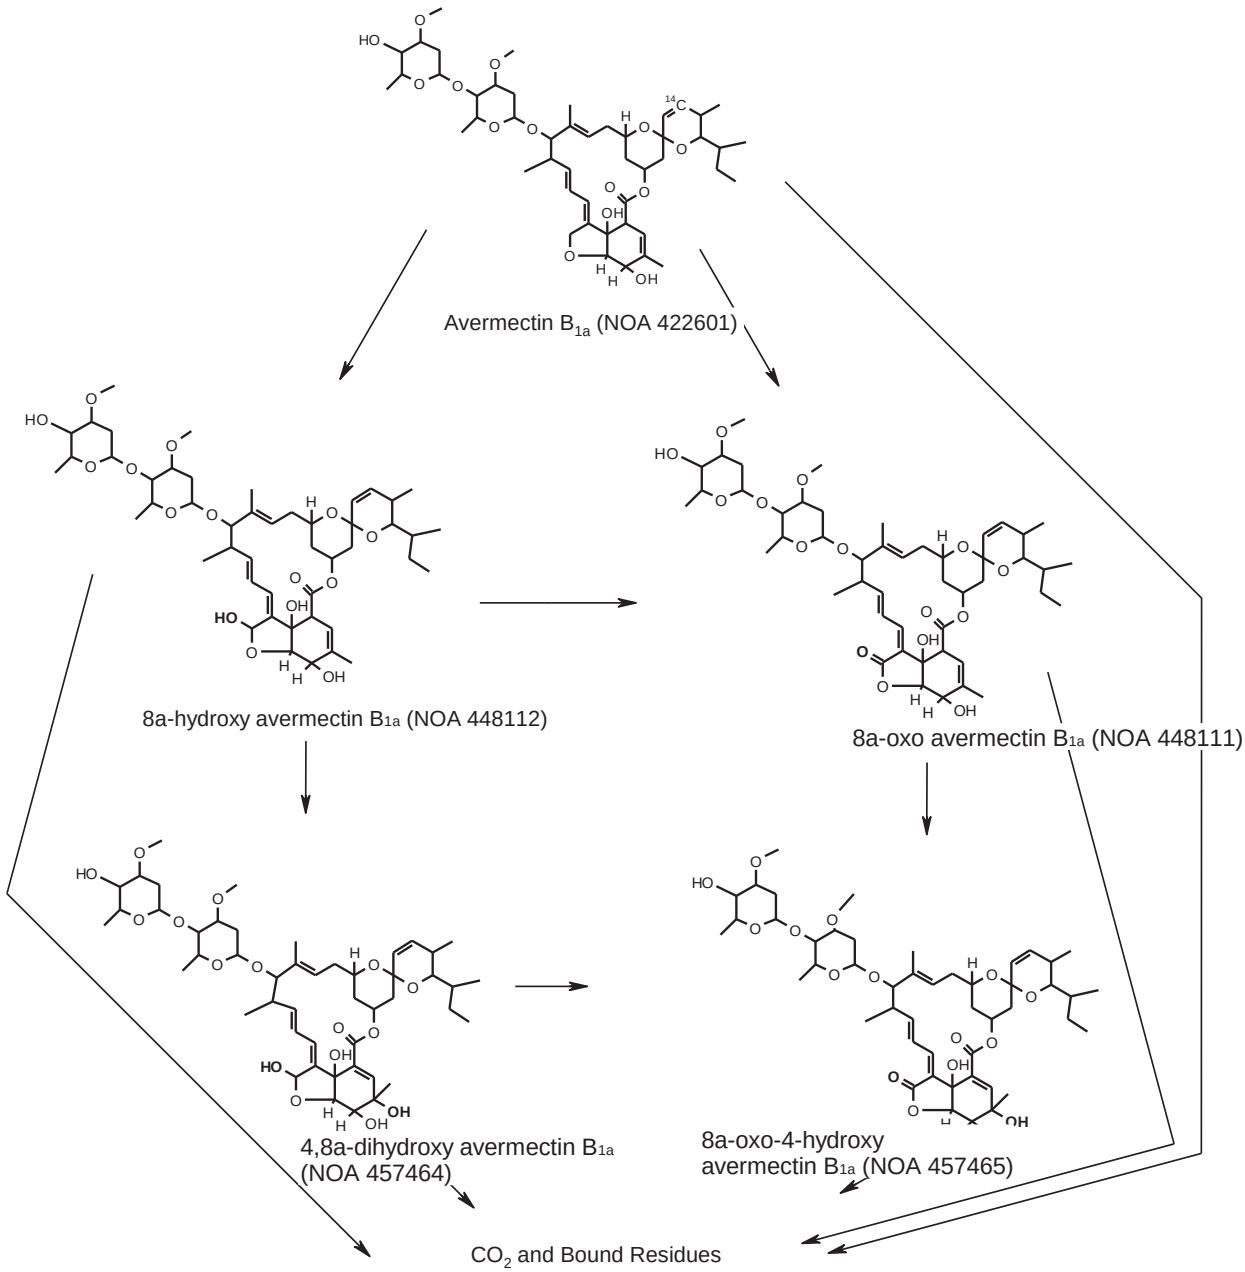

Figure 1 Metabolism of avermectin B_{1a} in soil

Plant metabolism

Citrus

The metabolism of [^{14}C]avermectin B_{1a} was investigated in citrus plants (oranges, lemons and grapefruit) (Maynard *et al.*, 1989). An open wooden frame with a fibreglass roof was constructed over each tree to minimize the reduction in residues by atmospheric precipitation. Solutions of [^{14}C]avermectin B_{1a}were prepared in an EC formulation blank (8 and 80 mg ai/L), and 0.5 mL solution was painted on each fruit using a small brush. Twenty one oranges, lemons and grapefruit were each treated with the 8 mg ai/L solution (4 µg), resulting in an initial concentration of 18 to 36 µg ai/kg on a whole fruit basis. Seventy eight oranges on two adjacent trees were treated with the 80 mg ai/L solution, resulting in initial deposits of 40 µg ai per whole fruit. Samples (three fruits) were collected on the day of application up to 12 weeks post application. For the 80 mg ai/L treatment, 15 additional fruits were sampled at weeks 2 to 12.

Each fruit was rinsed twice with methanol, the fruits peeled, the pulp rinsed with tap water, dried with a paper towel, combusted and the radioactivity, trapped as CO_2, measured. The skin was blended with dry ice, a portion taken for combustion analysis, the remainder extracted with acetone, the extracted dried, the residue partitioned between dichloromethane and water. The radioactivity remaining in the peel solids after acetone extraction was exhaustively extracted with methanol and tetrahydrofuran, followed by six additional methanol extractions or subjected to five successive Bligh-Dyer extractions (mixture of chloroform and methanol, dilution with chloroform and water, the chloroform layer containing all the lipids), methanol extraction, Soxhlet extraction, acid and enzyme hydrolysis procedures. Based on preliminary evidence that the degradation of avermectin B_{1a} was primarily photochemical in nature, the degradation of avermectin B_{1a} was investigated in thin film and aqueous photolysis. All extracts were analysed by reversed-phase HPLC.

The decline of the total radioactivity from the treated fruit over a 12-week period is shown in Table 12. At the end of the experiment, the residues ranged from 33.3% (grapefruit) to 49.8% (lemons) of the applied radioactivity (AR).

Table 12 Decline of radio-labelled residues in citrus following application of a [^{14}C]avermectin B_{1a} solution at 8 mg ai/L (4 μg/fruit) or 80 mg ai/L (40 μg/fruit)

Time (weeks)	Total Radioactive Residue, as % of the applied radioactivity [a] (in mg/kg)			
	Orange (8 mg ai/L)	Lemon (8 mg ai/L)	Grapefruit(8 mg ai/L)	Orange (80 mg ai/L)
0	100 (0.050)	100 (0.028)	100 (0.027)	100.0 (0.229)
1	61.3	72.5	60.5	90.0
2	58.7	72.2	52.9	79.0
4	51.6	59.2	48.2	66.3
8	38.4	45.2	41.5	45.1
12	43.9	49.8	33.3	41.6

[a] TRR is the sum of the radioactivity in all the fruit fractions.

In general, most of the residues were rinsed from the surface with methanol (Table 13). No residues were detected in the pulp portion without the peel/pulp interface at both rates for all fruits. When the interface was included, residues reached a maximum of 12–13%TRR after 8 weeks of application.

Table 13 Extracted residues (%TRR) in citrus following application of a [^{14}C]avermectin B1a solution with at 8 mg ai/L (4 μg/fruit) or 80 mg ai/L (40 μg/fruit)

	Orange (8 mg ai/L)			Lemon (8 mg ai/L)			Grapefruit (8 mg ai/L)			Orange (80 mg ai/L)

8	32.2	31.0	63.2	13.4	29.8	43.2	34.2	22.6	56.8	41.7	28.1	69.8
12	36.3	21.4	57.7	6.7	30.8	37.5	32.7	18.9	51.6	40.9	19.2	60.1

Table 14 shows the characterization of the extracted residues from the fruits treated at the lowest rate. At least 90% TRR was found to be avermectin B_{1a} at Day 0, a level that decreased rapidly at Day 1 (maximum of 17.4% TRR in orange). After 1 day, most of the extracted residues were of a polar nature, accounting for at least 46% TRR at Day 12 in oranges. The moderately polar fraction (up to 12.5% TRR in 1 day orange samples) included 5 to 10 moieties. The 8,9-Z isomer of avermectin B_{1a}, also identified in the photolysis experiment on orange peel sections, accounted for < 5% TRR in all samples.

The acetone-extracted peel from the 2-week 8 mg/kg fruits was extracted three times with methanol followed by three extractions with THF, releasing 51, 40 and 54% of the matrix radioactivity (or 21, 11 and 25% of TRR) for the oranges, lemons, and grapefruits, respectively. The methanol and THF extracts were combined and partitioned between dichloromethane and water; approximately 60% of the radioactivity partitioned into the dichloromethane phase. The spent peel was extracted six times with methanol, and released an additional 7.0, 6.0 and 5.3% of the matrix radioactivity for the oranges, lemons and grapefruits, respectively. Characterization of the extracted radioactivity from the methanol and THF extractions produced polar, moderately polar, avermectin B_{1a} and the 8,9-Z isomer of avermectin B_{1a} fractions. Avermectin B_{1a} represented 2, 7 and 1% of the radioactivity for the oranges, lemons and grapefruits, respectively. The degradate characterization was qualitatively similar to that observed with the acetone extraction for the same samples.

Table 14 Characterization of the Total Extracted Residue (methanol rinse plus acetone peel extract) from fruits treated (4 µg/fruit) of [^{14}C]avermectin B_{1a}

[a] Data are presented as percent of the normalized recovered radioactivity

Table 15 shows the work-up of non-extracted residues of the 12 week oranges using an 80 mg ai/L solution treatment. The acetone-extracted peel was extracted by five successive Bligh-Dyer procedures, which recovered 23.8% TRR. A fraction of this extract was tentatively identified by NMR and mass spectrometry as a mixture of linoleic fatty esters. Reverse-phase HPLC showed the major fraction of the radioactivity was polar degradates and avermectin B_{1a} represented between 9 and 12% TRR. The non-extracted residues after Bligh-Dyer (11.8% TRR) were subjected to Soxhlet extraction with methanol and the remaining peel subjected to acid hydrolysis (pH 1.3 for 24 hours at room temperature), leaving 8.8% TRR as non-extracted (Experiment 1). In another experiment, the peel solids remaining from the Bligh-Dyer were subjected to sequential enzymatic hydrolysis (cellulase, pectinase, and ß-glucosidase), that reduced the non-extracted residues to 7% TRR (Table 15).

Table 15 Removal of radioactivity from the orange peel non-extracted from fruit treated with an 80 mg ai/L solution (40 µg/fruit) of [^{14}C]avermectin B_{1a}

Fraction	% Radioactivity in Fraction [a]	% Whole Fruit TRR
12 week DAT 80 mg/kg		100.0
Methanol wash		40.9
Peel residue after methanol wash		54.7
Acetone Extraction		19.2
Bligh-Dyer Extraction		23.8
Experiment 1		
Bligh-Dyer Peel Solid	100	11.8
Methanol Soxhlet	10	1.2
Peel Solid after Soxhlet Extraction	90	10.6
Filtrate after Acid Hydrolysis	16	1.8
Peel Solid after Acid Hydrolysis	75	8.8
Experiment 2		
Bligh-Dyer Peel Solid	100	11.8
Filtrate after Cellulase, Pectinase, ß-glucosidase Hydrolysis	7	0.8
Peel Solid after Enzyme Hydrolysis	93	11.0

Values for solid samples were determined by subtraction of extracted residues from TRR. Combustion of the solid samples was not possible due to the condition of the solid with associated filter paper.

[a] Values are expressed as a percentage of the Bligh-Dyer Peel Solid

Celery

The metabolism of [^{3}H] and [^{14}C]avermectin B_{1a} was investigated in field-grown celery in two experiments (Moye, 1988). In the first, potted celery plants grown under field conditions were treated 10 times at weekly intervals and harvested at maturity. In the second experiment, potted celery plants were treated four times at weekly intervals and harvested as immature plants. [^{14}C]avermectin B_{1a} was applied at 16.8 g ai/ha and [^{3}H]avermectin B_{1a} was applied at 11.2 g ai/ha or 112 g ai/ha. The test material was applied to the foliar portion of the plants as EC formulated solutions at a rate equivalent to 460 L/ha. Two groups of three plants were harvested at each experiment. Immature celery plants were harvested from the [^{3}H]avermectin B_{1a} treatments at 0 day to 6 weeks after the fourth application and mature plants were harvested 0 days to 22 days after the tenth application of [^{3}H]avermectin B_{1a}. Immature celery plants were harvested from the [^{14}C]avermectin B_{1a} treatments at 0 days and 2 weeks after the fourth application and mature plants were harvested 0 day and 1 week after the tenth application. Samples were blended with acetone, an aliquot extracted three to six times with acetone, the residual solid dried and reconstituted with methanol/water (85:15) for chromatography, and further extracted with several solvents, including methanol/water (40:60 v/v). Hot DMSO was used to solubilise lignin and hot sulphuric acid to convert cellulose to glucose.

Residues in immature and mature celery from plants receiving 4 and 10 applications of [^{3}H]avermectin B_{1a} are shown in Table 16. In average, residues in immature leaves and stalks samples at 43 days after the 4th application accounted for < 1% of the residues at Day 0. In mature plants from the 11.2 g ai/ha treatment, residues after 22 days of the 10th application accounted for 23 and 15% of the residues at Day 0 in leaves and stalks, respectively. Similar results were found in plants treated at the higher rate.

Table 16 Radio-labelled residues in celery following application of [^{3}H]avermectin B_{1a} in µg/kg avermectin B_{1a} equivalents. Three plants per group.

On average, residues in immature plants harvested at 14 days after the 4th application of [^{14}C]avermectin B_{1a} at 16.8 g/ha accounted for 5,4 and 12% of the 0 day residues for leaves and stalks, respectively (Table 17). In mature plants harvested after 7 days of the 10th application, these values were 38 and 54%, respectively.

Table 17 Radio-labelled residues in celery following application of [^{14}C]avermectin B_{1a} at 16.8 g/ha. Three plants per group.

HPLC profiling of the acetone extracts from mature and immature celery plants are shown in Tables 19 and 20. Polar metabolites (more polar than parent) accounted for most of the residues in both leaves and stalks. In leaves, polar metabolite residues increased with the DAT, moderately polar metabolites remained relatively constant, while avermectin B_{1a} and its 8,9-Z isomer decreased during the sampling period. Residues in immature stalks showed a different profile, with polar metabolites decreasing and avermectin B_{1a} increasing after 7 days DAT. Further profiling indicated also the presence of 8-hydroxy avermectin B_{1a} (not quantified) and at least ten other unidentified minor components.

Table 21 shows the radioactivity released from the acetone non-extracted residues. In a preliminary experiment, residual solids following acetone extraction, which contain ^{3}H residues, were serially extracted with methanol/water (40:60), chloroform, dichloromethane, toluene and cyclohexane. Almost all (83%) of the radioactivity removed was associated with the methanol/water fraction, which was further treated with hot DMSO. Characterization of residues showed them to be mostly polar degradates of avermectin B_{1a} and < 1% TRR was released as parent compound. Further experiments with celery leaves using hot sulphuric acid indicated that 15% of the acetone non-extracted residues were incorporated into glucose. Residues in ^{3}H- and ^{14}C-leaves remaining after all treatments represented 10.6% and 4.1% of the TRR, respectively.

Table 21 Release of non-extracted residues from celery following application of [^{3}H] or [^{14}C]avermectin B_{1a}

Treatment/Product	Celery Leaves		Celery Stalks	
	Percent TRR	µg/kg eq.	Percent TRR	µg/kg eq.

Cotton

The metabolism of [^{14}C]avermectin B_{1a} was investigated in cotton in four experiments conducted in Texas and Florida (Wislock, 1986).

Experiment 1

Individual leaves were treated *in situ* by spreading 100 µg of [^{14}C]avermectin B_{1a} in an aqueous emulsion prepared from an EC formulation. Leaves were sampled in triplicate up to 8 days post-treatment, rinsed with alcohol and homogenized with acetone/water (9:1 v/v). Solids were separated by centrifugation and re-extracted twice with acetone.

Experiment 2

Small field plot of cotton plants was treated twice by foliar spray at 20 g ai/ha in a volume equivalent to 100 L/ha. Leaves were manually removed from plants when bolls reached maturity. Cotton bolls were de-linted with acid and the seeds extracted by Soxhlet with hexane for about 17 hours. The resultant solid fraction was extracted sequentially by reflux with methanol, acidic methanol, and basic

methanol. The hexane extract was evaporated, the resulting oil fractionated using a silica gel column, and the major radioactive fraction hydrolysed under alkaline conditions.

Experiments 3 and 4

In Florida, cotton plants were grown in buckets under normal field conditions and treated three times by foliar spray using an EC formulation at 22.4 g ai/ha (Experiment 3) or at 224 g ai/ha (Experiment 4), both using 467 L/ha. The bolls were harvested approximately 20 days after the last treatment (DAT), delinted, and leaves, stems, branches, roots and bract/calyx from each treatment were sampled. The cottonseeds were extracted as described before.

The incorporation of the radioactivity into the cotton leaves in Experiment 1 is summarized in Table 22. The total surface residues decreased by first order kinetics, with residues decreasing from 99.7% of the applied dose at Day 0 to 19.3% at Day 8. The parent compound degraded at a much faster rate, with an apparent half-life of approximately 12 hours, accounting for 1.7% of the applied dose after 8 days.

Table 22 Fate of [^{14}C]avermectin B_{1a}, in % AR,after foliar application to individual cotton leaves at 100 µg/leaf (Experiment 1)

	External rinse with methanol			Internal extract (acetone and water 9:1)				
		Avermectin B_{1a}			Avermectin B_{1a}			
DAT	Total	TLC	HPLC	Total	TLC	HPLC	Non-extracted	Lost
0	99.7	99.2	99.4	0.6	0.4	0.6	0.1	0.0
1/4	84.7	57.1	40.3	3.7	2.6	2.0	2.9	8.7
1	82.7	41.0	36.4	8.6	5.7	4.6	6.3	2.4
2	60.1	13.9	9.7	8.2	4.4	3.2	12.6	19.1
4	43.7	4.2	2.4	9.5	3.2	2.5	26.1	20.7
8	19.3	1.7	1.0	15.9	2.6	3.0	23.1	41.7

Table 23 shows the results of Experiments 2 to 4. In Experiment 2, the highest residues were in the leaves (396 µg/kg), and the lowest in the lint (37 µg/kg) and seeds (50 µg/kg). In Experiment 3, the highest residues were in the leaves (46 µg/kg) and the lint (44 µg/kg), and the lowest in the seeds (10 µg/kg) and roots (6 µg/kg). In Experiment 4, the last treatment was made when approximately 50% of the bolls were open, which may explain the high residues found in the lint (750 µg/kg).

The metabolic profiles based on HPLC/radiochemical analyses for both the methanol rinse and the acetone/water extracts of the leaves from Experiment 1 are shown in Table 24. The amount of the 8,9-Z isomer of avermectin B_{1a} ranged from 0.1 to 7.0% AR in both the methanol rinse and the acetone/water extract.

Table 24 Extracted radioactivity (% AR) from leaves of cotton plants treated with [^{14}C]avermectin B_{1a} (Experiment 1)

The radioactive residues extracted from cotton seed at harvest are shown in Table 25. A major fraction of the residues was extracted with hexane, mainly from cottonseed oil. When the oil was chromatographed on silica gel, the residues were found to co-elute with triglycerides. The hydrolysis of this fraction under basic conditions released linoleic acid and palmitic acid. Non-extracted material amounted to 25% of the TRR after sequential extraction with five solvents in Experiment 2.

The metabolism of [^{14}C]avermectin B_{1a} in citrus fruit, cotton leaves and celery leaves (also [^{3}H]avermectin B_{1a}) was compared with thin film photolysis on glass plates (Crouch, 1988). Nearly mature oranges were treated with [^{14}C]avermectin B_{1a} by application of an aqueous suspension of an EC formulation with a small brush, and oranges harvested at 1 and 2 weeks post-application. Individual leaves of cotton plants were treated with [^{14}C]avermectin B_{1a} and leaves harvested after 2, 4 and 8 days. Orange and cotton leaves were rinsed with methanol. Mature celery plants were treated with [^{3}H]avermectin B_{1a} at 112 g/ha or [^{14}C]avermectin B_{1a} at 16.8 g/ha, harvested at 0 or 7 days after the last application and leaves and stalks homogenized with acetone. In the separate photolysis experiment, a methanol solution of [^{14}C]avermectin B_{1a} was applied to the bottoms of two glass petri dishes and allowed to dry at room temperature. The dishes were placed under two racks of 275 W Suntanner bulbs located 66 cm from the dishes. After 19 hours, the avermectin film was solubilized in methanol, an aliquot removed, and the remaining methanol allowed to dry. The dish was replaced under the lights. The process was repeated at 30, 60 and 137 hours. The temperature under the bulbs was approximately 50 °C.

Reverse-phase HPLC profile of [^{3}H] or [^{14}C]avermectin B_{1a} and its degradates from citrus, cotton, celery and photolysis extracts showed the same profile (Table 26). Re-chromatography of the moderately polar fraction indicated the presence of 2–6 components, one co-chromatographed with 8α-hydroxy avermectin B_{1a}. Re-chromatography of the polar residues from the three treated crops and in the photolysis experiment showed four broad peaks. Spectrometric methods have indicated the presence of numerous multiple-oxygenated, hydrated or dehydrated and de-methylated species, which retain little of the macrocyclic characteristics of the avermectins.

Table 26 Profile of total solvent-extracted residues following application of avermectin B_{1a} to cotton leaves, citrus fruit, celery leaves and stalks and to glass plates using C_{18} HPLC

Tomato

Metabolism of avermectin B_{1a} was studied in greenhouse-grown tomato plants transplanted at growth stage BBCH 19 and placed in the greenhouse (Stingelin, 2003). Five spray applications (7 days interval) were made with formulated [23-^{14}C] avermectin B_{1a} at an average rate of 26.4 g/ha (2.2 g/hL) for the normal rate (Sub-Study 1) and three times (14 days interval) at an average rate of 280.8 g/ha (23.4 g/hL) for the exaggerated rate experiment (Sub-Study 2). The first treatment took place at growth stage BBCH 63 and the last at BBCH 71. For the Sub-Study 1, tomato fruits and leaves were collected one hour after the third and fifth application, and 3 to 28 days after the last treatment (final harvest). Sampling for the Sub-Study 2was performed one hour to 28 days after the last application. A cell tomato cells (variety Money Marker) grown as a cell suspension (Sub-Study 3) on medium AM1 under illumination at 27 °C were used for this study. Following sub-culturing, the cells were allowed to reach the log phase of growth prior to the addition of radio-labelled material, dissolved in dimethyl sulfoxide. The cell cultures were incubated for 41 days, separated from the medium by filtration under low vacuum, and washed three times with distilled water. This Sub-Study provided metabolites for identification purposes.

Tomato samples were washed with acetonitrile/water(50/50), washed tomatoes and leaves were homogenized in liquid nitrogen, extracted for at least six hours with acetonitrile/water (80/20 v/v), and the extraction procedure repeated five times or until the radioactivity in the last extract was less than 5% of the first extraction. The solid residues were extracted by microwave with 1-propanol/water (80/20) (10 min. at 100 °C, 20 min. at 120 °C, and 20 min. at 150 °C). Samples of the residual solid and after microwave extraction were air-dried, homogenized and taken for combustion to determine the non-extracted radioactivity.

Before partitioning the soluble radioactivity, samples were concentrated, the aqueous phase partitioned three times with n-hexane, dichloromethane or ethyl acetate. For storage

stability purposes the surface radioactivity washes and the crude extract from the tomato fruit were re-analysed by 2-D TLC after storage at ≤ 8 °C. Additionally, tomato fruit free of surface radioactivity were re-extracted at the end of the experimental phase and the corresponding crude extract was re-analysed by 2-D TLC. Harvested cells (Sub-Study 3) were homogenized in acetonitrile:water (80/20), the homogenate centrifuged, re-extracted and analysed by TLC, reversed-phase HPLC and LC-MS.

Table 30 shows the distribution of radioactivity from the sub-studies. The non-extracted radioactivity (NE) in tomato fruit did not exceed 2% of TRR.

n.a. = Not analysed

MW = Microwave extraction

NE = Non-extracted [a] in avermectin B_{1a} equivalents; [b] in %TRR determined by the sum of surface + extracted + non-extracted radioactivity; [c] corrected for 8,9-Z isomer of avermectin B_{1a} content

Tables 28 and 29 show the metabolite fractions from the two sub-studies. Avermectin B_{1a} and its 8,9-Z isomer was the major fraction in all samples, accounting for at least 38.3%TRR (14 days leaves Sub-Study 1), in a ratio of approximately 9:1. Other identified metabolites are 8α-oxo-avermectin B_{1a}, 8α-hydroxy-avermectin B_{1a}, and 3''-O-desmethyl-avermectin B_{1a}, present at levels < 8%TRR in tomato and leaves at any sampling time in both experiments.

[d] Sum of I_4 and all identified metabolites

Metabolism of avermectin B_{1a} was studied in field-grown tomato plants under similar conditions as the greenhouse study (Stingelin, 2003a).Five spray applications were made using formulated [23-^{14}C] avermectin B_{1a} at an average rate of 26.4 g/ha (Sub-Study 1) and five times at an average application rate of 245.9 g/ha (Sub-Study 2). The tomato plants were kept unprotected and exposed to all weather conditions over the whole of the growing period. Sample analysis was similar to the greenhouse study.

Table 30 shows the distribution of radioactivity from the sub-studies. Total residues in tomato and leaves from Sub-Study 1 (normal rate) reached 0.017 and 0.716 mg/kg eq at the end of the experiment, respectively. The non-extracted radioactivity in tomato fruit did not exceed 10% of TRR.

Tables 31 and 32 show the metabolite fractions from the two sub-studies. The major metabolite fraction in all of the analysed samples was fraction avermectin B_{1a} and the 8,9-Z isomer of avermectin B_{1a} in a ratio of approximately 9:1, accounting for about 70–80%TRR at 0 days and decreasing over time. Other identified metabolites are 8α-oxo-avermectin B_{1a}, 8α-hydroxy-avermectin B_{1a}, and 3''-O-desmethyl-avermectin B_{1a}, present at levels < 7% TRR in tomato and leaves at any sampling time in both experiments.

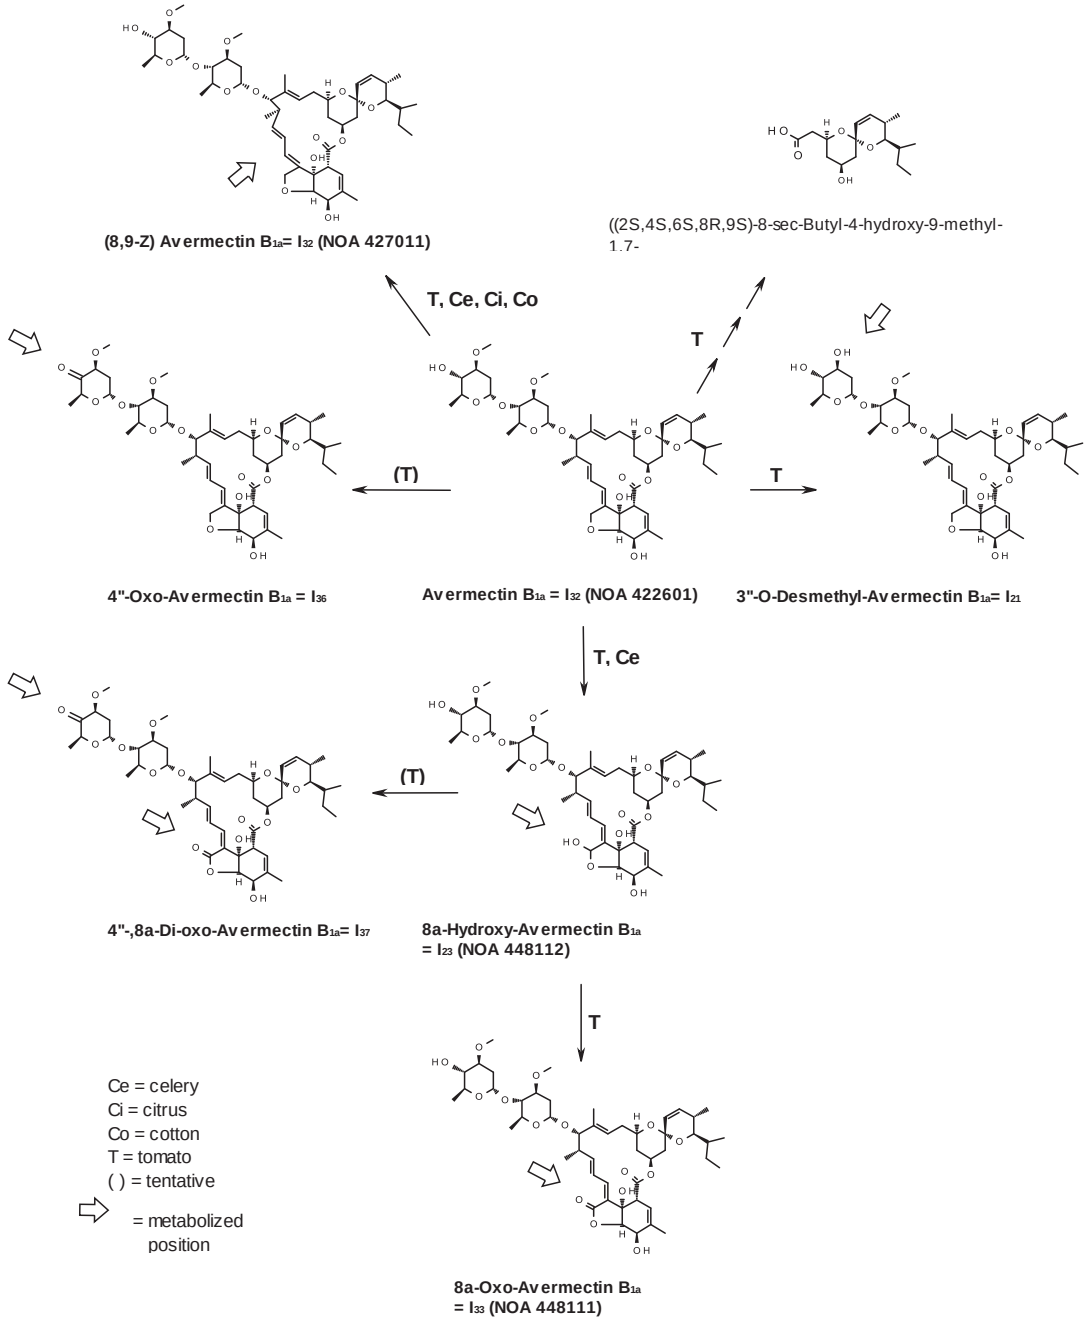

Figure 2 Proposed metabolic pathway of avermectin B_{1a} in plants

Confined rotational crop studies

The uptake, distribution and degradation of [^{14}C]avermectin B_{1a} were investigated in succeeding crops (Moye *et al.*, 1987). Sorghum, lettuce and carrot or turnip were planted in three soil types; a sandy soil, a sandy loam soil and a "muck" soil (high-organic drained swampland), typical US soils for cotton-growing in Georgia, vegetable-growing in California and vegetable-growing in Florida, respectively. The soils were filled into large tubes (three per soil type) and treated at 135 to 155% of the maximum label rate of 21.3 g ai/ha (for non-permanent crops). The sandy soil received three applications at 29.1 g ai/ha and sandy loam and muck soils received 12 applications at 33.6 g ai/ha. After the last application, each tube was divided into thirds and one rotational crop was planted in each third. Three plant-back intervals were used for each soil type. Sorghum and lettuce were planted in all soil types, turnip was planted in the muck soil and carrot planted in the sand and sandy loam soils. The plant-back intervals were 14, 123 and 365 days for the muck soil, 31, 120 and 365 days for the sandy soil and 29, 123 and 365 days for the sandy loam soil. All crops were seeded directly onto the plots. All rotational crops were harvested at 25, 50 and 100% (full) maturity. Soil cores (top 3 inches, middle 3 inches and bottom 3–6 inch layer) were also collected. Samples were combusted to measure radioactivity and lettuce (25% maturity) from a muck soil treatment was extracted with acetone.

The total radioactive residues in rotational crops following the treatment regimes are show in Table 33. The highest TRR was found in the 1/4 maturity lettuce sample from the muck soil (6.94 μg/kg), from which extraction with acetone released only 4.38% of the TRR. The resulting concentrations of radioactivity in succeeding crops were too low to characterize. Total radioactive residues in soil were also low (consistent with the low use rate). Residue levels in soil were proportional to the amount applied and decreased with the depth of sampling and the length of time between application and sampling (data not shown).

Animal metabolism

Metabolism in rats

The metabolism of abamectin in rats was evaluated the WHO group of the JMPR at the present Meeting. In summary, orally administered [^{3}H] and [^{14}C] abamectin B_{1a} was rapidly and almost completely absorbed, and maximum concentrations in blood were achieved within 4–8 hours after administration. Radio-label was distributed to all major tissues and organs. Elimination of radio-label occurred predominantly by non-biliary excretion into the gastrointestinal tract and excretion with the faeces, while urinary excretion accounted for only 0.5 to 1.4 of the dose. Elimination was moderately fast, with 80 to 101% of the dose excreted within 96 hours. Rate of oral absorption, tissue distribution and excretion were independent of the dose level, treatment regime and/or sex; however, the depletion of tissue residues in males was approximately 2-fold more rapid than in females. There was no evidence for tissue accumulation on repeated administration. Metabolism of avermectin B_{1a} in the rat was moderate to extensive and proceeded predominantly via demethylation, hydroxylation, cleavage of the oleandrosyl ring, and oxidation reactions. The metabolite pattern in urine, faeces and bile was complex but qualitatively independent of the sex and the dose level with some quantitative variations. Eleven metabolites were isolated. Unchanged avermectin B_{1a} and the metabolites 3"-O-desmethyl abamectin B_{1a}, 24-hydroxymethyl abamectin B_{1a}, 27-hydroxymethyl abamectin B_{1a}, 3"-O-desmethyl-24-hydroxymethyl abamectin B_{1a} and 3"-O-desmethyl-27-hydroxymethyl abamectin B_{1a} represented the majority of the faecal radioactivity.

Metabolism in lactating goats

One study was conducted in lactating goats using [^{3}H]avermectin B_{1a} (Merricks, 1983, 1983a, 1983b; Maynard *et al.,* 1986; 1989). Six lactating Nubian goats were dosed daily by gelatine capsule for ten consecutive days with [^{3}H]avermectin B_{1a} at 0.005, 0.05 and 1.0 mg/day (two animals at each dose level), corresponding to 0.00125, 0.0125 and 0.25 ppm, respectively, in the diet. Urine and faeces were collected daily and each goat was milked twice daily. The animals were sacrificed on Day 11 approximately 24 hours after the last dose, and tissue samples collected.

Radioactivity in milk samples were counted directly, and tissue, urine and faeces samples were combusted prior to liquid scintillation counting (LSC). Edible tissues and milk were homogenized, extracted with dichloromethane, and the extract cleaned-up in a silica gel SPE for reverse-phase HPLC analysis. Avermectin B_{1a} residues were determined by reverse isotope dilution assay (RIDA). Profiling of the ethyl acetate eluate from the SPE column produced metabolite regions that were defined by retention times relative to avermectin B_{1a}. A column wash was used to investigate the non-polar fraction; a high dose fat sample was subjected to acid hydrolysis. Avermectin B_{1a} and a metabolite standard were also subjected to the acid hydrolysis conditions to determine reaction products. Since the radioactivity in goat tissue was low, a rat liver microsomal incubation of [^{14}C]avermectin B_{1a} was conducted to generate metabolite standards that could be co-chromatographed with in-vivo goat metabolites. Following incubation, the metabolites were purified by various reversed-phase HPLC and the structures identified by NMR and Fast Atom Bombardment (FAB)-Mass Spectrometry.

The majority (79 to 98%) of the administered dose was found in the faeces, with urine accounting for 0.1 to 0.6% of the daily dose in the highest dosed animals. Milk residues reached plateau (steady state) by Day 4 and were dose dependent (Table 34).

S = Sacrifice after AM milking

The results of the tissue and organ assays for total radioactive residue (TRR) are shown in Table 35. Highest residues were found in liver, fat and kidney. Residues were not detected in muscle from the lower dose group (< 0.2 µg/kg eq.) and reached approximately 1.5 µg/kg eq. at the highest dose. Goat 5 at the highest dose level, had atypical consumption behaviour (off feed days 9–11, low water consumption).

Table 35 Residue levels in tissues from goats dosed with [^{3}H]avermectin B_{1a} for ten consecutive days(Maynard *et al.*, 1989)

Goat 6	41 (40)	40 (37)	68	73	86	70 (79)

[a] Tissue residue levels were very low (0.2 µg/kg–0.6 µg/kg), so results should be considered estimates.

Results in parenthesis are repeat determinations

Tables 37 and 38 show the HPLC profile of the residues in tissues, assigned according to retention time relative to that of avermectin B_{1a}. Metabolite 24-hydroxymethyl-avermectin B_{1a},

was a major residue in liver and kidney of the lower dosing goats and was present at 2–11% TRR in milk from D3.

[a] Retention times relative to avermectin B_{1a}

A second metabolite, isolated from the rat liver microsome incubations, and identified as 3"-desmethyl-avermectin B_{1a}, was isolated from Goat 5 liver, and was estimated to comprise < 1 to 5% TRR. This metabolite was identified in urine and faeces, but was not significant in tissues.

Fat tissue contained non-polar material (0–8%), which was captured in a methanol column wash. This fraction from Goat 6 (8%) was hydrolysed with sulphuric acid and analysed by HPLC. Avermectin B_{1a} was hydrolysed under these conditions to the monosaccharide-B_{1a} and further to the aglycone-B_{1a}; 24-hydroxymethyl avermectin B_{1a} was hydrolysed to the aglycone-24-hydroxymethyl avermectin B_{1a}. The reaction product produced from the fat corresponds to the aglycone-24-hydroxymethyl avermectin B_{1a} indicating that the fat must have contained 24-hydroxymethyl avermectin B_{1a} in a conjugated form. In summary Goat 6 fat tissue was shown to contain 85% avermectin B_{1a}, 3% unconjugated 24-hydroxymethyl avermectin B_{1a} and at least 3% conjugated 24-hydroxymethyl avermectin B_{1a} (acid hydrolysis released 40% of the 8% non-polar column-wash fraction).

Based on the structures identified, the metabolism of avermectin B_{1a} in the goat proceeds via oxidation of the methyl group (to a hydroxymethyl group) at the 24 carbon position and to a lesser extent demethylation at the 3" position. The proposed pathway is shown in Figure 3.

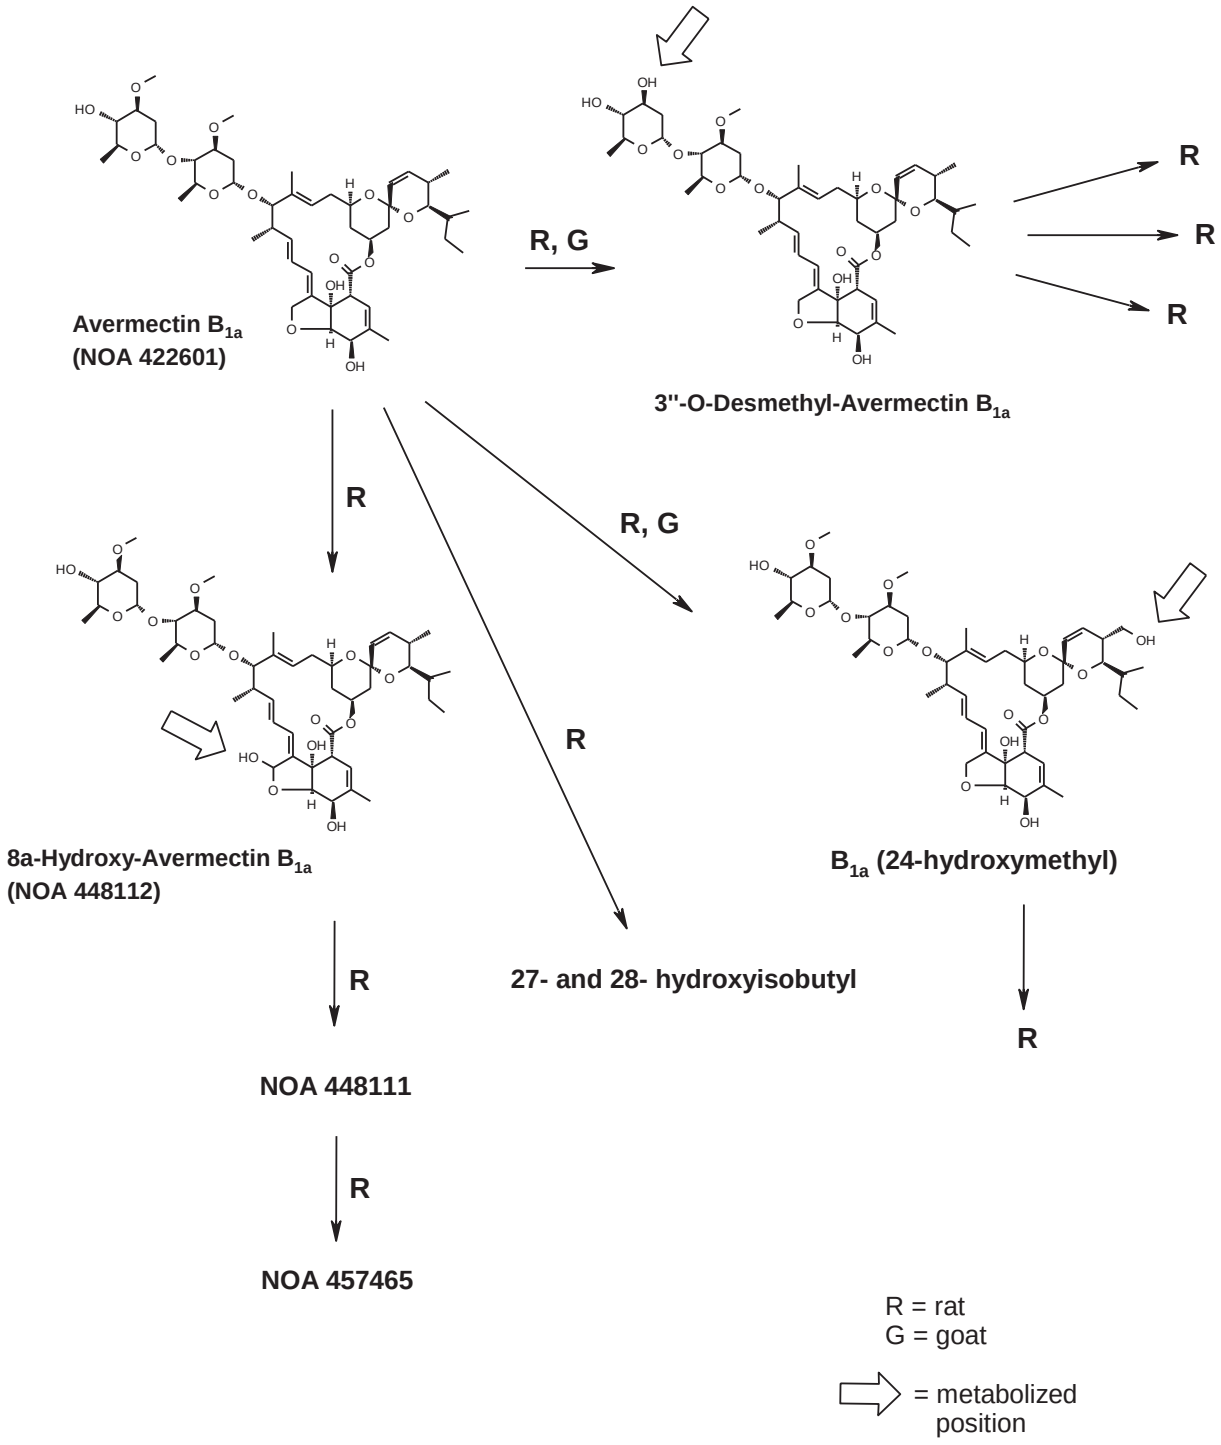

Figure 3 Metabolic pathway of avermectin B_{1a} in the goat and the rat

Residue analytical methods

Methods by HPLC-FL: avermectin B_{1a} is determined as the sum of avermectin B_{1a} and its 8,9-Z isomer and avermectin B_{1b} as the sum of avermectin B_{1b} and its 8,9-Z isomer

Method M-073 was developed to determine avermectin B_{1a}, avermectin B_{1b} and their 8,9-Z isomers in plant material (Arenas, 1996; 1998; Norton, 1997; Giles, 1996; Richard & Mackenzie, 2005).

Residues are extracted with acetonitrile/0.1% phosphoric acid and from the aqueous solution by partitioning into hexane. After adding sodium sulphate to the hexane phase, the organic extract is clean-up in an aminopropyl cartridge, and residues eluted with ethyl acetate/methanol. Fluorescent derivatives are formed by reaction with a mixture of triethylamine, trifluoroacetic anhydride and 1-methylimidazole, and determined by reversed-phase HPLC with fluorescence detection (HPLC-FL; Ex.: 365 nm, Em: 470 nm). HPLC analysis of avermectin B_{1a} and its 8,9-Z isomer results in a single peak, and avermectin B_{1a} is determined as the sum of avermectin B_{1a} and its 8,9-Z isomer and avermectin B_{1b} as the sum of avermectin B_{1b} and its 8,9-Z isomer. Validation data are summarized in Table 39. The limit of quantification for avermectin B_1 residues in crop matrices using Method M-073 was established at 0.002 mg/kg for each component analyte.

The extractability of abamectin residues in citrus fruit (with acetone), celery (with acetone), cotton (with 90/10 v/v acetone/water) and tomatoes (with 80/20 v/v acetonitrile/water)

was demonstrated in radio-labelled metabolism studies. The polarity of the extraction solvent used in analytical method M-073 is comparable to those used in the metabolism studies.

Methods M-007.1 (Cobin, 1995, 1995a; MSD 329/942555), 91-1 (Prabhu, 1991; Kvatemick, 1993, 1996; Richards & Mackenzie, 2005) and MSD 328/942104 (White, 1995) were developed to determine and quantify avermectin B_{1a}, avermectin B_{1b} and their 8,9-Z isomers in different crops, using similar procedures. Homogenized samples are extracted with a hexane/water/acetonitrile, hexane extracts are cleaned up in an aminopropyl SPE, residues derivatized with trifluoroacetic anhydride (reagent) and 1-methylimidazole (catalyst) and determined by reversed-phase HPLC-FL. Validation data for apple, tomato and grapes are summarized in Table 40.

Methods M-044 and M-036.2 were developed to determine and quantify avermectin B_{1a}, avermectin B_{1b} and avermectin B_{1a} 8,9-Z isomer in fresh and immature hops and in dried hops, respectively (Norton, 1997; Report No. MER/AVE/96091). The methods involve rehydration and extraction with a methanol/deionised water mixture, partition into hexane and extract purified on aminopropyl SPE cartridges. The purified extract is derivatised using trifluoroacetic anhydride and residues analysed by HPLC-FL. Validation data are summarized in Table 41. The LOQ was 0.0025 mg/kg for avermectin B_{1a} and 0.005 mg/kg for avermectin B_{1b} and the 8,9-Z isomer of avermectin B_{1a}.

Methods by LC-MS/MS: determination of individual analytes

Method Meth-192, rev.2 was developed to determine and quantify avermectin B_{1a}, avermectin B_{1b} and their 8,9-Z isomers in plant material by LC-MS/MS. Transition ions for avermectin B_{1a} and its isomer ($[M+Na]^+$) were m/z = 895.5 → 751.5 for quantification and m/z = 895.5 → 449.2 for confirmation. Transitions for avermectin B_{1b} ($[M+Na]^+$) were m/z = 881.2 → 737.0 for quantification and m/z = 881.2 → 449.2 for confirmation. Residues are extracted with acetonitrile: 0.1% H_3PO_4 (25:75), partitioned into toluene and clean-up using aminopropyl solid phase extraction (SPE). The purified extract is evaporated, dissolved in acetonitrile, and then submitted to LC-MS/MS (reverse-phase column). The LOQ for all three analytes, in all matrices, is 0.002 ppm. Validation data are summarized in Table 42.

Method 1002 Agri was developed to determine and quantify avermectin B_{1a} in raspberries (Baravelli, 2005). Homogenized samples were extracted with dichloromethane and filtered through sodium sulphate. Quantification was by reverse phase LC-MS/MS operating in Multiple Reaction Monitoring (MRM) mode. Transitions ($[M+H]^+$): m/z = 890.4 → 305.3 for quantification and m/z = 890.4 → 145.3 for confirmation. LOQ for avermectin B_{1a} was established at 0.02 mg/kg. Validation data for method 1002 on grapes are provided in Table 43.

Method REM 198.02 was developed for individual determination of avermectin B_{1a}, avermectin B_{1b} and the 8,9-Z isomer of avermectin B_{1a} in plant material and foodstuffs of animal origin (Satter, 2002; 2002a). Sample preparation and clean-up vary depending on the type of substrate. For high-water substrates, samples were extracted with methanol and cleaned up by C8-SPE. For fatty/oily substrates, the methanol extract was cleaned up by amino SPE, washed by partitioning with n-hexane and cleaned up by a C8-SPE tube. Hops samples were extracted with water and methanol, and after addition of a 5% calcium chloride solution partitioned with n-hexane and the organic phase was cleaned up by amino-SPE. Avermectin B_{1a}, avermectin B_{1b} and the 8,9-Z isomer of avermectin B_{1a} were eluted with a mixture of ethyl acetate/methanol. Residues were determined with a column-switching LC-MS/MS system. Validation data are summarized in Table 44. The LOQ was 0.002 mg/kg for all analytes in all crops, except for hops where the LOQ was 0.01 mg/kg.

Storage stability under frozen conditions

The frozen storage stability of residues of avermectin $B_{1a}$was tested in homogenised orange, lemon and grapefruit peel samples (Cobin, 1987). Samples were stored at or below –10 °C up to 52 months. Avermectin B_{1a} was extracted from citrus peel and derivatized to yield a residue that was determined by HPLC-FL. The results are presented in Table 46.

Studies to investigate the storage stability of residues of avermectin B_{1a}, avermectin B_{1b} and the 8,9-Z isomer of avermectin B_{1a} were conducted in tomatoes (Wertz, 1987), celery (Hughes, 1989), strawberries (Siirila, 1997) and pears (Hicks, 1995). Homogenised tomatoes were fortified, stored at frozen conditions (–20 °C to –10 °C) for 15 up to 35 months and analysed by HPLC-FL against an avermectin B_{1a} standard curve. The results are shown in Table 47.

The frozen storage stability of residues of avermectin B_{1a} or its 8,9-Z isomer at –20 °C was tested separately in grapes and grape products over approximately 1 year (Cobin, 1998). Samples were analysed by HPLC- FL. The results are presented in Table 48.

Table 48 Storage stability of avermectin B_{1a} in grape and processed fractions

[a] Interval not given in the report but report reflected that all matrices were stored for about one year

Samples of tomatoes, runner beans (beans, green with pods), sunflower seeds, potatoes and orange peel were fortified with avermectin B_{1a}, avermectin B_{1b} and avermectin B_{1a} 8,9-Z-isomer, and stored for up to two years in a deep freezer at ≤ –18 °C (Kwiatkowski & Hill, 2007). Six replicate samples were analysed at zero time and triplicate samples were removed afterwards by LC-MS/MS (REM 198.02).The results presented are an average of multiple samples and are not corrected for freshly fortified recoveries.

USE PATTERNS

Abamectin is registered in many countries using high or low volume sprayers or, in some countries, by very-low volume or ultra-low volume equipment for aerial application. Table 50 shows the registered uses in countries where supervised trials have been conducted or in countries with GAPs similar to those where the supervised trials were carried out.

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

Supervised residue trials conducted with abamectin on a variety of crops in China, Brazil, European countries, and USA from 1986 to 2012 were submitted to the Meeting. All trials were conducted using foliar spray of EC formulation. Studies were conducted according to GLP, except those

conducted before the 1990's. Concurrent determination of residues in untreated crops gave residues < LOQ. Residues of abamectin arising from independent trials that used patterns where rate or days after treatment (DAT) ± 25% of GAP are underlined and considered for estimation of maximum residue levels and STMRs. Trials which were not exactly within that range but, with the support of additional information were also considered for the estimations were also underlined.

When residues in samples harvested at a later stage were higher than those found at the critical DAT, they were used for the estimations. When multiple field samples from one plots were taken for analysis, the mean was selected for the estimations. When two field trials were conducted in the same location in the same period/season, only the highest result was considered. For protected trials, the location was considered not relevant.

The data submitted are summarized in Table 51. In total, 601 supervised trials were submitted and food commodities analysed for residues; in some trials, feed commodities were also analysed.

Table 51 Summary of supervised residue trials conducted with abamectin

Commodity	Location	Number of trials	Table	Commodity	Location	Number of trials	Table
Citrus	USA	21	52	Lettuce	Europe	34	70

Citrus fruits

Twenty one residue trials on citrus were carried out in the USA in 1986. Samples were stored deep-frozen for a maximum of 6.5 months (198 days) and analysed by HPLC-FL. In this study, LOQ was 0.005 mg/kg and LOD was 0.002 mg/kg. The results are shown in Table 55.

Table 52 Supervised trials conducted in the USA in 1986 with abamectin on citrus (whole fruit) (6012-172B and MK 936/0165)

Pome fruit

Forty two supervised residue trials were conducted on <u>pome fruit</u> (33 × apples, 7 × pears) in Europe from 1986 to 2012. Apple and pear samples were stored deep-frozen for a maximum of 24 months with exception of Study 4161, where samples were analysed after 26–37 months. Residues in pome fruit samples were analysed by HPLC-FL or LC-MS/MS. Residue data from supervised trials on pome fruits are summarized in Table 53.

Cherries

Eighteen supervised residue trials were conducted on cherries in the USA during 1998, 1999 and 2008. Samples were analysed by HPLC/FL or LC-MS/MS (2008 trials). Cherry samples were stored deep-frozen for a maximum of 15.2 months. Residue data from supervised trials on cherry are summarized in Table 54.

Peaches

Twelve supervised residue trials were conducted on <u>peaches</u> in Europe during 2002 and 2003. Samples were analysed by LC-MS/MS. Peach samples were stored deep-frozen for a maximum of 13 months (407 days). Seventeen supervised residue trials were conducted on peaches in the USA during 1998 and 2008. Samples were analysed either by HPLC/FL (1998 trials) or LC-MS/MS (2008 trials). Peach whole fruit samples were stored deep-frozen for a maximum of 15.2 months. Residue data from supervised trials on peaches are summarized in Table 55.

[a] Include the 8,9-Z-isomer of avermectin B_{1b}

Plums

Seventeen supervised residue trials were conducted on plums in the USA during 1996, 1997 and 2008. Samples were analysed either by HPLC-FL (1996/97 trials) or LC-MS/MS (2008 trials). Plum samples were stored deep-frozen for a maximum of 6.5 months (198 days). Residue data from supervised trials on plum are summarized in Table 56.

Table 56 Results of supervised residue trials conducted with abamectin in USA on plums

[a] Includes 8,9-z isomer of avermectin B_{1b}

Raspberries

Four supervised residue trials were conducted on raspberries in Italy in 2004, two open field trials and two trials in open tunnels. Samples of raspberries were stored deep-frozen for a maximum of 7.2 months (218 days). Samples were analysed by LC-MS/MS detection, with only abamectin B_{1a}being analysed. Residue data from supervised trials on raspberries are summarized in Table 57.

Table 57 Results of supervised residue trials conducted with abamectin in on raspberry in Italy in 2004

Strawberries

Eight supervised residue trials were conducted on protected strawberries in Europe during 1999, 2003 and 2004. Samples of strawberries were stored deep-frozen for a maximum of 12 months. Samples were analysed by HPLC-FL or LC-MS/MS. Twenty-eight supervised residue trials were conducted on strawberries in the USA during 1988, 1989, 2007/08 and 2010, protected strawberries or on open-field strawberries. Samples of strawberries were stored deep-frozen for a maximum of 8 months. Samples of the 1988/1989 trials were analysed by HPLC-FL and samples of the 2007–2010 trials were analysed by LC-MS/MS. Residue data from supervised trials on strawberries are summarized in Table 58.

Grapes

Twenty-four supervised residue trials were conducted on <u>grapes</u> in the USA during 1994, 1995 and 2008. Samples of grapes were stored deep-frozen for a maximum of ≤ 28 months. Samples were analysed using method 936-94-4, method M-073.1 and/or Meth-192, rev.2. Residue data from supervised trials on grapes are summarized in Table 62.

Bulb vegetables

Onions

Eight supervised residue trials were conducted on <u>onions</u> in the USA during 2000 to 2001. Onion bulb samples were stored deep-frozen for a maximum of 7 months and analysed by HPLC-FL. Summaries of the trial results are given in Table 63.

Melons

Thirteen supervised residue trials were conducted on protected melons in Europe during 2000 to 2002 and in 2008. Melon samples were stored deep-frozen for a maximum of 23 months and residues in peel and pulp analysed by LC-MS/MS. Residues in the whole fruit were calculated from residues in peel and pulp. Results from the supervised trials on protected melons in Europe are summarized in Table 66.

Peppers

Eighteen supervised trials were carried out on protected <u>peppers</u> between 1998 and 2013 in Europe. Samples of pepper fruits were stored deep-frozen for a maximum of 11 months and residues analysed either by LC/MS/MS or HPLC-FL. Four supervised trials were carried out on open field chilli peppers in the USA in 1994. Samples were stored deep-frozen for a maximum of 5.6 months and residues analysed by HPLC-LC. Summaries of the trial results are given in Table 67.

Tomatoes

Forty-two supervised trials were carried out on protected tomatoes in Europe in 1993, 1998, 2000, 2001, 2003, 2007 and 2008. Residues were analysed either by method 91.1 or by method REM 198.02 (equivalent to method MSD 8920 mod). Samples of tomato fruits were stored deep-frozen for a maximum of 16 months. Summaries of the trial results are given in Table 68.

Table 68 Results from supervised trials conducted with abamectin on tomato in Europe, either protected (P) or in the field (F)

Lettuce

Thirty four supervised trials on protected lettuce and twelve trials on open-field lettuce were carried out in 1999 to 2008. Samples of lettuce were stored deep-frozen for a maximum of 16 months, and samples analysed by HPLC-FL or LC-MS/MS. Summaries of the trial results are given in Table 70.

Spinach

Eleven supervised trials were conducted in the USA on open field spinach in 1995, 1996, and 2007/08. Samples of spinach were stored deep-frozen for a maximum of 6 months and analysed by HPLC-FL. Summaries of the trial results on spinach are given in Table 71.

Beans (dry)

Twelve supervised residue trials were conducted on beans in the USA during 1999. In all trials, duplicate samples of dry beans were analysed by HPLC-FL. Dry bean samples were stored deep-frozen for a maximum of 14 months. Summaries of the trial results are given in Table 73.

Celeriac

Two supervised residue trials were conducted on celeriac in the USA during 1998. Duplicate samples of celeriac (roots and tops) were analysed by HPLC-FL. Celeriac samples were stored deep-frozen for a maximum of 9.4 months for roots and 10.5 months for tops. Summaries of the trial results are given in Table 74.

Table 74 Results from supervised trials conducted with abamectin on celeriac in the USA in 1998 (Study: 06593)

Potatoes

Eighteen supervised residue trials were conducted on potatoes in the USA in the growing seasons 1992–1994 and 1998. Potato samples were stored deep-frozen for a maximum of 15 months and analysed by HPLC-FL. Summaries of the trial results are given in Table 75.

Radish

Three supervised decline trials were carried out on protected radishes in 1996 and 1999 in the Netherlands. Residues in radish (whole plant, roots, and leaves with tops) were analysed by HPLC-FL or LC-MS/MS. Samples of radish were stored deep-frozen for a maximum of 8 months. Summaries of the trial results are given in Table 76.

Celery

Seven trials were carried out on celery in southern European in the period 1999–2002. Samples of celery whole plant and leaf stalk were stored deep-frozen for a maximum of 8 months and residues in celery analysed by LC-MS/MS. Six trials on celery were conducted in the USA in the period 1999 and 2008. Samples were stored deep-frozen for a maximum of 16 months and analysed by HPLC-FL. Summaries of the trial results are given in Table 77.

Rice

Twenty four supervised residue trials were conducted on rice in China during 2010 and 2011. Samples of rice (paddy plant, husk and grain) were stored deep-frozen for a maximum of 16 month and analysed by HPLC-FL. Only avermectin B_{1a} was analysed and the results reported as total abamectin. Summaries of the trial results are given in Table 78.

Cotton

Eight supervised trials were carried out on cotton in the 1999 and 2000 in Europe. Samples were stored deep-frozen for a maximum of 12 months and analysed by LC-MS/MS. Fourteen supervised trials were carried in 2008 and 2010 in the USA. Samples of undelinted seeds were stored deep-frozen for a maximum of 10 months, cotton meal was stored for a maximum of 7 months, gin by-products

and refined oil for 14 months and cottonseed hulls for 6 months, and analysed by HPLC-FL. Summaries of the trial results are given in Table 80.

Peanuts

Four supervised residue trials were conducted on peanuts in Brazil during the growing seasons of 2009. Peanut seed samples were stored deep-frozen for a maximum of 5.7 months and analysed by HPLC-FL. Residue data from supervised trials on peanut are summarized in Table 81.

Table 81 Results from supervised trials conducted with abamectin on peanuts in Brazil in 1999 (Report: M09044)

Coffee

Five supervised residue trials were conducted on coffee in Brazil during the growing seasons 2009 and 2010. Coffee (bean) samples were stored deep-frozen for a maximum of 5.1 months and analysed

by HPLC-FL or LC-MS/MS. Residue data from supervised trials on coffee are summarized in Table 82.

Feed commodities

Some trials from the studies reported previously have include the analysis of feed samples. The results are shown in Tables 84 to 91.

Table 84 Results from supervised trials conducted with abamectin on rice in China (Report AHKW-BG-012-2011). The paddy rice plant is whole plant cut just above soil level (including grain and husk).

Fate of Residues in Processing

Four processing studies were conducted with grapes, yielding raisins, pomace, and juice, and two in plums, yielding prunes. The results are shown in Table 89. All the studies were conducted within the supervised trials. Grape processed commodities were analysed within a month after being produced.

Livestock feeding studies

A feeding study in dairy cows was performed (Wehner, 1986). Twelve lactating Holstein cows were assigned to four dosing level groups (0, 0.01, 0.03 and 0.10 ppm), administered daily in gelatin capsules for 28–30 days. Milk samples were collected pre-dose, Day 1 (a.m. and p.m.), 2, 3, 5, 7, 14, and 28 (a.m. and p.m.) and liver, kidney, fat, muscle collected at sacrifice. Milk and tissue samples were analysed by HPLC-FL for avermectin B_{1a}, with an LOQ of 0.0005 mg/kg in milk and 0.01 mg/kg in tissues. The results are shown in Table 90. Levels of avermectin B_{1a} were highest in liver at all three feeding rates.

Table 90 Avermectin B_{1a} residues in tissues of treated cows

Matrix	Feeding level, ppm	Range, mg/kg	Mean, mg/kg
Muscle	0.10	0.002–0.002	0.002

APPRAISAL

Abamectin is a broad-spectrum acaricide with additional insecticidal action on a limited number of insects. Abamectin was firstly evaluated by JMPR in 1992 (T,R), and was scheduled at the Forty-sixth Session of the CCPR (2014) for the periodic re-evaluation of toxicology and residues by the 2015 JMPR. For the residue evaluation, data were submitted on physical and chemical properties, environmental fate, metabolism on plants and lactating goats, analytical methods, GAP, supervised trials on fruits, vegetables, nuts, beans, coffee, cotton and cereals, processing studies and cow feeding studies.

Abamectin is a mixture containing ≥ 80% avermectin B_{1a} and ≤ 20% avermectin B_{1b}. The absolute stereochemistry of both compounds is known and defined at each chiral centre and stereogenic carbon-carbon double bond by their IUPAC nomenclature. Abamectin (> 98% purity) has a low solubility in water (1.2 mg/L at 7.6 pH and 25 °C), is soluble in most organic solvents (23 g/L in toluene up to 470 g/L in ethyl acetate) and has a log K_{ow} of 4.4.

Abamectin is also used as an anthelmintic drug in veterinary medicine. The JECFA residue definition for the compound is avermectin B_{1a}.

The abamectin structures and the main metabolites and degradates found in water, soil, plants and animals are shown below.

Environmental fate

Various studies were conducted to evaluate the aerobic degradation of [^{14}C- an/or ^{3}H-] avermectin B_{1a} in different non-sterile soils in the dark under various conditions (application rate, temperature and water capacity) over a period of up to 196 days. Avermectin B_{1a} degraded in soils with a half-life

ranging from 12 to 52 days, and a mean of 29 ± 14 days (n=14). The degradation pathway occurs via hydroxylation or oxidation in the C-8α position, with 8α-hydroxy-avermectin B_{1a} being the major metabolite (up to 18% of the applied radioactivity, AR), present as an equilibrium mixture between the hemiacetal and the ring cleaved aldehyde form. The oxidation product 8α-oxo-avermectin B_{1a} was found at a maximum of 14% AR. Further hydroxylation in the C-4 position resulted in two additional identified metabolites, 4,8α-dihydroxy-avermectin B_{1a} and 8α-oxo-4-hydroxy-avermectin B_{1a}, each at < 10% AR. 4,8α-dihydroxy-avermectin B_{1a} is also present in an equilibrium mixture as the hemiacetal and the aldehyde forms. At least 25 other residues were also formed at low levels, each representing < 10%. The non-extracted residues and volatile fractions (CO_2), reached their maximum at the end of the incubation period (44 and 28% AR, respectively). About 6% AR was released by harsh extraction of non-extracted residues, mostly humic, fulvic and humin acids, with only minor amounts identified as avermectin B_{1a}.

Soil photolysis studies demonstrated a similar degradation pattern, except that under the influence of light, avermectin B_{1a} initially isomerises to the 8,9-Z isomer before degrading, mainly to 8α-hydroxy-avermectin B_{1a} and 8α-oxo-avermectin B_{1a} (up to 4.7% AR). The half-life in these studies were 21–22 days. Photolysis significantly increases the rate of degradation of avermectin B_{1a}, as the dark controls showed a half-life of 119 days.

[^{3}H-avermectin B_{1a}] was stable to hydrolysis at pH 4 to 7 under sterile conditions, minimal hydrolysis was observed at pH 9 (DT_{50} of 380 days at 20 °C), with one major transient non-polar degradate 2-epi-avermectin B_{1a} being observed. At 60 °C, this degradate reached a maximum of 25%AR by Day 11 and then degraded with a DT_{50} of 1.5 days. [23-^{14}C-avermectin B_{1a}] degraded in water under light to 8,9-Z avermectin B_{1a} and 8α-oxo-avermectin B_{1a} (half-lives < 6 days).

In summary, avermectin B_{1a} degrades relatively fast in soils, with half-life < 60 days, and 8α-hydroxy- and 8α-oxo- avermectin B_{1a} being the major products. Light accelerates the degradation in water and soil, and isomerises the compound to its 8,9-Z isomer. Aqueous hydrolysis is not a significant degradation route for avermectin B_{1a} at environmentally relevant pHs and temperatures.

Plant metabolism

The metabolism of [^{14}C]avermectin B_{1a} was investigated in citrus plants kept under an open wooden frame with a fibreglass roof and treated at 18 to 40 µg ai/kg on a whole fruit basis. The [^{14}C]avermectin B_{1a} solutions, prepared in a EC formulation blank, was brushed on each fruit (0.5 mL). After 12 weeks of treatment, residues ranged from 33.3% (grapefruit) to 49.8% (lemons) of the AR. On the day of application, at least 98.4%AR was removed from the surface with methanol, and by week 12, surface residues corresponded to up to 41%TRR in oranges. No residues were detected in the pulp without the peel/pulp interface for all fruits; when the interface was included, residues reached 12–13%TRR after 8 weeks. At day 0, at least 85% TRR of the methanol rinse and acetone peel extract was avermectin B_{1a}, the level then decreased rapidly after one week (to 4.4 to 17.4%TRR) and ≤ 7.7% TRR after 12 weeks, when polar residues accounted for at least 46% TRR. The 8,9-Z isomer of avermectin B_{1a} was present in all sample extracts (0.7–4.7%TRR). Non extracted residues ranged from 40–62% TRR at week 12, but were reduced to < 10%TRR after successive treatments (Bligh-Dyer procedure, soxhlet with methanol and acid or enzyme hydrolysis). Most of the non-extracted residues were polar degradates, with avermectin B_{1a} representing 9–12% TRR, and a fraction identified as a mixture of linoleic fatty esters.

The metabolism of avermectin B_{1a} was investigated in celery in three field experiments:

1) plants treated with ^{3}H-avermectin B_{1a} at 11.2 g ai/ha

2) at 112 g ai/ha, with immature plants harvested from 0 to 43 days after the 4th application and mature plants harvested at 0 to 22 days after the 10th application

3) plants treated with [^{14}C]avermectin B_{1a} at 16.8 g ai/ha, with immature plants harvested at 0 and 14 days after the 4th application and mature plants harvested at 0 to 7 days after the 10th application.

In general, residues in immature or mature leaves and stalks decreased significantly during the study period. For example, after the 4th application at 11.2 g ai/ha, residues in immature leaves were 2.74 mg/kg eq, decreasing to 11.5 µg/kg eq 43 days later. Acetone extracts accounted for over 95% TRR in immature leaves after the 4th application at all rates, with avermectin B_{1a} accounting for 65–75% of the extracted residue. After 14 days, leaf acetone extracts were about 80%TRR, with avermectin B_{1a} accounting for 16–26% of the residues and the 8,9-Z isomer for about 5%. In general, stalks and mature leaves showed similar profiles. The 8-hydroxy avermectin B_{1a} and at least ten other unidentified minor components were also detected in the samples. Residual solids from the leaf acetone extract were mostly extracted with methanol/water and hot DMSO, being mostly polar degradates of avermectin B_{1a}. About 15% of the acetone non-extracted residues in the leaves were incorporated into glucose.

The metabolism of [^{14}C]avermectin B_{1a} was investigated in cotton in four field experiments:

1) individual leaves treated with 100 µg of [^{14}C]avermectin B_{1a} and analysed 8 days after treatment (DAT)

2) cotton plants received two foliar applications at 20 g ai/ha (100 L/ha) and mature bolls harvested at 8 DAT

3) cotton plants were grown in buckets under normal field conditions and treated three times by foliar spray at 22.4 g ai/ha

4) 3× 224 g ai/ha (467 L/ha), and the bolls harvested at 20 DAT.

Over 99.7%AR in the leaves from Experiment 1 were extracted with methanol at day 0, decreasing to 19.3% at Day 8. Avermectin B_{1a} accounted for 99.2%AR at Day 0 and 1.7% AR after 8 days. Non-extracted residues reached 26.1%AR at Day 4. Leaves from Experiments 2 to 4 contained the highest residues (up to 400 µg/kg). Seeds contained up to 85 µg/kg and lint up to 750 µg/kg; this very high level was probably due to the last application in Experiment 4, when approximately 50% of the bolls were open. Avermectin B_{1a} represented most of residues in the leaves methanol rinse from the Experiment 3, accounting for 36% AR at day 1, which decreased to 1% AR by Day 8. The 8,9-Z isomer accounted for 7% AR at 0.25 day, decreasing to 0.1% AR at Day 8. From 26 to 35% TRR in the cotton seed (Experiments 2 to 4) was extracted with hexane, and characterized as triglycerides (linoleic and palmitic acid). Methanol extracts accounted for 50 to 65% TRR and non-extracted material for up to 25% TRR (Experiment 2).

One study was conducted to compare the profile of the residues of [^{14}C]avermectin B_{1a} *in vivo* (citrus, celery and cotton) and *in vitro* photolysis conditions. In this study, a [^{14}C]avermectin B_{1a} methanol solution was dried at room temperature and placed under a 275W Suntanner bulb. Most of the residues in the cotton leaf and citrus fruit surface were of a polar nature, with avermectin B1a accounting for 5–11% TRR after 7–8 days. In stalk and leaf extracts, avermectin B_{1a} accounted for 17 and 10% TRR at 7 DAT, respectively. The *in vitro* study also showed a major decline of avermectin B_{1a} residues with time (from 37% TRR after 19 hours of exposure to light to 7.3% TRR after 30 hours). Re-chromatography of the polar residues from the three treated crops and in the photolysis experiment showed four broad peaks of multiple-oxygenated, hydrated or dehydrated and de-methylated species, which retained little of the macrocyclic characteristics of avermectin B_{1a}.

Metabolism of avermectin B_{1a} was studied in greenhouse-grown tomato plants treated with [^{14}C]avermectin B_{1a} at 5× 26 g ai/ha (sub-study 1) and 3× 281 g ai/ha (sub-study 2). The major metabolite fractions in all of the analysed samples were avermectin B_{1a} and the 8,9-Z isomer of avermectin B_{1a}, in a ratio of approximately 9:1. TRR at 28 DAT in tomato and leaves from sub-study 1 were 0.127 and 6.4 mg/kg eq., respectively, with 51 and 34% as avermectin B_{1a} + its 8,9-Z isomer (9:1), respectively. In sub-study 2, the parent compound and its isomer accounted for 75 and 50% of the residues found in tomato and leaves, respectively. 8α-oxo-avermectin B_{1a}, 8α-hydroxy-avermectin B_{1a}, and 3"-O-desmethyl-avermectin B_{1a} were present at levels < 8% TRR in tomato and leaves samples. The non-extracted radioactivity did not exceed 2% TRR in tomato fruit and 7%TRR in the leaves.

In a field study conducted at 5× 26 g ai/ha or 5× 246 g ai/ha, total residues in tomatoes were 0.017 and 0.108 mg/kg, respectively, with avermectin B_{1a} + its 8,9-Z isomer accounting for 7.1 and 25%TRR, and the 8α-oxo- and 8α-hydroxy- metabolites for less than 3%TRR. In leaves, total residues were 0.71 and 7.8 mg/kg, respectively, with avermectin $B_{1a\ and}$ its isomer accounting for 2.2 and 6.4%TRR and the two metabolites up to 1.2%TRR.

Metabolism of avermectin B_{1a} was investigated in field-grown tomatoes under similar conditions as the greenhouse studies. The major metabolite fraction in all of the analysed samples was avermectin B_{1a} and its 8,9-Z isomer, accounting for about 70–80%TRR at 0 days and decreasing over time (2–6% TRR 28 days after the 5th application). Other identified metabolites were 8α-oxo-avermectin B_{1a}, 8α-hydroxy-avermectin B_{1a}, and 3"-O-desmethyl-avermectin B_{1a}, present at levels < 7% TRR each in tomatoes and leaves at any sampling time in both experiments.

In a confined rotational crop study conducted in the field, sorghum, lettuce and carrots or turnips were planted in sandy, sandy loam and "muck" (high-organic drained swampland) soils. The soils were filled into large tubes and treated at 135 to 155% of the maximum label rate of 21.3 g ai/ha. The sandy soil received 3× 29.1 g ai/ha and sandy loam and muck soils 12× 33.6 g ai/ha. Sorghum and lettuce were planted in all soil types, turnip in the muck soil and carrot in the sand and sandy loam soils. The plant-back intervals (PBI) were 14, 123 and 365 days for the muck soil, 31, 120 and 365 days for the sandy soil and 29, 123 and 365 days for the sandy loam soil. The highest TRR was found in the lettuces samples from the muck soil (6.9 μg/kg eq.), from which extraction with acetone released only 4.4%TRR. Sorghum leaf-stem TRR ranged from 4 to 12 μg/kg eq. No identification of the residues were performed due to the low TRR levels in all samples.

In summary, the plant metabolism studies conducted in citrus, cotton, celery and tomatoes showed that the residues of avermectin B_{1a} are not significantly translocated into the plants, remaining on the surface, where it is photodegraded to its 8,9-Z isomer. The major proportion of the residues remains parent avermectin B_{1a}. The metabolism pathway include the re-arrangement to the 8,9-Z isomer, hydroxylation to 8α-hydroxy-avermectin $B_{1a,}$ further oxidation to 8α-oxo-avermectin B_{1a}, demethylation to 3"-O-desmethyl-avermectin B_{1a}, and oxidation of the 8α-hydroxy- to form the 4"-oxo-avermectin B_{1a} and 4"-,8α-di-oxo-avermectin $B_{1a.}$ The lack of uptake of radioactive material in succeeding crops indicates the non-systemic behaviour of avermectin B_{1a} and its soil degradates.

Animal metabolism

The metabolism of ^{3}H- and ^{14}C-radiolabelled abamectin B_{1a} in rats was evaluated by the WHO group. In summary, the metabolism of avermectin B_{1a} in the rat proceeded predominantly via demethylation, hydroxylation, cleavage of the oleandrosyl ring, and oxidation reactions. Unchanged avermectin B_{1a} and the metabolites 3"-O-desmethyl, 24-hydroxymethyl, 27-hydroxymethyl, 3"-O-desmethyl-24-hydroxymethyl and 3"-O-desmethyl-27-hydroxymethyl abamectin B1a represented the majority of the faecal radioactivity.

One goat metabolism study was submitted to the meeting. Six lactating goats were dosed daily for ten consecutive days with ^{3}H-avermectin B_{1a} at 0.00125 (D1), 0.0125 (D2) and 0.25 ppm (D3) (two animals per dose) and sacrificed after 24 hours. Urine and faeces were collected daily and goats were milked twice daily. The majority of the radioactivity was found in the faeces (79 to 98% AR). Milk residues plateaued by day 4–6 and were dose dependent (0.34 and 2.6 μg/kg eq. at D2 and D3, respectively). In tissues, highest residues were found in liver (mean of 0.4, 2.8 and 57.2 μg/kg eq. at D1, D2 and D3, respectively), fat (< 0.2, 1.8 and 40.9 μg/kg eq.) and kidney (0.3 to 13.8 μg/kg eq.). In muscle, residues were < 0.2, 0.32 and 5.2 μg/kg eq. Avermectin B_{1a} was the major residue in all tissues, comprising from 41–95%TRR in liver, 40–97%TRR in kidney, 73 to 96%TRR in muscle, 86–99% in fat, and 70–95%TRR in milk. Metabolite 24-hydroxymethyl-avermectin B_{1a} was a major residue in liver of the D1 goats (45.5%TRR) and was present at 2–11% TRR in milk from D3. A second metabolite, 3"-desmethyl-avermectin B_{1a}, was only isolated from Goat 5 liver (≤ 5% TRR). Fat tissue was shown to contain 24-hydroxymethyl avermectin B_{1a} in a conjugated form.

Based on the structures identified, the metabolism of avermectin B_{1a} in the goat proceeds via hydroxylation of the methyl group to 24-hydroxymethyl-avermectin B_{1a} and to a lesser extent demethylation at the 3" position. Avermectin B_{1a} is the major residues in all animal matrices. The metabolic pathway in rats showed a similar profile.

Methods of residue analysis

Abamectin residues in plant materials are analysed by two methods, one by HPLC with fluorescent detector (HPLC-FL; Exc.: 365 nm, Em.: 470 nm) and the other, used in more recent supervised trials, by LC-MS/MS. Transition ions for avermectin B1a and its isomer ($[M+Na]^+$) were m/z = 895.5 → 751.5 for quantification and m/z = 895.5 → 449.2 for confirmation.

In the HPLC-FL method, residues are extracted with acetonitrile or methanol and partitioned with hexane, the organic extract is cleaned-up in an aminopropyl solid phase extraction (SPE), and residues eluted with ethyl acetate/methanol. Fluorescent derivatives are formed by reaction with a mixture of triethylamine, trifluoroacetic anhydride and 1-methylimidazole and determined by HPLC-FL. Avermectin B_{1a} and its 8,9-Z isomer results in a single peak, and is determined as the sum of both compounds. It is the same for avermectin B_{1b} and its 8,9-Z isomer. The LOQ for the individual analytes were 0.002 or 0.005 mg/kg for most studies.

The LC-MS/MS methods quantify individually avermectin B_{1a}, avermectin B_{1b} and their 8,9-Z isomers. Residues are extracted with acetonitrile or methanol, partitioned into toluene and cleaned-up using aminopropyl, amino or C8 SPE (LOQ of 0.002 to 0.01 mg/kg), or only extracted with dichloromethane before the analysis (LOQ of 0.02 mg/kg). The method that included the clean-up step was also validated for avermectin B_{1a}, and its 8,9-Z isomer in animal matrices (LOQ of 0.002 mg/kg).

An LC-MS/MS multi-residue QuEChERS method for the determination of residues of avermectin $B_{1a,}$ avermectin B_{1b} and avermectin B_{1a} 8,9-Z isomer in lettuce, sunflower seeds, dried broad beans, wheat grain, oranges and dried hops was validated at the LOQ of 0.002 mg/kg.

Stability of residues during storage

Residues of avermectin B_{1a} in citrus peel samples fortified at levels of 0.005 or 0.025 mg/kg were stable for at least at 52 months when stored at ≤ -10 °C. Residues of avermectin B_{1a} (0.01 or 0.05 mg/kg), avermectin B_{1b} (0.004 mg/kg) and avermectin B_{1a} 8,9-Z isomer (0.009 mg/kg) were shown to be stable in tomato samples for at least 15 months, in celery and strawberry samples for at least 24 months and in pear samples for at least 35 months. Residues of the three analytes at 0.04 mg/kg were shown to be stable for at least 24 months at ≤ -18 °C when present in orange peel, green beans, sunflower seeds and potatoes. Residues of avermectin B_{1a} and its 8,9-Z isomer (0.02 mg/kg) in grapes and processed commodities were shown to be stable for at least one year under frozen conditions, with the exception of raisins, for which only 28% of avermectin B_{1a} residues remained after 12.5 years.

In summary, avermectin B_{1a} and its 8,9-Z isomer and avermectin B_{1b} were shown to be stable for at least 12 months in a variety of crop samples stored under frozen conditions, except raisins. The storage period of the samples in the residue trials guarantee the stability of the residues, unless it is specified otherwise.

Residue definition

Plant metabolism field studies conducted with ^{14}C and/or ^{3}H-avermectin B_{1a} in citrus, cotton, celery and tomatoes (also glasshouse studies) have shown that the major residue is avermectin B_{1a} (over 20% TRR), which remains on the surface of the crop and isomerizes to the 8,9-Z isomer. When present, the hydroxyl, oxo and desmethyl metabolites each accounted for < 10%TRR. Significant residues in rotational crops are not expected.

Abamectin is a mixture of ≥ 80% avermectin B_{1a} and ≤ 20% avermectin B_{1b}. In most residue trials, avermectin B_{1b} was found at levels < LOQ, and when present, the levels are significantly lower than avermectin B_{1a}. Hence, avermectin B_{1a} is an adequate marker for the use of abamectin products.

Although the HPLC-FL method used to analyse abamectin residues measure avermectin B_{1a} plus its 8,9-Z isomer together, the isomer is not expected to be a significant part of the residue (one study in tomato estimated a 9:1 ratio of both compounds) and was never detected in trials when the LC-MS/MS method was used. The toxicity of 8,9-*Z* isomer of abamectin B_{1a} is of no greater toxicity than the parent abamectin B_{1a}.

The Meeting agreed for the following residue definition for abamectin in plant commodities for enforcement and dietary risk assessment:

Avermectin B_{1a}

The metabolism of avermectin B_{1a} in lactating goats showed the parent compound as the main residue in all matrices (at least 40%TRR), with only one major metabolite (24-hydroxymethyl-avermectin B_{1a}), which accounted for 45.5%TRR in livers of the low dosed goats (0.00125 ppm) and up to 11% TRR in milk. The toxicity of 24-hydroxymethyl-avermectin B_{1a} is of no greater toxicity than the parent abamectin B_{1a}.

The Meeting agreed for the following residue definition for abamectin in animal commodities for enforcement and dietary risk assessment: Avermectin B_{1a}

Residues of avermectin B_{1a} are five times higher in fat than in muscle and the log K_{OW} is 4.4, which indicates fat solubility.

The residues are fat soluble.

Residues resulting from supervised residue trials on crops

As no trials were submitted on summer squash and watermelon, the Meeting withdraws its previous recommendations for these commodities

Citrus fruits

In the USA, GAP for abamectin in citrus is up to three applications at a maximum rate of 26 g ai/ha (max. of 53 g ai/ha per season), and 7 days PHI. Twenty one trials were conducted in the USA in citrus (grapefruit, orange, tangelo and lemon).

In nine trials conducted in oranges at GAP, abamectin residues at 7 days PHI were < 0.005 (6), 0.008, 0.010 and 0.014 mg/kg. The highest residue in a replicate samples was 0.015 mg/kg.

In two trials conducted at GAP in grapefruit, one in tangelos and one in lemons, residues were < 0.005 (4).

The median residues found in the different crops is the same, which allows the consideration of a group estimation. However, the residue populations are not similar, with residues in oranges being significantly higher than in the other crops.

Based on the residues in oranges, the Meeting estimated a maximum residue level of 0.02 mg/kg, a STMR of 0.005 mg/kg and a HR of 0.015 mg/kg for abamectin in citrus.

This estimation replaces the previous recommendation for abamectin in citrus.

Pome fruit

GAP for abamectin in pome fruit in Italy is up to 2× 22 g ai/ha and 28 days PHI. Various trials were conducted in Europe according to this GAP in apples and pears from 1986 to 2012.

In 26 trials conducted on apples in Europe according to Italian GAP, residues of abamectin were < 0.002 (20), 0.003 (2), 0.004 (2), 0.007 (2) mg/kg. The highest residue in a replicate samples was 0.010 mg/kg.

Two trials conducted in pears at GAP gave abamectin residues of < 0.002 mg/kg (2). Five trials using three applications of the GAP rate also found no residues.

Based on the residue data in apples, the Meeting estimated a maximum residue level of 0.01 mg/kg, a STMR of 0.002 mg/kg and a HR of 0.01 mg/kg for abamectin in pome fruit.

The Meeting withdraws its previous recommendations for apple and pears.

Stone fruit

GAP for abamectin in stone fruit in the USA is 2× 26 g ai/ha and 21 days PHI. Fifteen trials were conducted in cherry in USA according to this GAP, giving abamectin residues of 0.003 (2), 0.004, 0.005, 0.006, 0.007, 0.008, 0.009 (2), 0.010, 0.011, 0.015, 0.016, 0.024, 0.047 mg/kg. The highest residue in a replicate samples was 0.058 mg/kg.

Thirteen trials were conducted in peaches in the USA according to GAP, giving abamectin residues of < 0.002, 0.002 (6), 0.003, 0.004 (2), 0.005, 0.006 (2), 0.008 and 0.024 mg/kg.

Fifteen trials were conducted in plums in the USA according to GAP, giving abamectin residues of < 0.002 (7), 0.002, 0.003 and 0.004 (4) mg/kg. The highest residue in a replicate samples was 0.006 mg/kg

In Italy, GAP for abamectin in peaches is 2× 22 g ai/ha and 14 days PHI. In five trials conducted in France, Italy and Spain according to this GAP, abamectin residues in the whole fruit were < 0.002 (3), 0.004 and 0.006 mg/kg. Residues in the pulp were < 0.002 (3), 0.004 and 0.007 mg/kg

The residue populations in cherries, peaches and plums from the USA gave the highest residues and will be considered for the sub-group estimations.

The Meeting estimated a maximum residue level of 0.07 mg/kg, a STMR of 0.009 mg/kg, and a HR of 0.058 mg/kg for abamectin in cherries.

The Meeting estimated a maximum residue level of 0.03 mg/kg, a STMR of 0.002 mg/kg and a HR of 0.024 mg/kg for abamectin in peaches.

The Meeting estimated a maximum residue level of 0.005 mg/kg, a STMR of 0.004 mg/kg and a HR of 0.006 mg/kg for abamectin in plums.

Raspberry

GAP for abamectin in raspberries and blackberries in Italy is one application at 22 g ai/ha and 7 days PHI. In four trials conducted in Italy at GAP, abamectin residues were < 0.02 (2), 0.02 and 0.03 mg/kg

The Meeting estimated a maximum residue level of 0.05 mg/kg, a STMR of 0.02 mg/kg and a HR of 0.03 mg/kg for abamectin in raspberry, red, black.

The Meeting agreed to extend this estimation to blackberries.

Strawberry

In Denmark, GAP for abamectin in strawberries is greenhouse applications at 3× 22 g ai/ha and 3 days PHI. In eight greenhouse trials conducted in France and Spain according to this GAP, abamectin residues were 0.004, 0.006, 0.014, 0.020, 0.034, 0.042, 0.045 and 0.071 mg/kg. The highest residue in duplicate samples was 0.073 mg/kg.

In the USA, GAP is 4× 21 g ai/ha and 3 days PHI. In five protected trials conducted at GAP, residues were 0.005 (2), 0.006, 0.007 and 0.008 mg/kg. In seventeen field trials, residues were < 0.005 (5), 0.006 (4), 0.009 (2), 0.010 (2), 0.016, 0.020, 0.026, and 0.028 mg/kg.

Based on the protected trials conducted in Europe that gave the highest residues, the Meeting estimated a maximum residue level of 0.15 mg/kg, a STMR of 0.027 mg/kg and a HR of 0.071 mg/kg for abamectin in strawberries.

This estimation replaces the previous recommendation for abamectin in strawberries.

Grapes

GAP for abamectin in grapes in the USA is 2× 21 g ai/ha and 28 days PHI. In nineteen trials conducted in the USA at GAP, residues of abamectin were < 0.002 (10), 0.002 (4), 0.004 (3), and 0.006 (2) mg/kg. The highest residue in a replicate samples was 0.010 mg/kg

The Meeting estimated a maximum residue level of 0.01 mg/kg, a STMR of 0.002 mg/kg and a HR of 0.010 mg/kg for abamectin in grapes.

Avocado

In the USA, GAP for abamectin in avocados is 2× 26 g ai/ha and 14 days PHI. In five trials conducted at GAP in the country, residues were < 0.002, 0.003, 0.004 (2), and 0.007 mg/kg. The highest residue in a replicate samples was 0.009 mg/kg

The Meeting estimated a maximum residue level of 0.015 mg/kg, a STMR of 0.004 mg/kg and a HR of 0.009 mg/kg for abamectin in avocados.

Mango

In Brazil, GAP for abamectin in mangoes is 4× 14 g ai/ha and 7 days PHI. In five trials conducted in the country at GAP, abamectin residues were < 0.002 (3), < 0.004 and 0.004 mg/kg.

The Meeting estimated a maximum residue level of 0.01 mg/kg, a STMR of 0.002 and HR of 0.004 mg/kg for abamectin in mangoes.

Papaya

In Brazil, GAP for abamectin in papaya is 3× 22 g ai/ha and 14 days PHI. In eight trials conducted in the country at GAP, abamectin residues in papaya fruit were < 0.002, 0.002, 0.003 (2), 0.004, 0.005 (2) and 0.008 mg/kg. Residues in the pulp were < 0.002 (6) mg/kg. Six trials conducted at double rate did not show any residues in the pulp (< 0.002 mg/kg), confirming a no residue situation in the pulp when the fruit is treated at GAP.

The Meeting estimated a maximum residue level of 0.015 mg/kg, a STMR and HR of 0 mg/kg for abamectin in papaya.

Onion and shallot

GAP for onions, bulbs (include shallots) in the USA is 2× 21 g ai/ha and 30 days PHI. In eight trials conducted in the country using 3–4 applications at the GAP rate gave residues of < 0.002 (7) and 0.002 mg/kg. The highest residue in a replicate samples was 0.003 mg/kg.

Meeting estimated a maximum residue level of 0.005 mg/kg, a STMR of 0.002 and HR of 0.003 mg/kg for abamectin in onion bulbs. This estimation was extrapolated to shallots and garlic.

Leek

GAP for abamectin in leek in Belgium is 3× 9 g ai/ha and 7 days PHI. Twelve trials conducted in France and the Netherlands within this GAP gave abamectin residues of < 0.002 (10) and 0.002 (2) mg/kg. The highest residue in a replicate samples was 0.003 mg/kg.

The Meeting estimated a maximum residue level of 0.005mg/kg, a STMR of 0.002 mg/kg and HR of 0.003 mg/kg for abamectin in leek.

Cucumber/gherkin

In Denmark, GAP for abamectin in cucumbers and gherkins is four greenhouse applications at 22 g ai/ha with a 3 day PHI. Twenty-nine protected trials were conducted in Europe from 1989 to 2013. In twenty five trials (3-5 applications) conducted according to the Denmark GAP, abamectin

residues were < 0.002 (6), < 0.005 (5), 0.002 (6), 0.003, 0.004 (2), 0.005, 0.006, 0.007 (2) and 0.025 mg/kg. The highest residue in a replicate samples was 0.029 mg/kg.

The Meeting estimated a maximum residue level of 0.03 mg/kg, a STMR of 0.002 and HR of 0.029 mg/kg for abamectin in cucumbers. This estimation was extrapolated to gherkins.

Melon

In Denmark, GAP for abamectin in melons is three greenhouse applications at 22 g ai/ha and 3 days PHI. Twelve greenhouse trials (3-4 applications) were conducted in Europe from 2000 to 2008 according to this GAP, giving abamectin residues the whole fruit of < 0.002 (6), 0.002 (3), 0.003 (2) and 0.005 mg/kg. Residues in the pulp were < 0.002 (10) mg/kg.

The Meeting estimated a maximum residue level of 0.01 mg/kg, a STMR and HR of 0.002 mg/kg for abamectin in melons, except watermelon.

This estimation replaces the previous recommendation for abamectin in melons, except watermelons.

Pepper

In Denmark, GAP for abamectin in sweet or bell peppers is five greenhouse applications at 22 g ai/ha and 3 days PHI. In eighteen greenhouse trials conducted in Europe within this GAP, abamectin residues were < 0.005 (3), 0.002 (2), 0.004, 0.005, 0.006, 0.008, 0.010, 0.012, 0.015, 0.018, 0.019, 0.02, 0.025, 0.027 and 0.051 mg/kg.

In the USA, GAP for fruiting vegetables, except cucurbits, is 2× 21 g ai/ha and 7 days PHI. Four trials were conducted in chilli pepper using six applications, giving residues < 0.005 mg/kg (4).

The Meeting estimated a maximum residue level of 0.09 mg/kg, a STMR of 0.007 mg/kg and HR of 0.051 mg/kg for abamectin in peppers, sweet.

This estimation replaces the previous recommendation for abamectin in peppers, sweet.

The Meeting estimated a maximum residue level of 0.005* mg/kg, a STMR and a HR of 0.005 mg/kg for abamectin in peppers, chilli.

This estimation replaces the previous recommendation for abamectin in chilli pepper.

The Meeting withdraws its previous recommendation for pepper, chilli, dried.

Tomato and eggplant

GAP for abamectin in tomatoes in Denmark is five greenhouse applications at 22 g ai/ha and in Greece, GAP for tomatoes and eggplants is 4× 22 g ai/ha. In both countries, the PHI is 3 days. Metabolism studies have shown that abamectin degrades rapidly and the Meeting agreed that only the last applications will impact the final residues and decided to use the trials with a lower number of applications for the estimations.

In twenty six greenhouse tomato trials using two to five applications at the GAP rate gave residues of < 0.002 (5), 0.002, 0.003, 0.004 (6), 0.005, 0.006 (2), 0.007 (2), 0.010, 0.011, 0.012, 0.014, 0.24, 0.25 and 0.027 (2) mg/kg.

Nine tomato field trials were conducted in France, Italy and Spain using 3–4 applications of the GAP rate, matching the Greek GAP gave residues of < 0.002 (6) and 0.002 (3) mg/kg.

Based on the greenhouse trials, which gave the highest residues, the Meeting estimated a maximum residue level of 0.05 mg/kg, a STMR of 0.004 mg/kg and HR of 0.027 mg/kg for abamectin in tomato.

This estimation replaces the previous recommendation for abamectin in tomatoes.

In two field trials conducted in eggplants in France using six applications, no abamectin residues were detected at 3 days PHI (< 0.010 mg/kg).

As three trials is not enough for the estimations, the Meeting agreed to extend the estimations for tomatoes to eggplants.

Lettuce

Abamectin can be used in lettuce in Greece at 4× 9 g ai/ha and 14 days and in Italy (includes cos lettuce) at 3× 18 g ai/ha and 7 days PHI.

Nine field trials were conducted in Italy and France according to Italian GAP, giving abamectin residues at 7 days PHI of < 0.002, 0.003 (2) and 0.005 mg/kg in head lettuce, 0.004 and 0.007 mg/kg in leafy lettuce and < 0.002, 0.003, 0.006 and 0.008 mg/kg in cos lettuce.

In protected trials conducted in Europe according to GAP in Greece, residues at 14 days PHI in head lettuce were (n=8) 0.007, 0.011, 0.019, 0.020, 0.035, 0.045, 0.047 and 0.097 mg/kg. Residues from protected trials conducted according to GAP with unidentified lettuce type ranged from 0.003 to 0.012 mg/kg.

Protected trials conducted in head lettuce according to GAP in Greece gave the highest residues. The Meeting estimated a maximum residue level of 0.15 mg/kg, a STMR of 0.0275mg/kg and a HR of 0.097 mg/kg for abamectin in head lettuce.

The Meeting agreed that there are not enough trials to estimate a maximum residue level for abamectin in leafy lettuce and cos lettuce.

The Meeting withdraws its previous recommendation on leafy lettuce.

Corn salad (lambs lettuce)

Abamectin can be used in lambs lettuce in Italy at 3× 18 g ai/ha and 7 days PHI. Two trials were conducted in lambs lettuce in France, but they were not according to GAP.

The Meeting agreed not to estimate a maximum residue level for abamectin in lambs lettuce

Spinach

In the USA, GAP for abamectin in spinach is 2× 21 g ai/ha and 7 days PHI. Six declining trials using six application (7 days interval) and metabolism studies showed a rapid declining of the residues, indicating that the contribution of the early applications does not impact the final residue. In eleven trials conducted with 3–6 applications abamectin residues at 7 days PHI were < 0.002 (2), 0.016, 0.020, 0.021, 0.024, 0.028, 0.042, 0.044, 0.048 and 0.085 mg/kg. The highest residue in a replicate samples was 0.091 mg/kg.

The Meeting agreed to recommend a maximum residue level of 0.15 mg/kg, a STMR of 0.024 mg/kg and a HR of 0.091 mg/kg for abamectin in spinach.

The IESTI from the consumption of spinach represented 140% of the ARfD for abamectin (0.003 mg/kg bw). No alternative GAP was available to the Meeting.

Bean, green with pods

The GAP for abamectin in green beans in Spain is 3× 18 g ai/ha and 3 days PHI. In thirteen greenhouse trials conducted in Italy and Spain according to this GAP, residues in green bean with pods were < 0.002 (4), 0.003, 0.004, 0.007, 0.012, 0.014, 0.016, 0.017, 0.023, and 0.049 mg/kg

The meeting estimated a maximum residue level of 0.08 mg/kg, a STMR of 0.012 mg/kg and a HR of 0.049 mg/kg for abamectin in beans, except broad beans and soya beans (green pods and immature seeds).

Beans, dry

GAP for abamectin in beans, dry, in the USA is 2× 21 g ai/ha and 7 days PHI. In seven trials conducted in the USA using three applications, residues were < 0.002 (6) and 0.003 mg/kg.

As it is unlikely that the first application would impact the final residue, the Meeting agreed to use these trials for estimating a maximum residue level of 0.005 mg/kg and a STMR of 0.002 mg/kg for abamectin in beans, dry.

Celeriac

GAP for abamectin in celeriac in the USA is 2× 21 g ai/ha and 7 days PHI. Two trials were conducted in the country using three applications gave no residues in the root (< 0.002 mg/kg)

The Meeting agreed that two trials are not sufficient to estimate a maximum residue level for abamectin in celeriac.

Potato

In the USA, the GAP for abamectin in tuberous and corm vegetables, which include potatoes, sweet potatoes and yams, is 2× 21 g ai/ha and 14 days PHI. In thirteen potato trials conducted in the country from 1992 to 1998 using from 3-6 applicatons at GAP, no abamectin residues were detected in potato tubers (< 0.005 mg/kg). Trials conducted at 6 × 112 g ai/ha gave the same result.

The Meeting estimated a maximum residue level of 0.005* mg/kg, a STMR and a HR of 0 mg/kg for abamectin in potato. The Meeting agreed to extrapolate this recommendation to sweet potato and yams.

This estimation replaces the previous recommendation for abamectin in potatoes.

Radish

GAP for abamectin in radishes in Belgium is 2× 10 g ai/ha and 14 days PHI. In one protected trial conducted in the Netherlands in 1999 within this GAP, abamectin residues in the root were < 0.002 mg/kg.

The Meeting agreed that one trial is not sufficient to estimate a maximum residue level for abamectin in radishes.

Celery

GAP for abamectin in celery in Greece is 4× 9 g ai/ha and 14 days PHI. In seven trials conducted using three applications, samples were collected at 10 DAT.

In the USA, GAP is 2× 21 g ai/ha and 7 days PHI. Six trials conducted in the country using three applications gave residues of 0.003, 0.005 (2), 0.006 0.01 and 0.016 mg/kg

As it is unlikely that the first application would impact significantly the final residue, the Meeting agreed to use these trials to estimate a maximum residue level of 0.03 mg/kg, a STMR of 0.005 mg/kg and a HR of 0.016 for abamectin in celery.

Rice

In China, GAP for abamectin in rice is 2× 14 g ai/ha and 21 days PHI. In six trials conducted in the country according to GAP, abamectin residues in rice husked were < 0.001 mg/kg (6). Six trials conducted at 2× 20 g ai/ha rate gave residues of < 0.001 (4), 0.001 and 0.002 mg/kg. Applying the proportionally principle to this dataset, residues according to GAP are < 0.001 (5) and 0.0015 mg/kg.

Residues on the 12 trials combined are < 0.001 mg/kg (11) and 0.0015 mg/kg.

The Meeting estimated a maximum residue level of 0.002 mg/kg and a STMR of 0.001 mg/kg for abamectin in rice, husked.

Tree nuts

In the USA, GAP for abamectin in tree nuts is 2× 26 g ai/ha and 21 days PHI. In three trials conducted in almonds according to GAP, residues were <0.005 mg/kg. In another 29trials conducted

in almond, pecan and walnut using 3 applications of 28 or 56 g ai/ha, residues at 3 to 14 DAT gave the same result.

As trials conducted at higher GAP or shorter DAT do not give rise to residues in nut meat, the Meeting estimated a maximum residue level of 0.005* mg/kg, a STMR and a HR of 0 mg/kg for abamectin in tree nuts.

The Meeting withdraws its previous recommendation for almonds and walnuts.

Cotton

GAP for abamectin in cotton in Spain is 3× 18 g ai/ha and 3 days PHI. Five trials were conducted in Greece and Spain using two applications, giving abamectin residues at 3 days PHI of < 0.002 mg/kg (5).

In the USA, GAP is 2× 21 g ai/ha and 20 days PHI. In eleven trials conducted in the country according to GAP, residues were < 0.002 (9), 0.005 and 0.01 mg/kg.

The Meeting estimated a maximum residue level of 0.015 mg/kg and a STMR of 0.002 mg/kg for abamectin in cotton seed.

This estimation replaces the previous recommendation for abamectin in cotton.

Peanut

Abamectin is registered in Argentina to be used in peanuts at 1× 2 g ai/ha and 30 days PHI. Four trials were conducted in Brazil using 3× 14 g ai/ha, giving residues < 0.005 mg/kg (4).

Based on the Brazilian trials conducted at high rate and metabolism studies that showed no translocation of abamectin residues in the plant, the Meeting estimated a maximum residue level of 0.005* mg/kg, and a STMR of 0 mg/kg for abamectin in peanuts.

Coffee

Critical GAP for abamectin in coffee in Brazil is one application at 27 g ai/ha and 14 days PHI. Five trials were conducted in the country using 7–9 g ai/ha, giving residues < 0.002 mg/kg (5).

As no trials were conducted according to GAP, the Meeting could not estimate a maximum residue level for abamectin in coffee.

Hops

Abamectin is registered in hops in Slovenia and the USA to be used at 2× 21–22 g ai/ha and 28 days PHI. In seven trials conducted in Germany according to this GAP, abamectin residues in dried cones were < 0.005 (2), 0.010, 0.012 0.02, 0.021 and 0.028 mg/kg. In four trials conducted in the USA at GAP, residues were 0.012, 0.020, 0.056 and 0.061 mg/kg.

Trials conducted in the USA gave the highest residues, and the Meeting estimated a maximum residue level of 0.15 mg/kg and a STMR of 0.038 mg/kg for abamectin in hops, dry.

This estimation replaces the previous recommendation for abamectin in hops, dry.

Feed commodities

Rice husks

In six trials conducted with abamectin in rice in China according to GAP (2× 14 g ai/ha), abamectin residues in rice husks (hulls) at 21 days PHI were < 0.001 (5) mg/kg and 0.006 mg/kg.

The Meeting estimated a median residue of 0.001 mg/kg for abamectin in rice hulls.

Residues in paddy rice plant (including grain with husks) in trials according to GAP were < 0.001 mg/kg (6). Trials conducted at 20 g ai/ha gave the same results.

As no residues were found in rice plant, the Meeting estimated a maximum residue level of 0.001 mg/kg, a median and highest residue of 0.001 mg/kg for abamectin in rice straw.

Green beans

In four European trials conducted in green beans according to GAP in Spain (3× 18 g ai/ha, 3 days PHI), abamectin residues in the vines were 0.329, 0.349, 0.354, and 0.581 mg/kg.

The Meeting estimated a median residue of 0.352 mg/kg and highest residue of 0.581 mg/kg for abamectin in green bean vines.

Almond hulls

In six trials conducted in almonds in the USA at the GAP, residues in the hulls at 21 days PHI were < 0.002, 0.012, 0.035, 0.037, 0.102 and 0.11 mg/kg.

The Meeting estimated a maximum residue level of 0.2 mg/kg and a median residue of 0.036 mg/kg for abamectin in almond hulls.

Cotton hulls

As no trials were conducted in cotton according to GAP that analysed the hulls, the Meeting could not make any estimation for abamectin in cotton hulls.

Fate of residues in processing

Three processing studies were conducted in grapes, with abamectin residues in grapes of 0.012, 0.007 and 0.048 mg/kg. Although the stability study on grape processed commodities have shown that abamectin residues were not stable after 12 months in raisins, in the processed study the samples were analysed within a month after being generated, and the results are evaluated. Eleven studies were conducted in cotton, all in the context of the residue trials described before. The estimated processing factors with the respective recommendations of STMR-P, based on the recommended maximum residue level, are shown in the Table.

RAC	Processed product	PF (median or best estimate)	STMR-P, mg/kg	HR-P, mg/kg	MRL, mg/kg
Grapes	Dried grape	1, 2.8, 3.1	0.0056	0.028	0.03
MRL = 0.01 mg/kg	Grape juice	< 0.25, < 0.57, 1.4	0.0028		0.015
STMR = 0.002 mg/kg	Wet pomace	4.75	0.009		
HR = 0.01 mg/kg	dry pomace	15.8	0.0316		
Plums	Prune	0.8 [a]			
Cotton	Meal	< 0.028, < 0.067	0.000		
STMR = 0.002 mg/kg	Refined oil	< 0.028, < 0.67	0.000		

[a] Recommendation for Plums includes prunes

Residues in animal commodities

A feeding study was conducted in dairy cows (n=3) with abamectin dosed at 0.01, 0.03 and 0.10 ppm levels for 28–30 days. Avermectin B1a residues were determined by HPLC-FL, with an LOQ of 0.001 mg/kg in tissues and 0.0005 mg/kg in milk. Residues in muscle at any feeding level were < 0.01 mg/kg (traces at 0.002 mg/kg at all levels), and in kidney (traces at 0.004–0.005 mg/kg at 0.10 ppm). At this highest dose, maximum residues were 0.014 mg/kg (mean of 0.012 mg/kg) in fat and 0.020 mg/kg in liver (mean of 0.019 mg/kg). In milk, residues were only detected after 2 days dosing at 0.10 ppm (0.001 mg/kg), reaching a maximum of 0.004 mg/kg at day 14, and decreasing to the initial levels at the end of the dosing period. Overall mean was < 0.0005 mg/kg.

Farm animal dietary burden

The Meeting estimated the dietary burden of abamectin in farm animals on the basis of the OECD Animal Feed data published in the 2009 FAO Manual, the STMR, STMR-Ps or highest residue levels estimated at the present JMPR Meetings.

The commodities used to estimate the dietary burden were rice, husked, rice straw, rice hulls, grape pomace dried, bean vines, almond husk, bean dry, and cotton meal. As abamectin is not registered in beans and grapes in Australia, and is unlikely that bean vines and grape pomace would be animal feed in the country, as they are not imported commodities, they were excluded in the calculation for the Australian diet.

Livestock dietary burden for abamectin, ppm of dry matter (DM) diet

	US-Canada		EU		Australia		Japan	
Commodity	Max	Mean	Max	Mean	Max	Mean	Max	Mean
Beef cattle	0.0003	0.0003	0.0007	0.0007	0.004	0.004	0.0006	0.0006
Dairy cattle	0.004	0.004	0.333 [a, b]	0.202 [c, d]	0.004	0.004	0.0003	0.0003
Poultry—broiler	0.0007	0.0007	0.0006	0.0006	0.002 [e]	0.002		
Poultry—layer	0.0007	0.0007	0.0007	0.0006	0.002	0.002 [f]		

[a] Highest maximum beef or dairy cattle dietary burden suitable for maximum residue level estimated for mammalian tissues

[b] Highest maximum dairy cattle dietary burden suitable for maximum residue level estimated for mammalian milk

[c] Highest mean beef or dairy cattle dietary burden suitable for STMR estimated for mammalian tissues.

[d] Highest mean dairy cattle dietary burden suitable for STMR estimated for milk.

[e] Highest maximum poultry dietary burden suitable for maximum residue level estimated for poultry tissues and eggs.

[f] Highest mean poultry dietary burden suitable for STMR estimated for poultry tissues and eggs.

Animal commodity maximum residue level

The calculated maximum cattle dietary burden suitable for the estimation of maximum residue level of tissues and milk is 0.333 ppm. For the estimation of STMRs, the cattle dietary burden was 0.202 ppm.

The feeding level in lactating cows was conducted in a much lower dose (up to 0.10 ppm) than the estimated dietary burden. The Meeting agreed not to make any estimation for abamectin in mammalian commodities.

The Meeting withdraws its previous recommendations for cattle fat, cattle kidney, cattle liver, cattle meat, cattle milk, goat meat, goat milk and goat, edible offal.

Currently, the existing Codex MRLs for abamectin as a veterinary drug only intended to be used in beef cattle are 0.1 mg/kg in cattle liver and cattle fat and 0.05 mg/kg in cattle kidney.

The calculated maximum poultry dietary burden suitable for maximum residue level estimated for poultry tissues and eggs was 0.002 ppm. No feeding study on poultry was submitted to the Meeting.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed in Annex 1 are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

Residue definition for plant commodities for enforcement and dietary risk assessment: *Avermectin B_{1a}*

Residue definition for animal commodities for enforcement and dietary risk assessment: *Avermectin B_{1a}*

The residues are fat soluble.

[a] On the basis of information provided to the JMPR it was concluded that the estimated short-term intake of abamectin for the consumption of spinach may present a public health concern

DIETARY RISK ASSESSMENT

The intake assessments conducted by the Meeting did not include the uses of abamectin as a veterinary drug.

Long-term intake

The International estimated daily intakes (IEDI) of abamectin based on the STMRs estimated by this Meetings for the 17 GEMS/Food regional diets were 1–5% of the maximum ADI of 0.001 mg/kg bw (see Annex 3 to the 2015 Report). The Meeting concluded that the long-term dietary intake of residues of abamectin is unlikely to present a public health concern.

Short-term intake

The ARfD for abamectin is 0.003 mg/kg bw. The International Estimated Short-Term Intake (IESTI) of abamectin for the commodities for which STMR, HR and maximum residue levels were estimated by the current Meeting. The results are shown in Annex 4 to the 2015 Report.

For spinach, the IESTI represented 140% of the ARfD for children. No alternative GAP was available. On the basis of information provided to the Meeting, it was concluded that the short-term intake of abamectin residues from the consumption of spinach may present a public health concern.

The IESTI for the other commodities considered by the Meeting represented a maximum of 70% of the ARfD, and for these commodities, the Meeting concluded that the short-term-intake of abamectin is unlikely to present a public health concern when abamectin is used in ways considered by the Meeting.

ACETAMIPRID (246)

The first draft was prepared by Professor Mi-Gyung Lee, Andong National University, Republic of Korea

EXPLANATION

Acetamiprid is a neonicotinoid insecticide with contact and stomach action against a range of plant pests such as Hemiptera, Thysanoptera and Lepidoptera acting as an agonist of the nicotinic acetylcholine receptor in the insect central nervous system. It exhibits translaminar activity in plants and is authorized for use in a variety of crops worldwide.

Acetamiprid was evaluated for the first time by the 2011 JMPR, where an ADI of 0–0.07 mg/kg bw and an ARfD of 0.1 mg/kg bw were established, and maximum residue levels were recommended for a range of plant and animal commodities. In 2012, JMPR reconsidered acute dietary risks from maximum residue levels recommended for leafy vegetables (except spinach) and spinach and then withdrew them. Currently, there are no CXLs established for any leafy vegetables.

At the 46th Session of the CCPR (2014), acetamiprid was listed for residue evaluation for additional maximum residue levels by the 2015 JMPR. The Meeting received information on supervised residue trials for cucumber (including fruit cucumber) and tomato (including cherry tomato) from China and for sweet corn (corn-on-the-cob), mustard greens and asparagus from USA. For sweet corn (corn-on-the cob), residue trials were also conducted in Canada.

For both compliance with MRL and estimation of dietary intake, the residue is defined as acetamiprid for plant commodities and the sum of acetamiprid and desmethyl-acetamiprid for animal commodities. The residue is not fat-soluble.

Residue Analysis

Analytical methods

The Method KP-216 (considered suitable by the 2011 JMPR) was used as a reference for residue analysis of acetamiprid in asparagus, mustard greens and sweet corn (kernel plus cob with husk removed, forage and stover from USA trials). Briefly, the analytical methods for those crop samples involved extraction with methanol and water, clean-up by Strata-X (or Oasis HLB) solid phase extraction (SPE) and LC-MS/MS analysis. At fortification levels of 0.01, 0.1 and 1.0 mg/kg, the mean recoveries (n=3 or 6) ranged within 80–120% (CV, < 7.9%) in each sample matrix of asparagus, mustard greens, sweet corn, and kernel plus cob with husk removed. For forage and stover of sweet corn, the mean recoveries were 82–122% (CV, < 6.6%) and 87–124% (CV, < 6.1%), respectively at the three fortification levels. In all matrices, the limit of quantification (LOQ) for acetamiprid was 0.01 mg/kg.

For sweet corn samples (kernel plus cob with husk removed, forage and stover) from trials conducted in Canada, the analytical method involved extraction with methanol, partitioning with hexane and again with methylene chloride, clean-up by SPE Florisil column and LC-MS/MS analysis. At fortification levels of 0.01, 0.02, 0.1, 1 (only for stover) and 5 (only for forge) mg/kg, the mean recoveries (n=3) ranged within 76–99% (CV, < 17%). The LOQ for acetamiprid in matrices of sweet corn was 0.01 mg/kg.

Table 1 Analytical recoveries of acetamiprid in asparagus, mustard and sweet corn

Matrix	Fortification, mg/kg	n	Range of recoveries, %	Mean recovery, %	CV, %	Ref. method
Asparagus (spears)	0.01	3	84–90	86	3.7	Method KP-216
	0.1	3	80–82	81	1.8	
	1.0	3	90–92	91	1.1	

Matrix	Fortification, mg/kg	n	Range of recoveries, %	Mean recovery, %	CV, %	Ref. method
Mustard greens (leaves)	0.01	3	109–126	120	7.9	Method KP-216
	0.1	3	113–122	117	4.3	
	1.0	3	102–111	106	4.3	
	10	3	82–85	83	2.5	
Sweet corn, kernel plus cob with husk removed (USA)	0.01	6	101–120	108	6.4	Method KP-216
	0.1	3	99–109	103	5.0	
	1.0	3	91–97	93	3.4	
Sweet corn, forage (USA)	0.01	6	112–135	122	6.6	Method KP-216
	0.1	3	95–103	100	4.4	
	1.0	3	80–84	82	2.4	
Sweet corn, stover (USA)	0.01	6	106–120	113	4.4	Method KP-216
	0.1	3	119–133	124	6.1	
	1.0	3	80–99	87	11	
Sweet corn, kernel plus cob with husk removed (Canada)	0.01	3	89–93	91	2.2	
	0.02	3	88–91	89	2.2	
	0.1	3	85–86	85	1.2	
Sweet corn, forage (Canada)	0.01	3	87–119	99	17	
	0.02	3	82–85	84	2.4	
	0.1	3	81–82	81	1.2	
	5		71–80	77	7.8

	0.02	3	69–82	78	10	
	0.1	3	77–95	84	11	
	1	3	74–78	76	2.6	

LOQs, < 0.01 mg/kg

In cucumber, acetamiprid residue was extracted with acetonitrile (mixed with acetic acid, 99:1). The extract aliquots were cleaned up by dispersive SPE (use of C_{18}, primary secondary amine and anhydrous magnesium sulphate) and analysed using LC-MS/MS. At fortification levels of 0.01, 0.2, 1.0 mg/kg, the mean recoveries (n=5) ranged within 89 and 101% (CV, < 9.9%). The LOQ was 0.01 mg/kg in cucumber (Li, Yiqiang; Report No. AC-01).

Acetamiprid residue in tomatoes was extracted with acetonitrile. Extract aliquots were purified by SPE using NH_2 cartridges and analysed by LC-MS/MS. At fortification levels of 0.01, 0.1, and 0.5 mg/kg, the mean recoveries (n=5) ranged within 82–95% (CV, < 5.9%). The LOQ was 0.01 mg/kg in tomatoes (Li, Zhou; Report No. AT-01).

Table 2 Analytical recoveries of acetamiprid in cucumber and tomato

Matrix	Fortification, mg/kg	n	Range of recoveries, %	Mean recovery, %	CV, %
Cucumber	0.01	5	79–98	89	9.9
	0.2	5	95–107	101	4.1
	1.0	5	95–96	96	0.5

Matrix	Fortification, mg/kg	n	Range of recoveries, %	Mean recovery, %	CV, %
Tomato	0.01	5	76–86	82	5.2
	0.1	5	86–101	95	5.9
	0.5	5	85–97	92	5.2

LOQs, < 0.01 mg/kg

Stability of residues in stored analytical samples

Stability of acetamiprid was tested for asparagus, cucumber, mustard greens, sweet corn and tomato stored frozen at or below –20 °C. The residue was analysed using analytical methods described above for each matrix. Maximum tested storage durations were 426 days for asparagus, 304 days for cucumber and tomato, 382 days for mustard greens and 384–391 days for sweet corn kernel plus cob with husk removed, forage and stover samples. No zero-day residues were measured except in cucumber and tomato.

The amount of acetamiprid remaining at each storage sampling interval ranged between 72% and 120% of the nominally applied amount for all matrices. Corresponding procedural recoveries ranged 76–114%. In 2011, the JMPR concluded that acetamiprid is stable for at least 12 months in apple, cabbage, cucumber, grape and tomato, and 16 months for lettuce.

Actual storage durations of the samples from residue studies were shorter than the tested storage stability durations, with an exception of asparagus (stored 473 days, tested 426 days). Based on the available information, it is considered that acetamiprid in crop samples relevant to this submission, including asparagus, was stable until analysis.

Table 3 Storage stability of acetamiprid in plant matrices

Matrix	Fortification level, mg/kg	Tested storage days	Procedural recoveries, %	Residue in fortified samples, mg/kg	Actual max. storage days
Asparagus (spears)	1.0	426	86	0.87, 0.86, 0.85	473
Cucumber	0.1	0		0.10, 0.10, 0.10	205
		31	99, 101, 105	0.095, 0.097, 0.099	
		92	98, 101, 105	0.090, 0.096, 0.096	
		182	98, 100, 104	0.096, 0.098, 0.098	
		304	100, 101, 101	0.096, 0.097, 0.098	
Mustard greens (leaves)	1.0	382	93, 94, 106	0.87, 0.91, 0.85	382
Sweet corn, kernel plus cob with husk removed (USA)	0.1	390	95, 97, 99	0.086, 0.089, 0.093	362
Sweet corn, forage (USA)	0.1	384	86, 99, 114	0.10, 0.12, 0.12	359
Sweet corn, stover (USA)	0.1	391	102, 106, 107	0.10, 0.10, 0.096	373
Tomato	0.5	0	91, 96	0.48, 0.50, 0.50	157
		30	87, 92	0.43, 0.50, 0.53	
		95	77, 87	0.46, 0.49, 0.51	
		108	108, 113	0.38, 0.41, 0.42	
		273	83, 90	0.36, 0.40, 0.46	
		304	76, 78	0.38, 0.42, 0.58	

Sweet corn trial samples conducted in Canada were stored for up to 203 days for kernel plus cob with husk removed, 212 days for forage and 194 days for stover.

USE PATTERN

Information on the registered uses of acetamiprid made available to this Meeting is shown in Table 4.

Table 4 Registered uses of acetamiprid on crops relevant to submitted residue data

Crop	Country	Form.	Method	Application			
				Rate, kg ai/ha	Max. no.	Interval days	PHI, days
Cucumber	China	200 SP (200 g ai/L)	Spray	0.090	3		2
Tomato	China	30 ME (30 g ai/L)	Spray	0.014–0.027	2		7
Sweet corn	USA	30 SG	Foliar spray	0.11 [a]	2	14	7
				0.060 [a]	4	7	1
	Canada	70 WP	Foliar spray	0.060 [b]	2	21	10
Leafy Cole crops and turnip greens (mustard greens)	USA	30 SG, 70WP	Foliar spray	0.11 [c]	4	7	3
Asparagus	USA	30 SG, 70 WP	Foliar spray	0.11 [d]	2	10	1

Formulation: SP (soluble powder), ME (micro emulsion), WP (wettable powder), SG (soluble granule)

Leafy Cole crops and turnip greens include broccoli raab, collards, cabbage (bok choy), kale, mizuna, mustard greens, mustard spinach, rape greens, and turnip greens.

[a] Do not exceed a total of 0.24 kg ai/ha/growing season; do not exceed two crop seasons per year

[b] Do not exceed a total of 0.12 kg ai/ha per season

[c] Do not exceed a total of 0.42 kg ai/ha/growing season

[d] Do not exceed a total of 0.224 kg ai/ha/growing season

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received residue trial data on asparagus, mustard greens and sweet corn from the USA, sweet corn from Canada, and on cucumber (including fruit cucumber) and tomato (cherry tomato) from China. Studies were conducted according to GLP or under the supervision of a study director.

All trials included one control plot and one treated plot. There was no acetamiprid detected above LOQ value, 0.01 mg/kg in control samples. In all trials, at least two samples were taken from a single treated plot. The average residue value was considered for estimation of the maximum residue level. The storage period of the field trial samples did not impact the residue levels, as described in the above section on *stability of residues in stored analytical samples*.

Crop group	Commodity	Table No.
Fruiting vegetables, Cucurbits	Cucumber	5, 6
Fruiting vegetables, other than Cucurbits	Tomato	7, 8
	Cherry tomato	9
	Sweet corn (corn-on-the-cob)	10, 11
Leafy vegetables (incl. Brassica leafy vegetables)	Mustard greens	12
Stalk and stem vegetables	Asparagus	13
Primary feed commodities	Sweet corn, forage	14, 15
	Sweet corn, stover	16, 17

Fruiting vegetables, Cucurbits

Cucumber

Eight residue trials on field-grown cucumbers were conducted in China (Shandong, Fujian, Jilin, Yunnan, Guangdong, Zhejiang, Hunan and Anhui) in 2013. In addition, three trials (Shandong, Fujian and Jilin) on cucumbers and fruit cucumbers were conducted under greenhouse conditions.

At each trial, one treated plot received three applications of the test substance (200 SP formulation, 200 g ai/L) 6–7 days apart. Foliar spray applications were made at growth stages of BBCH 61–71 and the application rate was 0.090 kg ai/ha. Cucumber (or fruit cucumber) in each trial was harvested 0, 1, 2, 3 and 5 days after the last application.

Two decline studies on field-grown cucumber were also conducted in the Shandong and Jujian. One application was made at a rate of 0.090 kg ai/ha and cucumber was harvested 0, 1, 3, 5, 7, 10 and 14 days after the last application.

Six samples from each trial were harvested (1.2–5 kg per sample). From the each sample, a sub sample of 200–320 g was taken and stored in a freezer at –20 °C or below. The deep-frozen sub samples were shredded in a cutter. Representative parts of the shredded samples were transferred into polystyrene box and stored at –18 °C or below until analysis. Residue analysis was made with three samples of the six.

Fruiting vegetables, other than Cucurbits

Tomato, Cherry tomato

Eight residue trials on field-grown tomatoes were conducted in China (Shandong, Fujian, Jilin, Yunnan, Guangdong, Zhejiang, Hunan and Anhui) in 2013. In addition, three trials (Shandong, Fujian and Jilin) on tomatoes and cherry tomatoes each were conducted under greenhouse conditions.

At each trial, one treated plot received two foliar applications of the test substance (30 ME formulation, 30 g ai/L) 7 days apart. Foliar spray application was made at growth stages of BBCH 79 and 83 and the application rate were 0.027 kg ai/ha. Tomatoes (or cherry tomatoes) were harvested 3, 5, 7, 10 and 14 days after the last application. Residue trials on tomato and cherry tomato made under greenhouse conditions were carried out in the same site of each region and at the same application time.

Two decline studies on field-grown tomato were also conducted in the Shandong and Fujian regions of China. One application was made at a rate of 0.041 kg ai/ha and tomato was harvested 0, 1, 3, 5, 7, 10, 14, 21, 28 and 35 days after the last application.

Six samples from each trial were harvested (1.2–4 kg per sample). From each sample, a sub sample of 132–400 g was taken and the sub samples were shredded in a food processor. Representative parts of the shredded samples were then transferred into polystyrene boxes and stored at –18 °C or below until analysis. Residue analysis was made with three samples of the six.

Sweet corn (corn-on-the-cob)

Eight trials were conducted in Canada (ON, BC, QC and AB) in 2006. At each site, sweet corn plants were treated with four applications (70 WP formulation, broadcast foliar spray) 6–8 days apart. The application rate ranged from 0.059 to 0.063 kg ai/ha (total, 0.24 to 0.25 kg ai/ha/season), with the exception of Trial No. 138. In that trial, the first three applications were made at 0.083–0.087 kg ai/ha and the forth application was made at 0.060 kg ai/ha (total, 0.32 kg ai/ha/season) due to calculation error. Samples of kernel plus cob with husk removed were collected 1–2 days after the last application. At Trial No. 131, additional samples were collected 0, 3 and 7 days after the last application.

In addition, seven trials were conducted in the USA (CA, FL, GA, ID, NY, SC and WI) in 2009. One treated plot received four foliar applications of the test substance (30 SG formulation) 6–8 days apart, except in the GA*14 trial in which the intervals were as short as 4 days. The application rates were in the range 0.059 to 0.064 kg ai/ha (total, 0.24 to 0.25 kg ai/ha/season). A second treated plot received two foliar applications of the test substance (30 SG formulation) 12–16 days apart. The application rates were in the range 0.11 to 0.12 kg ai/ha (total, 0.22 to 0.24 kg ai/ha/season).

Samples of kernel plus cob with husk removed were collected one day from the four application plot and 5–8 days from the two application plot, after the last application.

Table 10 Residues resulting from acetamiprid application to sweet corn in Canada in 2006 (Report: AAFC06-034R)

30 SG (30% soluble granule) formulation was used; residue in kernel plus cob with husk removed was analysed.

Leafy vegetables (incl. Brassica leafy vegetables)

Mustard greens

Eight supervised residue trials were conducted in the USA (AR, CA, GA, NC, OH, SC and TX) in 2009. At each trial, four foliar applications of the test substance (70 WP) were made 6–8 days apart, except in the GA*06 trial where a fifth application was needed because the crop was not mature after four applications. The application rates were in the range of 0.083–0.12 kg ai/ha/application. The total rate range per growing season was 0.42–0.43 kg ai/ha (GA*06 trial, 0.53 kg ai/ha). A non-ionic surfactant was included in the tank mix for each application. Samples of mustard green leaves were collected 2–4 days after the last application

Table 12 Residues resulting from acetamiprid application to mustard greens in the USA in 2009 (Report: IR-4 PR No. 09271)

Location (Variety) Year	Application			DALA	Residue, mg/kg	Mean residue, mg/kg	Trial No.
	kg ai/ha	n.	Inter. days				
GAP, USA	0.11	4	7	PHI, 3 days			
Alma, AR (Florida Broadleaf)	0.085–0.12	4	6–8	3	8.4, 10	9.2	AR07
Salinas, CA (Red Giant)	0.084–0.12	4	7–8	3	2.4 2.9	2.7	CA*51
Salinas, CA (Green Wave)	0.087–0.12	4	7	4	1.5, 1.6	1.6	CA*52
Tifton, GA (Florida Broadleaf)	0.083–0.11	5 [a]	7–8	3	2.1, 2.2	2.2	GA*06
Clinton, NC (Southern Giant Curled)	0.083–0.11	4	7–8	4	1.2, 1.2	1.2	NC10

Location (Variety) Year	Application			DALA	Residue, mg/kg	Mean residue, mg/kg	Trial No.
	kg ai/ha	n.	Inter. days				
Willard, OH (Green Wave)	0.090–0.12	4	7	2	0.20, 0.40	0.30	OH*04
Charleston, SC (Florida Broadleaf)	0.085–0.11	4	6–8	3	1.4, 2.0	1.7	SC*03
Weslaco, TX (Florida Broadleaf)	0.087–0.12	4	6–7	2	2.4, 2.4	2.4	TX*19

70 WP (70% wettable powder) was applied in all trials.

CA*51 and CA*52 trials were conducted two months apart.

[a] Extra treatment was made as samples were maturing too slowing due to excessive rain. A total rate was 0.53 kg ai/ha/season.

Stalk and stem vegetables

Asparagus

Eight supervised residue trials were conducted in the USA (CA, ID, MD, MI, WA) in 2008 and 2009. At each trial, two applications of the test substance (70 WP) were made 10–14 days apart. The application rates were in the range of 0.11–0.12 kg ai/ha/application. Non-ionic surfactant was included in the tank mix in trials CA34, ID05, MI33, MI34 and in the second application of WA06. Samples of asparagus spears were harvested one day after the last application. One decline study (CA37 trial) was conducted and samples were collected 0, 1, 4, 8 and 11 days after the last application.

Table 13 Residues resulting from acetamiprid application to asparagus in the USA (Report: IR-4 PR No. 09939)

Location (Variety) Year	Application			DALA	Residue, mg/kg	Mean residue, mg/kg	Trial No.
	kg ai/ha	n	Inter. days

				4	0.08, 0.08	0.08	
				8	0.01, 0.01	0.01	
				11	< 0.01, < 0.01	< 0.01	
Marsing, ID (Jersey King) 2008	0.11, 0.11	2	12	1	0.38, 0.43	0.41	ID05
Sailsbury, MD (Jersey Knight) 2008	0.11, 0.11	2	11	1	0.11, 0.13	0.12	MD17
East Lansing, MI (Jersey Giant) 2008	0.11, 0.11	2	12	1	0.28, 0.29	0.29	MI33
East Lansing, MI (Jersey Giant) 2008	0.11, 0.12	2	12	1	0.26, 0.26	0.26	MI34
Eltopia, WA (Jersey Knight) 2008	0.11, 0.11	2	13	1	0.25, 0.27	0.26	WA06

70 WP (70% wettable powder) was applied in all trials.

CA35* and CA37* trials were conducted at the same site however application was made 7 days apart. These trials were considered as independent as asparagus is shortly grown for 7 days.

Primary feed commodities

Sweet corn, forage and stover

Residue trials on sweet corn were conducted in Canada (eight trials in 2006) and the USA (seven trials in 2009). Application methods of test substance are described above in food commodity of sweet corn (corn-on-the-cob). Forage samples were collected on the same day as harvesting samples of kernel plus cob with husk removed in both Canada and USA.

For stover in Canada, samples (stalks with ear removed) were collected 38–89 days after the last application. This was a period after the ears were harvested and allowed to dry, free-standing in the field.

In the USA, stover samples were collected concurrently with sampling of forage (except Trial No. NY14). The samples (stalks with ear removed) were cut and dried (either in the field or in a sheltered area/low temperature "oven"). In the NY14 trial, stover samples were not cut and were allowed to dry in the field before being harvested. Harvesting was 35 days and 28 days after four and two applications of the test substance, respectively.

30 SG (30% soluble granule) formulation was used. Residues are expressed on a dry matter.

APPRAISAL

Acetamiprid was evaluated for the first time by the 2011 JMPR, where an ADI of 0–0.07 mg/kg bw and an ARfD of 0.1 mg/kg bw were established and maximum residue levels were recommended for a range of plant and animal commodities. The compound was re-evaluated by the 2012 JMPR.

At the Forty-sixth Session of the CCPR (2014), acetamiprid was listed for residue evaluation for additional maximum residue levels by the 2015 JMPR. The Meeting received information on supervised residue trials for asparagus, cucumber, mustard greens, sweet corn (corn-on-the-cob) and tomato including cherry tomatoes.

For both compliance with MRL and estimation of dietary intake, the residue is defined as acetamiprid for plant commodities, and the sum of acetamiprid and desmethyl-acetamiprid for animal commodities. The residue is not fat-soluble.

Methods of analysis

Acceptable analytical methods were developed and validated for determination of acetamiprid in asparagus, mustard greens and sweet corn. These methods were based on Method KP-216 which was considered suitable by 2011 JMPR. Other analytical methods used for sweet corn, cucumber and tomato were also fully validated. All methods used analysis by LC-MS/MS and the limits of quantification (LOQs) were 0.01 mg/kg in all matrices.

Stability of residues in stored analytical samples

In 2011, JMPR concluded that acetamiprid is stable for at least 12 months in apple, cabbage, cucumber and 16 months for lettuce.

The present Meeting received acetamiprid stability studies on asparagus, cucumber, mustard greens, sweet corn and tomato, showing that residues were stable under frozen condition for at least 426 days for asparagus, 304 days for cucumber and tomato, 382 days for mustard greens and 384–391 days for sweet corn samples (kernel plus cob with husk removed, forage and stover).

Based on the available storage stability information, the Meeting concluded that acetamiprid was stable for the period of actual storage days associated with the submitted residue trials.

Results of supervised residue trials on crops

Fruiting vegetables, Cucurbits

Cucumber

Supervised trials were conducted in China in 2013, matching the China GAP on cucumber (3 sprays applications at 0.090 kg ai/ha and a PHI of 2 days). Eight trials were conducted under field conditions. Another six trials were conducted under greenhouse conditions, two trials of which were not independent and another two trials were also not independent. Additionally, two decline studies on field-grown cucumber were conducted with one application at a rate of 0.090 kg ai/ha. The residues decreased with a half-life of 2.1 or 3.9 days.

From residue trials matching the China GAP on cucumber, acetamiprid residue values were as follows:

Field-grown cucumber (n=8): 0.011, 0.020, 0.024, 0.042, 0.059, 0.070, 0.12 and 0.13 mg/kg.

Greenhouse-grown cucumber (n=4): 0.027, 0.055, 0.072 and 0.089 mg/kg.

As the residue distributions of acetamiprid between field-grown and greenhouse-grown cucumber were similar, residue values were combined (n=12): 0.011, 0.020, 0.024, 0.027, 0.042, 0.055, 0.059, 0.070, 0.072, 0.089, 0.12 and 0.13 mg/kg.

The Meeting estimated a maximum residue level of 0.3 mg/kg, an STMR of 0.057 mg/kg and an HR of 0.17 mg/kg (based on a highest single sample) for cucumber.

Further, the Meeting withdrew its previous recommendations for Fruiting vegetables, Cucurbits and estimated a maximum residue level of 0.2 mg/kg, an STMR of 0.05 mg/kg and an HR of 0.11 mg/kg for Fruiting vegetables, Cucurbits (except cucumber).

Fruiting vegetables, other than Cucurbits

Tomato

Supervised trials were conducted in China in 2013, matching the China GAP on tomato (2 sprays at 0.027 kg ai/ha and a PHI of 7 days). Eight trials on tomato were conducted under field conditions and an additional three trials on each of tomato and cherry tomato were conducted under greenhouse conditions. Additionally, two decline studies on field-grown tomato were conducted with one application at a rate of 0.041 kg ai/ha. The residues decreased with an average half-life of 11.6 days.

From residues trials matching the China GAP on tomato, acetamiprid residue values were as follows:

Field-grown tomato (n=8): < 0.01, 0.011, 0.011, 0.012, 0.020, 0.022, 0.022 and 0.025 mg/kg.

Greenhouse-grown tomato (n=3): < 0.01, 0.015 and 0.027 mg/kg.

Greenhouse-grown cherry tomato (n=3): 0.018, 0.021 and 0.050 mg/kg.

The 2011 JMPR recommended a maximum residue level of 0.2 mg/kg, an STMR of 0.04 mg/kg and an HR of 0.14 mg/kg for Fruiting vegetables, other than Cucurbits, based on residues in tomato (outdoor), sweet pepper and chili pepper conducted according to the US GAP (four foliar applications at 0.084 kg ai/ha and a PHI of 7 days). Since the authorization in the US represents the critical GAP, this Meeting confirmed its previous recommendations for Fruiting vegetables, other than Cucurbits (except sweet corn & mushrooms).

Sweet corn

Seven trials were conducted in the USA in 2009, matching a critical US GAP (two foliar sprays at 0.11 kg ai/ha with a 14-day retreatment interval and a PHI of 7 days). Residue concentrations in sweet corn (kernel plus cob with husk removed) from the USA trials were all < 0.01 mg/kg (n=7).

The Meeting estimated a maximum residue level of 0.01* mg/kg, an STMR of 0.01 mg/kg and an HR of 0.01 mg/kg for sweet corn (corn-on-the-cob).

Leafy vegetables (including Brassica leafy vegetables)

Mustard greens

Eight trials on mustard greens were conducted in the USA in 2009, matching the US GAP (four foliar sprays at 0.11 kg ai/ha with a 7-day retreatment interval and a PHI of 3 days).

Acetamiprid residues in mustard greens were (8): 0.30, 1.2, 1.6, 1.7, 2.2, 2.4, 2.7 and 9.2 mg/kg.

The Meeting estimated a maximum residue level of 15 mg/kg, an STMR of 2.0 mg/kg and an HR of 10 mg/kg (based on highest single sample) for mustard greens. However, this would result in an exceedance of the ARfD and an alternative GAP for mustard greens was not identified.

Stalk and stem vegetables

Asparagus

Eight trials on asparagus were conducted in the USA in 2008 and 2009, matching the US GAP (two sprays at 0.11 kg ai/ha with a 10-day retreatment interval and a PHI of 1 day).

Acetamiprid residues in asparagus were (n=8): 0.12, 0.16, 0.21, 0.26 (3), 0.29 and 0.41 mg/kg.

The Meeting estimated a maximum residue level of 0.8 mg/kg, an STMR of 0.26 mg/kg and an HR of 0.43 mg/kg (based on highest single sample) for asparagus.

Primary feed commodities

Sweet corn forage and stover

The trial conditions are described under the food commodity. For feed commodity, sweet corn forage and stover samples were harvested in the seven USA trials. In one trial, the PHI in sampling of stover did not match the US GAP.

Acetamiprid residues in sweet corn forage were (n=7): 0.41, 0.76, 1.4, 1.4, 2.4, 4.7 and 9.1 mg/kg.

Acetamiprid residues in sweet corn stover were (n=6): 0.21, 2.6, 2.8, 2.8, 8.4 and 20 mg/kg.

The Meeting estimated a median residue of 1.4 mg/kg and highest residue of 9.1 mg/kg for sweet corn forage.

The Meeting estimated a maximum residue level of 40 mg/kg, median residue level of 2.8 mg/kg and highest residue of 20 mg/kg on a dry weight basis for sweet corn stover.

Residues in animal commodities

Livestock dietary burden

Dietary burden calculations considered by the current Meeting for beef cattle and dairy cattle, incorporating sweet corn, are presented in Annex 6. Dietary burdens for poultry were not calculated as sweet corn (forage, stover and cannery waste) is not a relevant feed item.

The dietary burdens for beef cattle and dairy cattle were estimated using OECD diets listed in Appendix IX of the 2009 edition of the FAO Manual.

Summary of cattle dietary burdens (ppm of dry matter diet)

	US-Canada		EU		Australia	
	max	mean	max	mean	max	mean
Beef cattle	1.1	0.29	0.83	0.28	18[a]	2.7[b]
Dairy cattle	9.5[c]	1.6	0.84	0.29	9.0	1.7[d]

[a] Highest maximum beef or dairy cattle dietary burden suitable for maximum residue level estimates for mammalian meat and edible offal

[b] Highest mean beef of dairy cattle dietary burden suitable for STMR estimates for mammalian meat and edible offal

[c] Highest maximum dairy cattle dietary burden suitable for maximum residue level estimates for milk

[d] Highest mean dairy cattle dietary burden suitable for STMR estimates for milk

Animal commodity maximum residue levels

Livestock feeding studies involving administration of acetamiprid to dairy cows were reported in the 2011 JMPR Report.

Estimated maximum and mean dietary burdens were 18 ppm and 2.7 ppm for beef cattle and 9.5ppm and 1.7 ppm for dairy cattle, respectively. The calculation to estimate total residues

(acetamiprid plus desmethyl-acetamiprid) for maximum residue levels, STMR and HR values are shown below.

	Feed level (ppm) for milk residues	Residues (mg/kg) in milk	Feed level (ppm) for tissue residues	Residues (mg/kg) in			
				Muscle	Liver	Kidney	Fat
Maximum residue level beef or dairy cattle							
Feeding study [a]	5.77	0.063					
	17.4	0.209	17.4	0.289	0.64	0.86	0.153
Dietary burden and residue estimate	9.5	0.11	18	0.30	0.67	0.89	0.16
STMR beef or dairy cattle							
Feeding study [b]	5.77	0.063	5.77	0.048	0.15	0.24	0.037
Dietary burden and residue estimate	1.7	0.019	2.7	0.022	0.070	0.11	0.017

[a] Highest residues for tissues and mean residue for milk

[b] Mean residues for tissues and milk

For beef and dairy cattle, the Meeting estimated HR values for acetamiprid (total residue) of 0.30 mg/kg in muscle, 0.89 mg/kg in edible offal (based on kidney) and 0.16 mg/kg in fat. STMR values were estimated at levels of 0.019 mg/kg for milk, 0.022 mg/kg for muscle, 0.11 mg/kg in edible offal (based on kidney) and 0.017 mg/kg for fat.

The Meeting also estimated the following maximum residue levels to replace its previous recommendations: 0.2 mg/kg for milk, 0.5 mg/kg for meat (from mammals other than marine mammals), 0.3 mg/kg for mammalian fats (except milk fats) and 1.0 mg/kg for edible offal (mammalian).

The previous recommendations for poultry tissues and eggs are maintained.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed in Annex I are appropriate for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of the residue for plant commodities (for compliance with MRL and estimation of dietary intake): *acetamiprid.*

Definition of the residue for animal commodities (for compliance with MRL and estimation of dietary intake): *sum of acetamiprid and desmethyl-acetamiprid, expressed as acetamiprid*.

The residue is not fat-soluble.

CCN	**Commodity**	**Recommended Maximum residue level (mg/kg)**		**STMR or STMR-P mg/kg**	**HR or HR-P mg/kg**
		New	**Previous**		
VS 0621	Asparagus	0.8		0.26	0.43
VC 0424	Cucumber	0.3		0.057	0.17

		New	Previous		
	Sweet corn, stover	40		2.8	20
	Sweet corn forage			1.4	9.1

[a] On the basis of information provided to the JMPR it was not possible to conclude that the estimated short-term intake of acetamiprid for consumption of mustard greens was less than the ARfD

DIETARY RISK ASSESSMENT

Long-term intake

The WHO panel of the 2011 JMPR established an ADI of 0–0.07 mg/kg bw for acetamiprid. The International Estimated Daily Intakes (IEDIs) for acetamiprid were calculated for the 17 GEMS/Food cluster diets using STMRs and STMR-Ps estimated by the current and previous Meeting. The results are shown in Annex 3 in the 2015 JMPR Report.

The calculated IEDIs represented 0–4% of the maximum ADI. The Meeting concluded that the long-term intake of residues of acetamiprid from used that have been considered by the JMPR is unlikely to present a public health concern.

Short-term intake

The WHO panel of the 2011 JMPR established an ARfD of 0.1 mg/kg. The International Estimated Short Term Intakes (IESTIs) for acetamiprid was calculated for the food commodities using HR/ STMR estimated by the current Meeting. The results are shown in Annex 4 in the 2015 JMPR Report.

For mustard greens, the IESTI represented 490% and 200% of the ARfD for children and general population, respectively. No alternative GAP was available. On the basis of information provided to the JMPR, the meeting concluded that the short-term intake of acetamiprid from consumption of mustard greens may present a public health concern.

Estimates of intake for the other commodities considered by the 2015 JMPR were within 0–10% ARfD. The Meeting concluded that the short-term intake of acetamiprid for these other commodities is unlikely to present a public health concern when acetamiprid is used in ways that were considered by the Meeting.

ACETOCHLOR (280)

First draft prepared by Dr D.J. MacLachlan, Department of Agriculture and Water Resources, Canberra, Australia

EXPLANATION

Acetochlor is a selective herbicide, which after application is absorbed mainly by the shoots of germinating plants and to some extent by roots. Acetochlor controls annual grasses and broadleaf weeds, germinating from seeds; however, its action against perennial weeds is very limited. Acetochlor is a pre-emergence or early post-emergence soil-applied herbicide for the control of annual grasses and certain annual broadleaf weeds. At the 46th Session of the CCPR (2014), it was scheduled for evaluation as a new compound by 2015 JMPR.

The Meeting received information on the metabolism of acetochlor in lactating goats and cows, laying hens, maize, soya beans and cotton, follow crops, methods of residue analysis, freezer storage stability, GAP information, supervised residue trials on maize (forage, grain, stover and silage), sweet corn (forage, kernels plus cob with husks removed, stover and silage), cotton (gin by-products and seed), sorghum (grain, forage and stover), soya bean (meal and seed), sugar beet (dried pulp, roots, tops, sugar and molasses), peanut (hay and meal) and livestock transfer studies (lactating cows and laying hens).

IDENTITY

Common name	Acetochlor
Chemical name	
IUPAC:	2-chloro-*N*-ethoxymethyl-6'-ethylacet-*o*-toluidide
CAS:	2-chloro-*N*-(ethoxymethyl)-*N*-(2-ethyl-6-methylphenyl)acetamide
Manufacturer's code numbers:	MON 097
CAS number:	34256-82-1
CIPAC Code:	496
Molecular formula:	$C_{14}H_{20}ClNO_2$
Molecular mass:	269.77 g/mole
Structural formula:	
Specifications

Specifications for acetochlor have not been developed by the FAO.

Physical and chemical properties (pure acetochlor 99.9%)

Property	Results (method)	Reference
Appearance	Pale yellow, free-flowing liquid	
Melting point	10.6 ±0.1 °C	Pigeon 1999 MLL-31389
Boiling point	172 °C at 665 Pa	Pigeon 1999 MLL-31389

Property	Results (method)	Reference
Relative density	1.1221 g/cm³ at 20 ± 0.5 °C	Pigeon 1999 MLL-31389
pH	Non-ionisable	
Vapour pressure	2.2×10^{-5} hPa at 20 °C 4.6×10^{-5} hPa at 25 °C	Franke 2002 MLL-31685
Solubility in water	282 mg/L at 20 °C	Pigeon 1999 MLL-31389
Solubility in organic solvents (at 20 °C) (g/L)	methanol > 5000 g/L acetone > 5000 g/L n-heptane > 5000 g/L ethyl acetate > 5000 g/L p-xylene > 5000 g/L 1,2-dichloroethane > 5000 g/L	Pigeon 1999 MLL-31389
Partition coefficient n-octanol/water	log K_{ow} = 4.14 at 20 °C	Pigeon 1999 MLL-31389
Hydrolysis under sterile conditions	Stable at pH 5,7 and 9 and at 25 °C; No hydrolysis detected after 31 days	Myers 1989 WRC-88-70
Photolysis	Photolytically stable in sterile water at 25 °C	Chotalia & Weissler 1989 RJ0726B

Formulations

Acetochlor is available in emulsifiable concentrate (EC) and micro-encapsulated suspension (CS) formulations.

Formulations	Active ingredient content
EC	839 g/L
CS	359 g/L

METABOLISM AND ENVIRONMENTAL FATE

To enable interpretation of the different studies a common numbering scheme for metabolites has been developed based on one reported in the EU. The metabolite summary table provides a reference for the numbering scheme used in the current evaluation.

Table 1 Degradation compounds from metabolism of acetochlor in plants, animals, soil, or water

Code no	Company code	Term used in evaluation	Structure	Found in:
1		acetochlor		rat faeces goat faeces
2	R290130 MON52755 ICIA5796/17	*tert*-oxanilic acid		maize forage, stover soya bean forage, hay sediment/water, aerobic soil

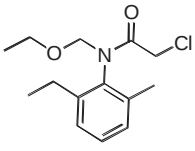
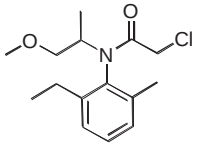
117		1-hydroxyethyl *sec*-thiolactic acid		cotton stems and leaves
118		*sec*-sulfinyllactic acid		maize forage, stover, and grain soya bean forage and hay cotton leaves and stems

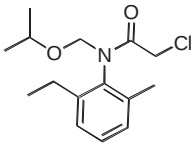
Acetochlor is a member of the chloroacetamide herbicides, a group that also includes metolachlor, propisochlor, alachlor and butachlor. The structures of these herbicides are similar, especially in the case of acetochlor, metolachlor and propisochlor, which all contain ethyl and methyl group substitutions at the 2- and 6-positions, respectively, of the phenyl group. These three herbicides share some common secondary amide metabolites that result from cleavage of their alkyl ether groups from the nitrogen.



Acetochlor



Metolachlor

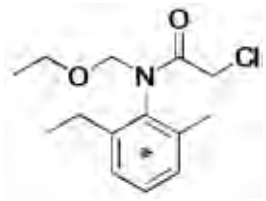


Propisochlor

The Meeting received studies on the metabolism of acetochlor in plants (maize, soya bean, and cotton), laboratory animals (rats, mice and rhesus monkey) as well as lactating goats and laying

hens. The metabolism of acetochlor in plants and animals was investigated using [14C-U-phenyl]-acetochlor. The structural formula and the positions of the 14C label are shown below. The studies on rats, mice and monkeys were evaluated by the WHO Core Assessment Group.

In addition, information is provided on the metabolic fate of acetochlor *tert*-sulfonic acid, acetochlor *tert*-oxanilic acid, acetochlor *tert*-sulfinylacetic acid, and *tert*-hydroxyacetochlor in hens and goats, the fate of acetochlor 1-hydroxyethyl *tert*-oxanilic acid in goats, and the fate of N-(6-ethyl-3-hydroxy-2-methylphenyl) oxamic acid in the lactating cow.



[^{14}C-U-phenyl]-acetochlor
Figure 1 Label positions of acetochlor: marked as * to indicate uniform labelling of the six carbons in the phenyl ring

The identification of residue components in the animal and plant metabolism studies was achieved using, where available, authentic standards of the compounds involved as well as mass spectral techniques. Additional techniques such as hydrolysis, derivatization, and enzymatic degradation were used in many cases to aid in characterizing metabolites. Individual studies utilised different numbering schemes for metabolites, sometimes even within the same study. A harmonised numbering scheme is used in this report.

In the metabolism reports that follow, acetochlor and certain metabolites are sometimes listed as occurring in multiple fractions of a single chromatogram. Hindered rotation about the amide nitrogen results in different rotational isomers (rotamers) and for some cases diastereomers.

Plant metabolism

Acetochlor is typically used for three different situations:

- Incorporation into the soil prior to planting the crop (PP)
- As a broadcast spray to weeds and bare soil after seeding but prior to crop emergence (PE)
- As a broadcast spray to weeds and the growing crop, i.e. post-emergence (PO)

The Meeting received plant metabolism studies with acetochlor following pre- and post-emergent applications to maize (corn), cotton and soya bean.

Herbicide safeners are utilised when using acetochlor for weed control in monocotyledonous cereals such as maize. The metabolism studies reviewed here for maize included the safener furilazole. Ekler *et al.* (1993) [Ekler Z, Dutka F, Stephenson GR (1993), *Safener effects on acetochlor toxicity, uptake, metabolism and glutathione S-transferase activity in maize*. *Weed Research*, 33: 311–318] noted that safeners significantly increased the uptake of [^{14}C]acetochlor, the rate of its metabolism, maize GSH content and GST activity. Seedlings receiving pre-treatment with the herbicide safener BAS-145138 metabolised almost 70% of the absorbed [^{14}C]acetochlor within 10 minutes. In contrast, Jackson *et al.* (1989) (Jackson LA, Yopp JH, Kapusta G (1989*) Absorption and distribution of flurazole and acetochlor in grain sorghum*. *Pesticide Biochemistry and Physiology* 25: 373–380.) observed that safened plants did not exhibit more rapid breakdown of acetochlor compared to non-safened plants. The metabolites formed, judged by comparison of TLC plates, were similar for plants treated with and without flurazole.

Maize

Kurtzweil (2009, MSL0020769) studied the metabolism of [^{14}C]acetochlor in maize grown in outdoor plots. The test substance consisted of [U-^{14}C-phenyl]-acetochlor and also contained a ^{13}C-label at the C-2 position of the 2-chloroacetamide moiety to aid in structure elucidation of metabolites by mass spectroscopy. Roundup Ready® corn NK603 (*Zea mays* L., hybrid DKC69-72) was planted in two plots (1.49 m^2 each) consisting of plastic-lined plywood boxes embedded in the ground to simulate field conditions. One of the plots (PE) was treated with a pre-emergence (PE) application of a [^{14}C]acetochlor spray solution immediately after seeding. After allowing the corn plants to grow to a height of 66–71 cm (growth stage V6–V7), the other plot was treated post-emergence (PO) by uniformly applying the test substance to the foliage via a spray bottle. The effective treatment rate of acetochlor test substance for the PE application 3.65 kg ai/ha and the effective treatment for the PO application was 3.52 kg ai/ha. In addition to an initial V3 thinning from the PE plot 26 days after treatment (DAT), four samplings were conducted for both the control and treated maize plots: a harvest at 95 DAT (PE) and 54 DAT (PO) of kernels plus cob with husk removed corresponding to a typical sweet corn harvest, a forage harvest at 111 DAT (PE) and 70 DAT (PO), and a final harvest of mature maize at 141 DAT (PE) and 100 DAT (PO) that sampled grain and stover.

The ^{14}C found in maize immature plants, forage, and stover (expressed as mg/kg acetochlor equivalents) is summarized in Table 2. The TRR in forage were 0.67 and 3.44 mg equiv/kg for the PE and PO treatments, respectively. In stover, the TRRs follow the same trend where they are 1.84 and 6.41 mg equiv/kg for the PE and PO treatments, respectively. In the sweet corn (KWHR) and grain were much lower (0.009–0.037 mg equiv/kg).

Table 2 TRR in maize commodities after application of [^{14}C]acetochlor

Treatment	Matrix	DAT	Matrix TRR (mg equiv/kg)
Pre-emergence	V3 immature plant (thinnings)	26	1.19
	Sweet corn (KWHR)	95	0.011
	Forage	111	0.67
	Grain	141	0.037
	Stover	141	1.84
Post-emergence	Sweet corn (KWHR)	54	0.009
	Forage	70	3.44
	Grain	100	0.022
	Stover	100	6.41

Homogenised samples were extracted with CH_3CN/H_2O (4×) (20:80 v/v for forage and immature plant 40:60 v/v in the case of grain and stover). A fifth extraction was with CH_3CN. Subsamples of the forage and stover PES were extracted sequentially with 0.1 N HCl and 0.1 N NaOH. Additional sub-samples of PES were subjected sequentially to (in order) a phosphate rinse, hydrolysis with α-amylase to produce a starch fraction, hydrolysis with protease to yield a protein fraction, EDTA extraction to produce the pectin fraction, oxidation with chlorite to yield the lignin fraction, hydrolysis with cellulase to produce the cellulose fraction and hydrolysis with strong base to yield the hemi-cellulose fraction.

CH_3CN/H_2O extracted ≥ 79% of the TRR present in immature plants, forage and stover samples. Extraction of ^{14}C present in grain with the solvent system used was lower at 58–63% TRR. The majority of the ^{14}C present in PES of forage and stover was associated with natural products, especially starch, protein, lignin and hemicellulose.

Table 3 Characterisation of ^{14}C residues in maize commodities following pre- or post-emergence application (%TRR)

[a] CH_3CN/H_2O extracts were adjusted to pH 8–9 and partitioned with ethyl acetate. The organic layer from the base partition contains neutral metabolites. The pH of the aqueous layer was adjusted to pH 2 and partitioned with ethyl acetate. The organic layer from the acid partition contains weak and moderate acids. Strong acids, polar and hydrophilic compounds are retained in the aqueous layer.

Analysis of extracts by reverse-phase HPLC showed that the metabolism of acetochlor in maize was extensive giving rise to a large number of metabolites with no unchanged acetochlor observed in any of the matrices. Identification was not possible for 16–25 fractions for PE and 15 fractions for PO matrices. Nearly all metabolites present at 0.05 mg/kg or higher were isolated and purified by preparative HPLC and either identified by mass spectrometry or thoroughly characterized. A fraction containing 9.4% TRR PE forage, 4.8% PE stover, 5.0% PO forage and 7.4% PO stover appeared to comprise large molecular weight material possibly phenolic conjugates of *tert*-sulfinyllactic acid as well as with some other acetochlor related metabolites.

Metabolite isolation was only conducted on forage and stover extracts as TRRs in grain were too low to permit identification or characterization of isolated metabolites. For grain, metabolite identification was based on retention time comparison of metabolites. In grain, no individual compound exceeded 10% of TRR and no discrete component characterized by chromatography exceeded 0.001 mg equiv/kg.

The acetochlor metabolites identified in PO forage and stover primarily resulted from initial glutathione conjugation of acetochlor followed by oxidation to give sulfoxide-type metabolites. One compound exceeded 10% of TRR: *tert*-sulfinyllactic acid (21) was observed at 12.6% TRR (0.434 mg equiv/kg) in forage and 11.3% of TRR (0.722 mg equiv/kg) in stover. Two other metabolites exceeded 0.1 mg equiv/kg: *sec*-sulfinyllactic acid (72) and *sec*-sulfinyllactic acid glucose conjugate (83).

In contrast, the metabolism of acetochlor in PE maize resulted in large part from the uptake of soil metabolites to give oxanilate-type metabolites. None of the individual components exceeded 10% of TRR in immature plant, forage or stover. The major metabolite was 5-hydroxy *sec*-oxanilic acid (68) present at levels of 8.4% (0.099 mg equiv/kg), 6.2% (0.042 mg equiv/kg) and 4.3% (0.080 mg equiv/kg) TRR in immature plants, forage and stover respectively.

Compounds containing an intact phenyl ring can be classified according to the aniline that would be generated in base hydrolysis. Nonhydroxylated metabolites give EMA, those hydroxylated at the 1-position of the ethyl side-chain give HEMA, those hydroxylated at the methyl side-chain HMEA, those hydroxylated at the 3, 4 or 5 positions of the phenyl ring could be classed as “OH” anilines and the remaining as “other”. The individual metabolites identified are plotted according to their aniline metabolite class for forage and stover. The major aniline metabolite class observed is EMA followed by OH (Figures 2 and 3).

The use of a common moiety may potentially be useful for residue analytical methods.

Acid pressure hydrolysis (6 M HCl, 150 °C, capped vials, > 2 hr) was used to characterize both whole CH_3CN/H_2O extracts of each matrix and isolated metabolites. This hydrolysis technique converts the relevant metabolites to their corresponding anilines. For PO forage and stover, approximately 45 to 64% of the ^{14}C residues in the extracts of forage and stover were converted to EMA with smaller amounts to an aniline corresponding to HEMA class metabolites (3.6–8.7%). PE forage and stover contained 26–28% EMA aniline class metabolites, 8.4–8.9 HEMA class, 2.5–3.1 HMEA class and 11–12% 5-OH class.

Pathways for the metabolism of acetochlor in maize from PE and PO treatments are shown in Figures 4 and 5, respectively.

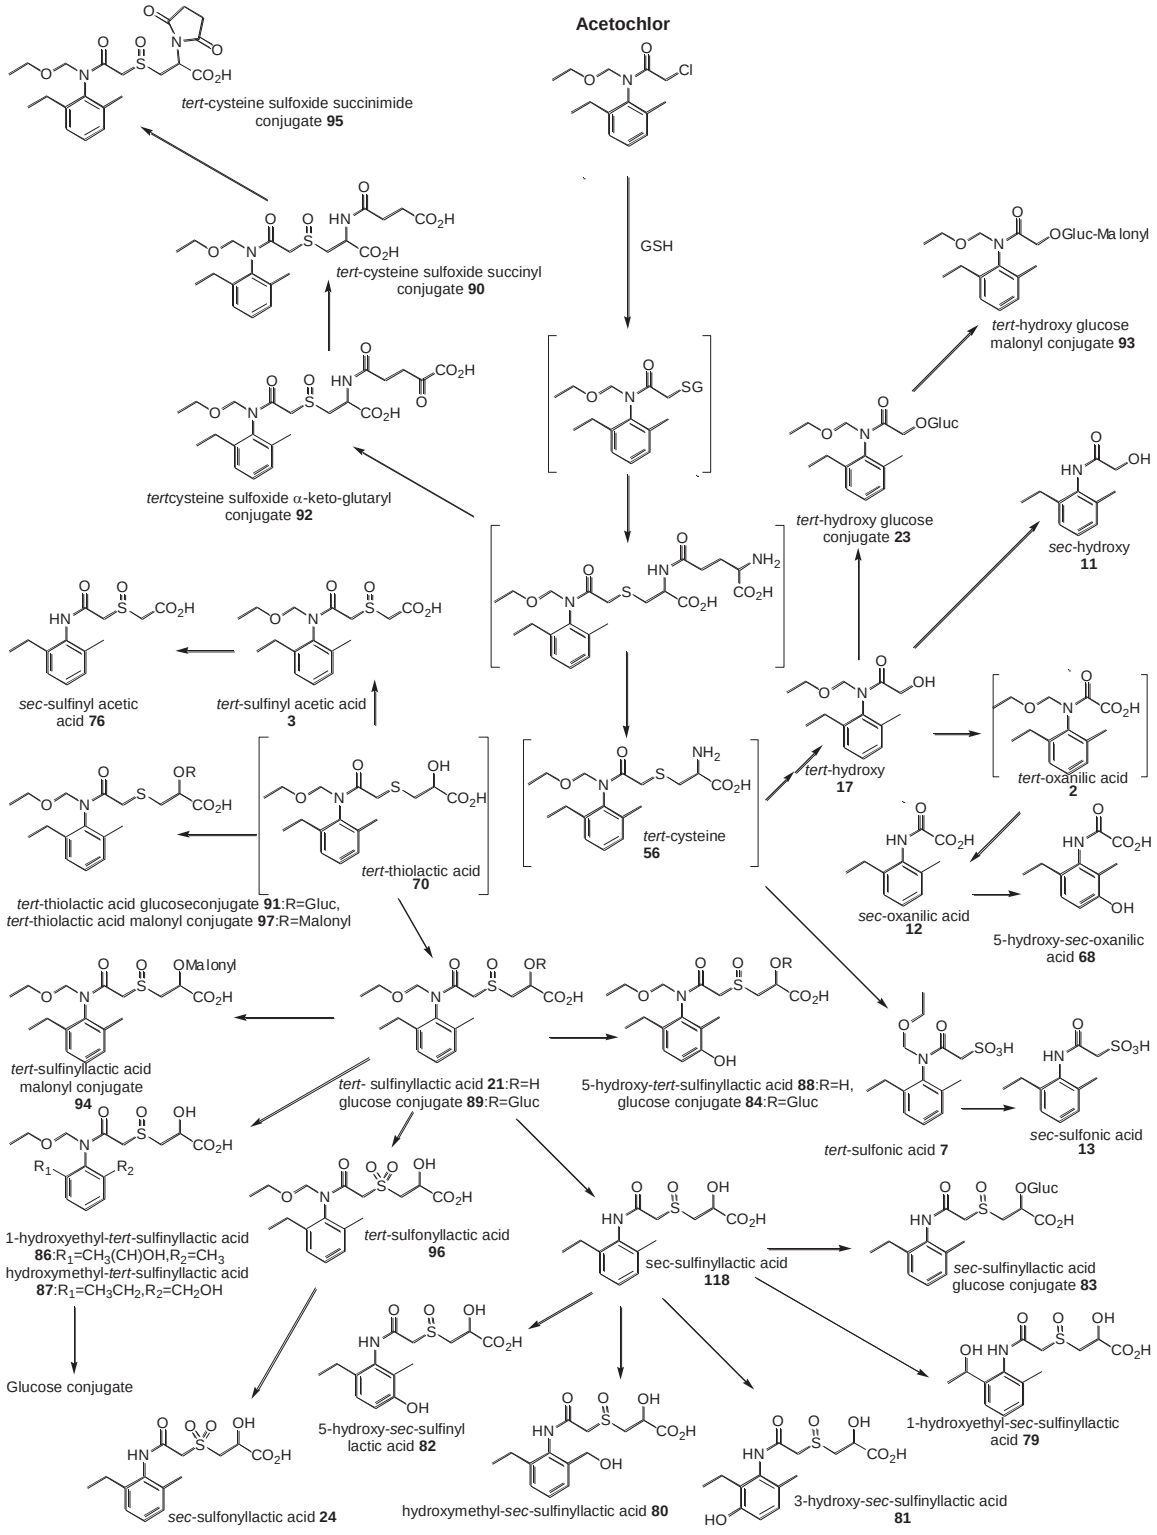

Figure 5 Proposed pathway for metabolism of acetochlor in maize after post-emergence application

Woodbury *et al.* (2009 MSL0021112) studied the metabolism of [^{14}C]acetochlor on outdoor grown soya beans following pre-plant (PP) or post-emergence (PO) application. The test substance consisted of [U-^{14}C phenyl] labelled acetochlor and also contained a ^{13}C-label at the C-2 position of the 2-chloroacetamide moiety to aid in structure elucidation of metabolites by mass

spectroscopy. The PP application was made to the soil (loamy sand) 45 days before seed planting. A separate PO application was made to a second group of plants 42 days after planting seed, when the plants were approximately at the R1–R2 growth stage. The application rates were 3.54 kg ai/ha for the PP and 3.66 kg ai/ha for the PO application.

Forage samples were harvested 91 days and 7 days after the application for PP and PO, respectively. Hay samples were harvested 122 days and 34 days after the application for PP and PO, respectively, while seed samples were harvested 191 and 101 days after the application for PP and PO, respectively. Soya bean seed was removed from pods on the day of harvest.

Harvested forage, hay, and seed samples were homogenised. Combustion analysis gave TRRs of 1.67 and 11.45 mg equiv/kg in PP and PO forage, respectively; 3.48 and 57.7 mg equiv/kg in PP and PO hay, respectively; and 0.175 and 0.192 mg equiv/kg in PP and PO seed, respectively.

Soya bean forage was extracted sequentially with CH_3CN/H_2O (3×), water (1×), 0.1 N HCl, and 0.1 N NaOH (1×). CH_3CN/H_2O extracts contained 1.64 mg equiv/kg (98.4% TRR) and 11.8 mg equiv/kg (103.2% TRR) in PP and PO treated forage, respectively. Water, 0.1 N HCl, and 0.1 N NaOH extracted 0.007 mg equiv/kg (0.4% TRR), 0.002 mg equiv/kg (0.1% TRR), and 0.015 mg equiv/kg (0.9% TRR), respectively, from PP forage. Corresponding extracts from PO forage contained 0.034 mg equiv/kg (0.3% TRR), 0.046 mg equiv/kg (0.4% TRR), and 0.12 mg equiv/kg (1.0% TRR), respectively.

Soya bean hay was also extracted sequentially with CH_3CN/H_2O (3×), water (1×), 0.1 N HCl, and 0.1 N NaOH (1×). CH_3CN/H_2O extracts contained 3.59 mg equiv/kg (103.2% TRR) and 49.51 mg equiv/kg (85.8% TRR) in PP and PO treated forage, respectively. Water, 0.1 N HCl, and 0.1 N NaOH extracted 0.028 mg equiv/kg (0.8% TRR), 0.021 mg equiv/kg (0.6% TRR), and 0.035 mg equiv/kg (1.0% TRR), respectively, from PP hay. Corresponding extracts from PO hay contained 0.58 mg equiv/kg (1.0% TRR), 0.35 mg equiv/kg (0.6% TRR), and 0.75 mg equiv/kg (1.3% TRR), respectively.

Soya bean seed was first extracted with hexane, which resulted in extraction of 0.012 mg equiv/kg (7.0% TRR) from PP seed and 0.017 mg equiv/kg (8.6% TRR) from PO seed. CH_3CN/H_2O extracts of de-fatted seed, from which lipids had been removed, contained 0.104 mg equiv/kg (59.2% TRR) and 0.154 mg equiv/kg (80.2% TRR) from PP and PO treatments, respectively. A further series of extractions with water, 0.1 N HCl (1×), and 0.1 N NaOH (1×) each extracted only a small fraction of the TRR.

Hexane extracts from soya bean seed were characterised by solvent partitioning and fractionation. Acetonitrile phases (polar-lipids or metabolites) contained 0.001 mg equiv/kg (0.6% TRR) and 0.002 mg equiv/kg (1.0% TRR) in PP and PO, respectively. The corresponding hexane phases (lipids) contained 0.011 mg equiv/kg (6.3% TRR) and 0.015 mg equiv/kg (7.8% TRR). The lipid phase was saponified and the non-saponifiable, saponifiable (fatty acids), and acidic aqueous (e.g., glycerol) fractions were quantified. In the PP samples, these fractions corresponded to < LOD, 0.002 mg equiv/kg (1.1% TRR), and 0.009 mg equiv/kg (5.1% TRR), respectively. In the PO sample, the distribution was 0.001 mg equiv/kg (0.4% TRR), 0.011 mg equiv/kg (5.7% TRR), and 0.004 mg equiv/kg (2.1% TRR), respectively. Thus, there was evidence of reincorporation of the radiolabel into natural products in the seed. Combined acetonitrile/water extracts of the seed from each treatment were concentrated and analysed. Both PP and PO seed extracts contained numerous low-level metabolites (more than 27), none of which exceeded 0.03 mg equiv/kg. PP seed metabolites were generally more polar than PO seed metabolites.

Combined CH_3CN/H_2O extracts from each treatment and matrix (forage or hay) were concentrated, and the residues were analysed by reverse-phase HPLC.

As was the case with maize, a large number of metabolites were detected in the solvent extracts but not unchanged acetochlor. There were notable differences in the pattern of metabolites observed following PP compared to PO application.

In PP soya bean the compounds detected resulted in large part from the uptake of soil metabolites to give oxanilate-type metabolites. None of the individual components exceeded 10% of TRR in immature plant, forage or hay. The major metabolites were *tert*-oxanilic acid (> 9.5% TRR, > 0.158 mg equiv/kg) in forage (Table 11) and *tert*-oxanilic acid combined with *tert*-sulfonic acid present at levels of > 9.7% (0.34 mg equiv/kg) in hay (Table 12).

In contrast, the metabolites identified in PO forage and hay primarily resulted from initial glutathione conjugation of acetochlor followed by oxidation to give sulfoxide-type metabolites. Five compounds exceeded 10% of TRR (Tables 13 and 14): *tert*-cysteine (39% TRR), *tert*-malonylcysteine (18–23%TRR), *tert*-sulfinyllactic acid and *tert*-malonylcysteine sulfoxide (combined 24–30%TRR). A large number of other metabolites were present at levels in excess of 0.1 mg equiv/kg.

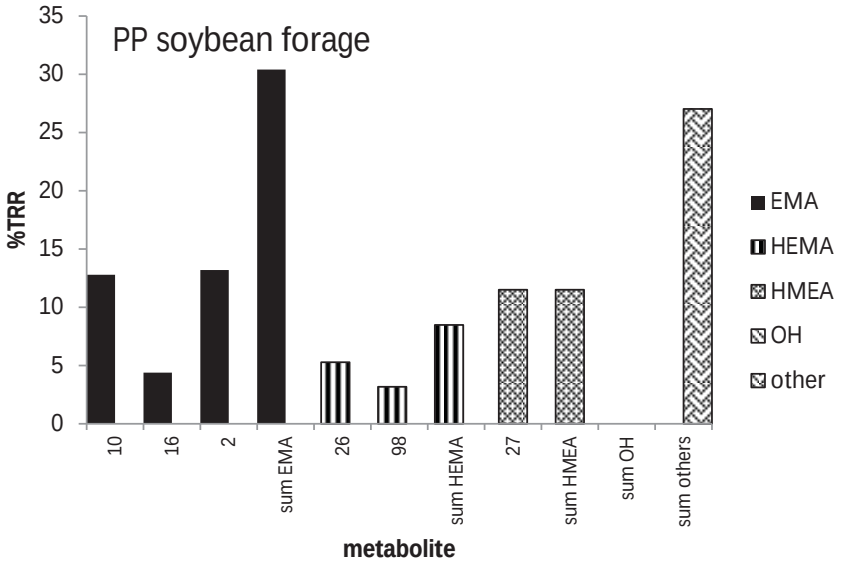
The identified metabolites are plotted according to their aniline metabolite class for forage and hay (Figure 6). The major aniline metabolite class in soya bean commodities are EMA and "other" for PE forage, HEMA, EMA and "other" for PE hay and EMA for PO hay.



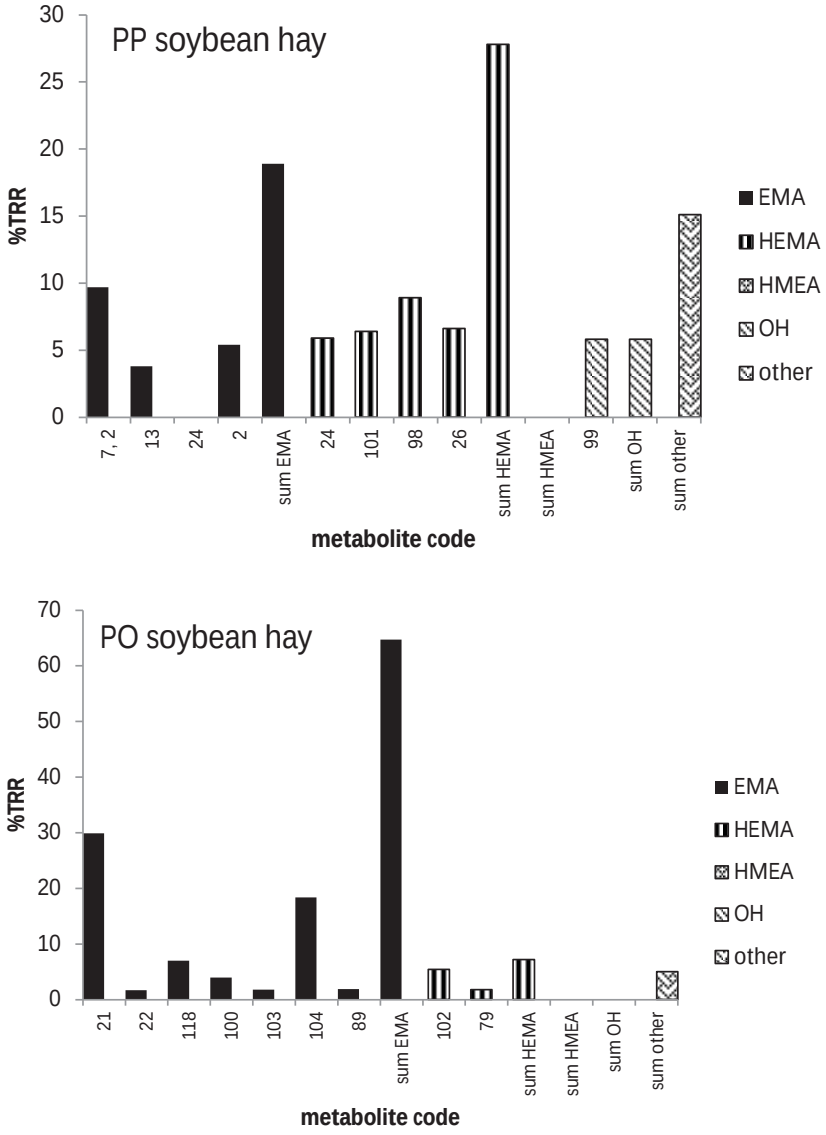


Figure 6 Aniline metabolite classes for pre- and post-emergence application of acetochlor to soya beans

A pathway for the metabolism of acetochlor in soya beans is shown in Figure 7.

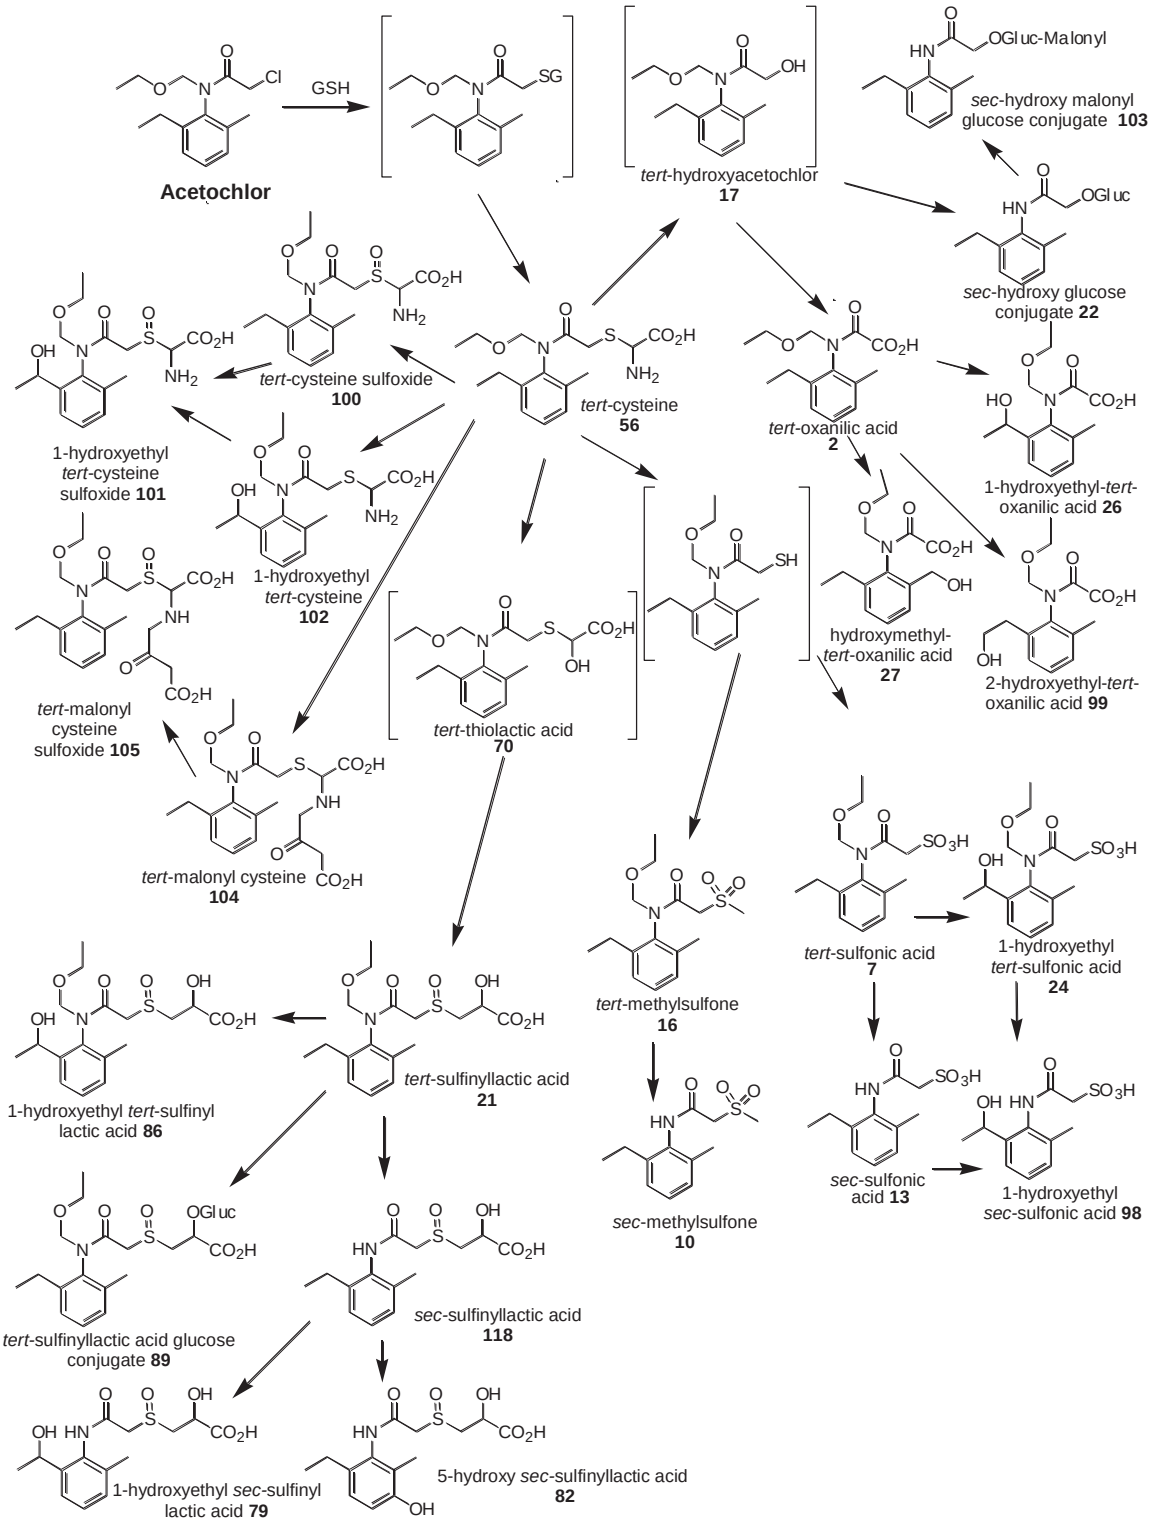

Figure 7 Proposed pathway for metabolism of acetochlor in soya bean plants

Woodbury and Baker (2008 MSL0021111) conducted a metabolism study with [^{14}C]acetochlor on cotton maintained outdoors. The test substance consisted of [U-^{14}C phenyl] labelled acetochlor and also contained a ^{13}C-label at the C-2 position of the 2-chloroacetamide moiety to aid in structure elucidation of metabolites by mass spectroscopy. A PP application was made to the soil (sandy loam) 30 days before seed planting. A separate PO application was made to a second group of plants 15 days after the majority of plants had reached their first white

flower stage. The application rates were 3.6 kg ai/ha for the PP and 3.6 kg ai/ha for the PO application.

Mature leaves/stems and seed were harvested 205 and 91 days after the application for PP and PO, respectively. Cotton was processed in a miniature gin at the field site. The leaves/stems were used as a surrogate for gin trash to increase the potential for obtaining sufficient material for metabolite identification. The use of leaves and stems provided not only a larger quantity of plant material for extraction and identification of metabolites, but also provided plant matrix with potentially higher ^{14}C levels because of the direct application of the test substance to the foliage.

Analysis of PO leaves/stems gave a TRR of 63.9 mg equiv/kg while the TRR in PP leaves/stems was much lower at 5.7 mg equiv/kg. The TRRs in seed from both treatments were both similar at 0.133 mg equiv/kg for the PO treatment and 0.103 mg equiv/kg for the PP treatment.

Cotton seed was subjected to an exhaustive extraction procedure. Hexane extracted 0.013 mg equiv/kg (12.2% TRR) from PP seed and 0.008 mg equiv/kg (5.8% TRR) from PO seed. CH_3CN/H_2O extracts of defatted seed contained 0.030 mg equiv/kg (29.3% TRR) and 0.058 mg equiv/kg (43.7% TRR) from PP and PO seeds, respectively. A further series of extractions with 0.1 N HCl (2×), 0.1 N NaOH (2×), methanol, DMSO, and THF followed by reflux with 0.1 N HCl each extracted only a small fraction of the TRR. Extraction with 24% KOH to release residues from the hemicellulose fraction was more successful and removed 0.030 mg equiv/kg (29.5% TRR) from PP seed and 0.029 mg equiv/kg (21.6% TRR) from PO seed. The latter 24% KOH extracts were characterised by partitioning with EtOAc under basic and acidic conditions that showed the majority of the radioactivity remained in the aqueous phase. This could indicate polar neutral products were released as a result of cell wall disintegration. A final treatment of the PES from the above with 72% H_2SO_4, followed by dilution with water and autoclaving, solubilised only 0.007 mg equiv/kg (6.7% TRR) and 0.009 mg equiv/kg (6.6% TRR) from PP and PO treated seed, respectively. The material following these harsh procedures still contained 0.030 mg equiv/kg (28.8% TRR) and 0.036 mg equiv/kg (26.7% TRR), respectively, in the PP and PO treatments. The general similarity of the extraction data could indicate that comparable radioactive components were formed in both PP and PO treatments. The relatively high percentage of TRR remaining in the material after exhaustive extraction may indicate covalently bound residues or reincorporation of radiolabel into natural products. Because of the low level of ^{14}C remaining, no further characterisation was conducted.

The radioactivity in hexane extracts from cotton seed was further characterised by solvent partitioning experiments. The CH_3CN phases (polar lipids or metabolites) contained 0.002 mg equiv/kg (1.9% TRR) and 0.002 mg equiv/kg (1.5% TRR) in PP and PO, respectively. The corresponding hexane phases (lipids) contained 0.011 mg equiv/kg (10.7% of TRR) and 0.006 mg equiv/kg (4.5% TRR). The lipid phase was saponified into three fractions: the non saponifiable, saponifiable (free fatty acids), and acidic aqueous (e.g., glycerol) fractions. In the PP hexane extracts, the non-saponifiable fraction represented 0.002 mg equiv/kg (1.9% TRR), saponifiable fraction 0.007 mg equiv/kg (6.8% TRR), and acidic aqueous fraction 0.002 mg equiv/kg (1.9% TRR), respectively. In the PO hexane extracts, the corresponding fractions represented < 0.001 mg equiv/kg, 0.005 mg equiv/kg (3.8% TRR), and 0.001 mg equiv/kg (0.8% TRR), respectively. Thus, there was evidence for incorporation of radiolabel into natural products, albeit at a low level.

The radioactivity in CH_3CN/H_2O extracts (polar lipids/metabolites) from cotton seed was analysed by HPLC. Both PP and PO CH_3CN/H_2O extracts contained numerous metabolites (more than 17), each < 0.01 mg equiv/kg. PP metabolites were generally more polar in character than PO metabolites.

Cotton leaves/stems were extracted sequentially with CH_3CN/H_2O, water, 0.1 N HCl, and 0.1 N NaOH. CH_3CN/H_2O extracts contained 5.098 mg equiv/kg (88.7% TRR) and

54.825 mg equiv/kg (85.8% TRR) in PP and PO treated leaves/stems, respectively. Water, 0.1 N HCl, and 0.1 N NaOH extracted 0.144 mg equiv/kg (2.5% TRR), 0.040 mg equiv/kg (0.7% TRR), and 0.161 mg equiv/kg (2.8% TRR), respectively, from PP leaves/stems. Corresponding extracts from PO leaves/stems contained 1.661 mg equiv/kg (2.6% TRR), 0.575 mg equiv/kg (0.9% TRR), and 2.173 mg equiv/kg (3.4% TRR), respectively.

CH_3CN/H_2O extracts from leaves/stems from either the PP or PO were combined and concentrated, and the residues were analysed by HPLC.

In contrast to maize and soya bean, the metabolites identified following PP and PO applications were both from initial conjugation of acetochlor with glutathione, followed by subsequent loss of glutamate, then glycine. The resulting cysteinyl product underwent oxidation, deamination, dealkylation, and further conjugation with malonate or glucose to produce numerous metabolites. Only one compound exceeded 10% of TRR in PP leaves/stems: 1 hydroxyethyl-*sec*-methylsulfone glucosylsulfate conjugate (14.8%TRR) and one following PO application: *sec*-sulfinyllactic acid (20% TRR).

[a] Fraction contained multiple components

[b] The position of substitution of the hydroxy group has not been conclusively determined. One of these metabolites may be hydroxymethyl *sec*-thiolactic acid.

The identified metabolites are plotted according to their aniline metabolite class for leaves and stems (Figure 8). The major aniline metabolite class in cotton leaves and stems are EMA and HEMA.

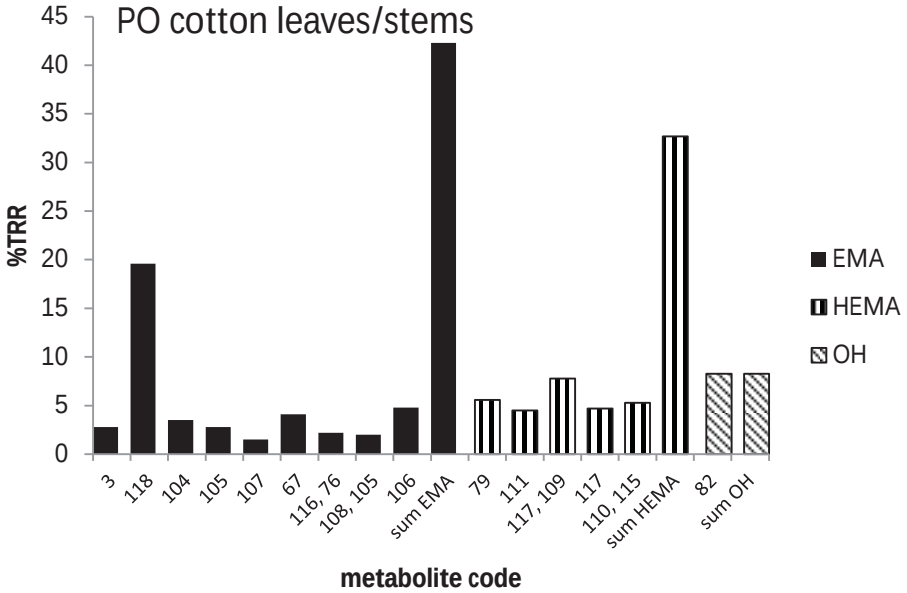

Figure 8 Aniline metabolite classes for post-emergence application of acetochlor to cotton

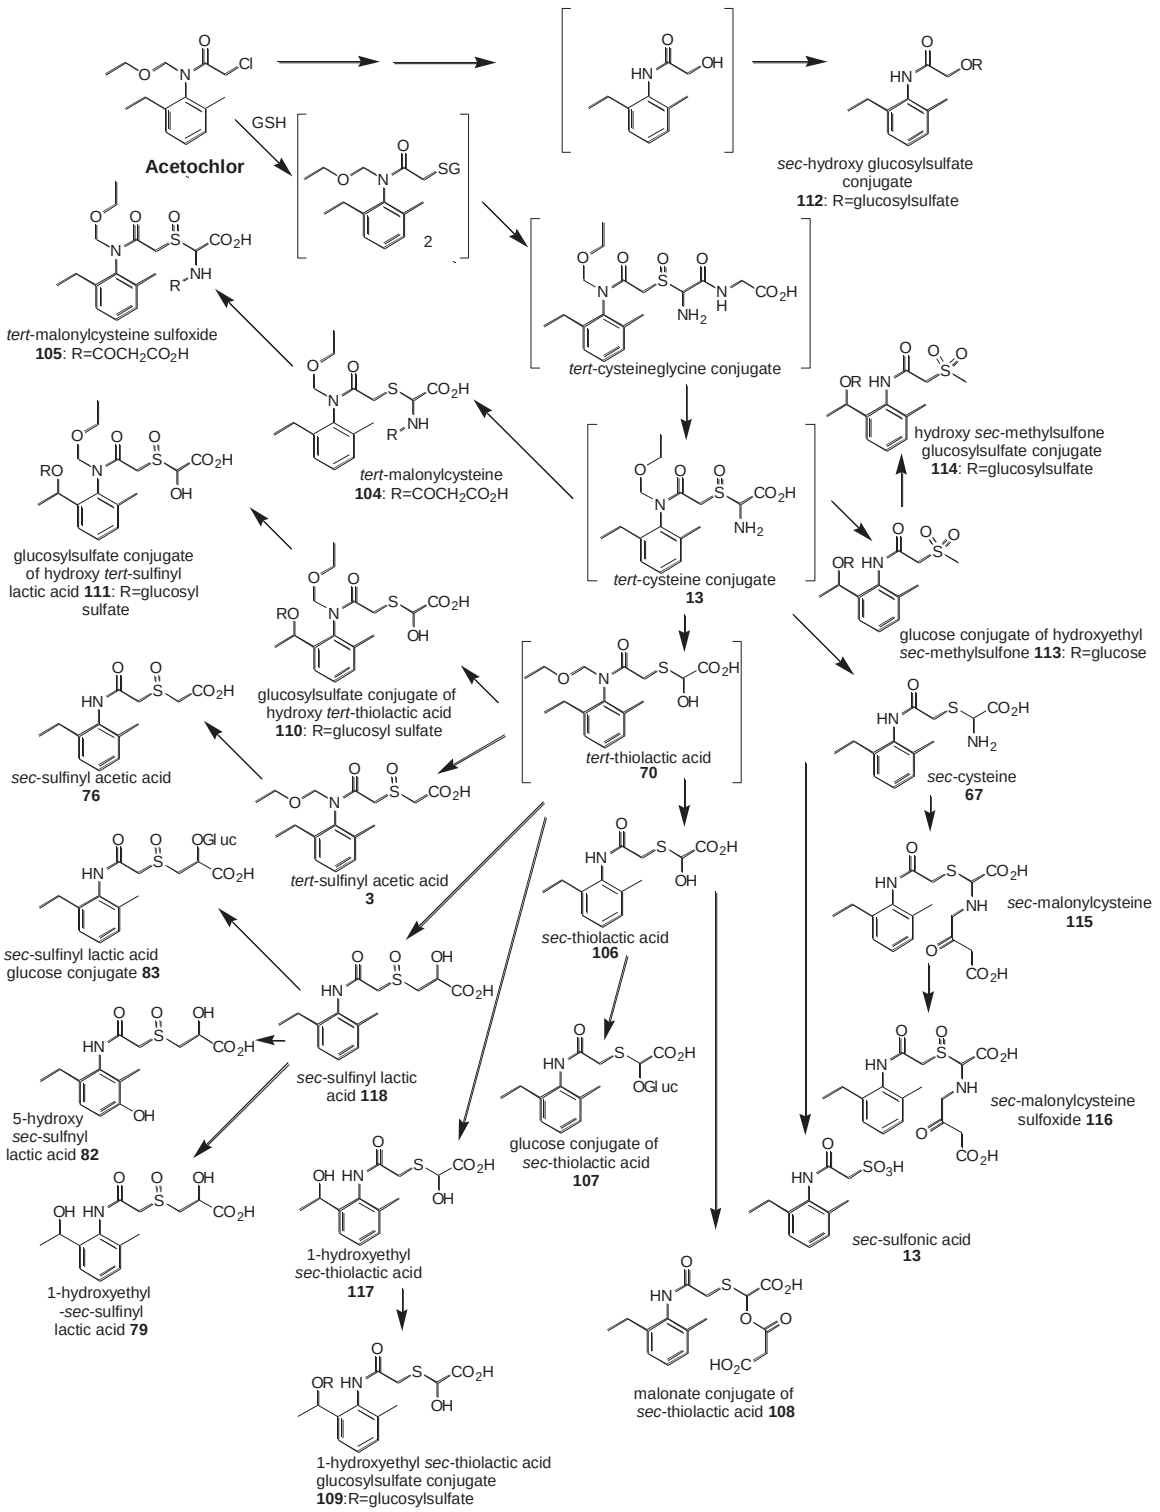

Figure 9 Proposed pathway for metabolism of acetochlor in cotton plants

Primary metabolic pathways of acetochlor in plants included:

- hydrolytic/oxidative dechlorination to form the alcohol (and conjugates) and subsequent oxidation of the alcohol to the oxanilic acid
- displacement of chlorine by glutathione (or homoglutathione) and further catabolism of the products to cysteine or lactic acid metabolites, and the S-oxides and conjugates, or to sulfonic acids and methyl sulfones
- ethyl/methyl side-chain or ring hydroxylation
- N dealkylation.

Oxanilate, sulfonic acid, and sulfone metabolites were more prevalent in pre-plant matrices. Glutathione/homoglutathione conjugation followed by catabolism to cysteine and lactic acid metabolites, and their oxidized derivatives and conjugates, was the primary metabolic pathway for acetochlor after post-emergence treatment.

The metabolism on maize, soya bean and cotton is consistent with less exhaustive studies reported in the literature for metabolism of acetochlor by other plants. Breaux (1987) [Breaux EJ (1987) *Initial Metabolism of Acetochlor in Tolerant and Susceptible Seedlings. Weed Science* 35: 463–468.] reported the initial metabolism of acetochlor in tolerant and susceptible plants (six crop and ten weed species) involved conversion of acetochlor initially to thioether conjugates. In thirteen of the species, initial conjugation was with glutathione (GSH).

Animal metabolism

Laboratory animal studies

Metabolism of acetochlor in rats, mice and monkeys was evaluated by the WHO Core Assessment Group of the 2015 JMPR.

Lactating goat

Powell and Skidmore (1991 RJ1019B) studied the metabolism of acetochlor in lactating goats (British Saanen X Nubian, 58.0–59.5 kg bw; 2.0 kg milk/d). Two goats were orally administered [^{14}C-U-phenyl]-acetochlor at 10 mg/doses, twice daily for a period of four consecutive days. Feed consumption during the dosing period was 1.7 kg/d for one goat and 2.6 kg/d for the other. The dosages were equivalent to 11.0 and 8.1 ppm in the diet. Milk production averaged 3.1 L/d. During the treatment period, milk, urine, and faeces were collected daily from both goats. Approximately 23 hours after the final dose, the goats were sacrificed and tissues were collected.

The majority of the ^{14}C residues was recovered in the excreta; between 77 and 100% of the radioactive residues were found in the excreta. Urine contained between 58 and 71% of the administered dose while faeces contained 20 to 29%.

Transfer of radioactivity into milk was very low reaching 0.016 mg equiv/L after two days. Following centrifugation and partition with hexane, the majority (98.1% TRR) of the radioactivity in the milk remained with the aqueous phase, indicating that insignificant levels of radioactivity were associated with butter fat/cream.

Further 'clean-up' of the aqueous fraction resulted in 51.3% of the total milk residue being analysed by chromatography. Up to nine individual components were observed, two of which were identified as *sec*-cysteine (67) (3.2% TRR; 0.00045 mg equiv/kg) and *tert*-cysteine (56) (18.6% TRR: 0.0026 mg equiv/kg). No other component represented > 4.4% TRR (0.00062 mg equiv/kg) of the milk residue.

For tissues, ^{14}C residues were highest in liver, (0.277–0.588 mg equiv/kg), followed by the kidney (0.247–0.479 mg equiv/kg). In general, levels of radioactivity were lowest in fat

(0.002–0.003 mg equiv/kg). Muscle tissues also featured radioactivity levels that ranged from 0.012 to 0.024 mg equiv/kg.

The majority of the residue that was found in the muscle (100%), liver (94.6%), and kidney (85.9%) tissues was bound, and was not recovered by mild extraction techniques using organic solvents or water at ambient temperatures. Incubation in the presence of β-glucuronidase also did not release the ^{14}C from these tissues.

That majority of the radioactive residue was solubilised only after acid hydrolysis at elevated temperatures (70 °C) or by digestion with a protease enzyme (papain). These results suggest that a large proportion of the radioactive residues are associated with natural proteins.

No parent acetochlor was found in the urine and tissues analysed, although small quantities were observed in the faecal samples. The metabolites of acetochlor in ruminants produce an extensive and complex mixture of components. The proposed biotransformation pathway involves the conjugation of acetochlor with glutathione or N-de-ethoxy methyl acetochlor followed by subsequent metabolism to the respective cysteine and mercapturic acid conjugates.

Due to the complex nature of the residue in animals, residue analytical methods have been developed which determined residues as common moieties, i.e. substituted anilines designated as EMA and HEMA. Strong base hydrolysis was used to convert relevant metabolites to their corresponding anilines. Radioactive residues solubilised with papain were shown to contain components containing the EMA/ HEMA moieties. In muscle, a fraction containing, on average, 29.1% of the residue was found in the extract expected to contain EMA/HEMA. Similarly, in liver and kidney an average of 43.4% and 33.8% respectively, were extracted into organic solvent after strong base hydrolysis. EMA was quantified as representing 0.07 and 0.03 mg equiv/kg in liver and kidney respectively, while HEMA was present at 0.01 and approximately 0.01 mg equiv/kg for liver and kidney respectively.

No acetochlor was found in the urine and tissues analysed but small quantities were observed in the faecal samples. It can be concluded that the metabolism of acetochlor in a ruminant species is extensive, with little or no potential for accumulation of metabolites in milk or tissues at the levels expected in the feed under normal agricultural practice.

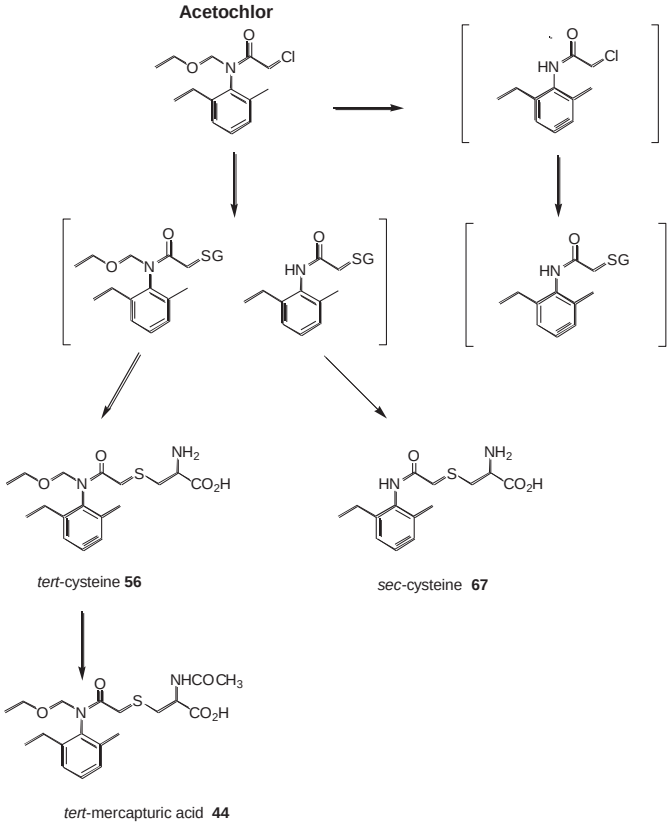

Figure 11 Metabolism of acetochlor in lactating goats

Laying hen

Hand *et al.* (1991 RJ0987B) studied the metabolism of acetochlor in laying hens. Ross Hisex Brown hens (32 weeks old, 1.8–2.1 kg bw) were dosed orally *via* capsules, once a day for seven consecutive days, with [^{14}C-U-phenyl]acetochlor at doses equivalent to 10 ppm in the diet. Feed consumption was 104–150 g/d. Laying efficiency during the dosing period was 62%. Egg samples were collected twice a day, excreta samples were also collected twice daily. Eggs were separated into egg whites and yolks. Hens were sacrificed 23 hours after the final dose, and samples of skin plus subcutaneous and peritoneal fat, leg and breast muscle, kidneys, liver, and gastrointestinal tract and contents were collected from different hens. Eggs, tissues, and excreta were extracted and analysed within five months of sampling.

Recovery of the administered dose was 73.9 to 85.8% after the dosing period based on the eggs, tissues, and excreta with the majority found in the excreta (72.3 to 68.0% AD). Carcass (3.3 to 4.5% AD) and gastrointestinal tract and contents (0.19 to 1.05% AD), eggs (0.05–0.50% AD) and edible tissues (muscle, liver, fat, and skin; 0.27–0.52% AD) accounted for relatively minor amounts of the dose.

Table 23 Percent of administered dose recovered in eggs, tissues, and excreta of laying hens following seven consecutive daily oral doses of [^{14}C-U-phenyl]acetochlor

Sample	% Dose [a]	Residue (mg equiv/kg)
Excreta	68–82	
Gastrointestinal tract and contents	0.19–1.1	
Eggs	0.05–0.5	
Liver	0.16–0.21	0.337
Kidneys	0.06–0.11	
Fat [b]	0–0.04	0.041 skin/sub cut 0.019 peritoneal

Total	74–86	

[a] Determined from initial combustion or solubilisation analysis of tissues, eggs, and excreta, expressed as percentage of the total activity dosed

[b] Summation of skin and subcutaneous fat and peritoneal fat

[c] Summation of leg and breast muscle

Radioactivity reached its highest level in eggs on Day 7 from the start of dosing, with average concentrations of 0.072 mg equiv/kg for yolk and 0.007 mg equiv/kg for egg whites. Mean TRR levels in edible tissues were 0.337 mg equiv/kg in liver, 0.054 mg equiv/kg in breast muscle, 0.072 mg equiv/kg in leg muscle, 0.019 mg equiv/kg in peritoneal fat, and 0.041 mg equiv/kg in skin plus subcutaneous fat.

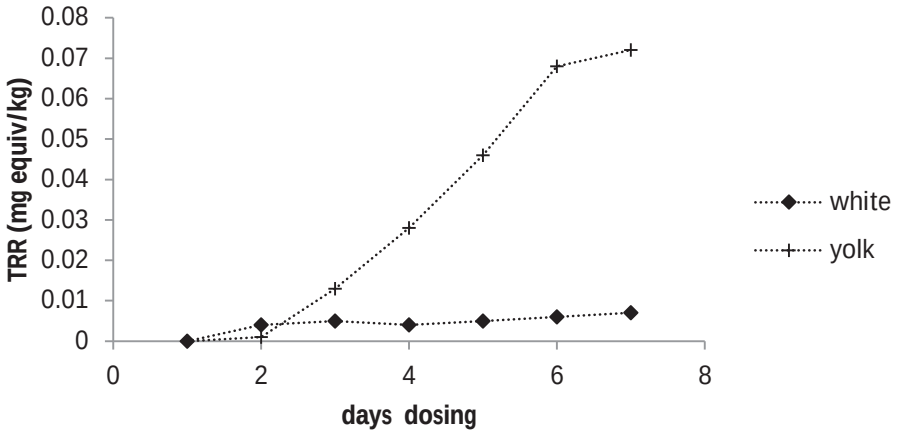

Figure 12 TRR in whole eggs of laying hens following seven consecutive daily oral doses of [^{14}C]acetochlor

Sequential extraction with CH_3CN, CH_3CN:H_2O, then water recovered 13.4 to 28.2% TRR for liver, muscle, and fat and 27.1 to 27.4% TRR for egg yolks. The extraction of excreta was nearly quantitative at 96.1%. Approximately 24–36% TRR in the fat was extracted using hexane, acetonitrile, and acetonitrile/water. Subsequent enzymatic treatment of the unextracted radioactivity in the liver, muscle, fat, and egg yolk with the protease papain (and β-glucuronidase digestion in selected samples) released an additional 21.6–56.0% TRR. The remaining radioactivity in debris and other extractions in the eggs and tissues accounted for 17.7–46.2% TRR from each tissue.

The nature of the metabolites in the excreta showed that the biotransformation pathway of acetochlor in hens includes glutathione conjugation and metabolism to *sec*-cysteine (67), which represents 2.7% of the total excreta residues. From the cysteine conjugate, the pathway diverges to give *sec*-mercapturic acid (40) and *sec*-oxanilic acid (12), which represent 1.2% and 7.9% of the total residues respectively. The *sec*-oxanilic acid (12**)** is speculated to be formed as a result of glutathione initiated dehalogenation of the cysteine conjugate. The remainder of the residue consisted of at least 31 components, indicating that the metabolism of acetochlor in hens is extensive and complex.

The nature of the radioactive residues in the tissues and egg yolks is complex and none of the standard reference markers available co-chromatographed with ^{14}C components from either the organosoluble or the solubilized bound residues. TLC showed that at least eight organosoluble components, all < 0.01 mg equiv/kg, and that at least six "bound" components, the largest of which represented 0.018 mg equiv/kg, were extracted or digested from the liver. The muscle and egg yolk showed at least 12 and 10 organosoluble components, respectively, all of which were < 0.01 mg equiv/kg. Bound residues in the muscle and egg yolk represented < 0.05 mg equiv/kg. To obtain further characterization on the residues, tissue and egg samples were subjected to the cell fractionation procedure. This showed that, in all cases, the majority of the residue was associated with proteins, glycan, and lipid fractions. It also showed that, in the fat, the majority of the residue was associated with the skin rather than the fat itself. Results from cell fractionation in liver, muscle, egg yolk, and fat are provided in Table 23.

Due to the complex nature of the residue in animals, strong base hydrolysis was used to identify the aniline class of metabolites. From the acetochlor residues, two main anilines were generated: EMA and HEMA. Excreta contained 20.7% and 12.5% of the total residue as EMA and HEMA containing metabolites, respectively. The liver contained 16.3% EMA class metabolites (9.3% free and 6.9% bound to the solids) and 7.6% as the HEMA metabolites. Levels of both EMA and HEMA in hydrolysed extracts of muscle, fat, and egg yolks were at or below the limit of determination (0.01 mg equiv/kg). Acid hydrolysis of the papain extract of liver samples identified 5.3% EMA and 3.4% of methylaniline. Although no individual HEMA-containing molecules were identified, the presence of the moiety shows that hydroxylation of the ethyl side chain is an important metabolic pathway for acetochlor.

In summary, laying hens were dosed with [^{14}C-U-phenyl]acetochlor at a nominal rate of 10 ppm in the diet for seven consecutive days. Acetochlor and its metabolites were readily eliminated in the excreta where 68–82% of the dose was recovered. Radioactivity reached its highest average level on Day 7 of 0.072 and 0.007 mg equiv/kg in egg yolk and whites, respectively. Overall, transfer of radioactive residues to the eggs represented 0.5% or less of eliminated doses over the seven days. Low amounts of the doses were found in the liver, muscle, and fat at the time of sacrifice, indicating very little bioaccumulation potential. The highest concentration of radioactive residues in the tissues was observed in the liver. Greater than 50% of the radioactivity in the tissues and eggs could be extracted using solvents and enzyme digestions.

The nature of the metabolites is complex, and most of the metabolites were present at levels at or below the LOD necessary for identification. Unmetabolised acetochlor was not detected in the excreta, tissues, or eggs. At least 34 metabolites were observed in excreta, indicating acetochlor undergoes degradation in hens via various metabolic pathways. Three metabolites, *sec*-cysteine (67), *sec*-mercapturic acid (40), and *sec*-oxanilic acid (12), were identified in the excreta at 5.9, 1.2, and 7.9%, respectively. A major metabolic pathway of acetochlor degradation is glutathione conjugation and catabolism to the mercapturic acid with a concomitant loss of the N-ethoxymethyl group. An alternative pathway involves the glutathione

mediated reductive dechlorination resulting in the formation of *sec*-oxanilic acid (12). Additionally, base hydrolysis of acetochlor residues to EMA and HEMA moieties in excreta, eggs, and tissues indicates that hydroxylation of the ethyl side chain is another important metabolic pathway for acetochlor.

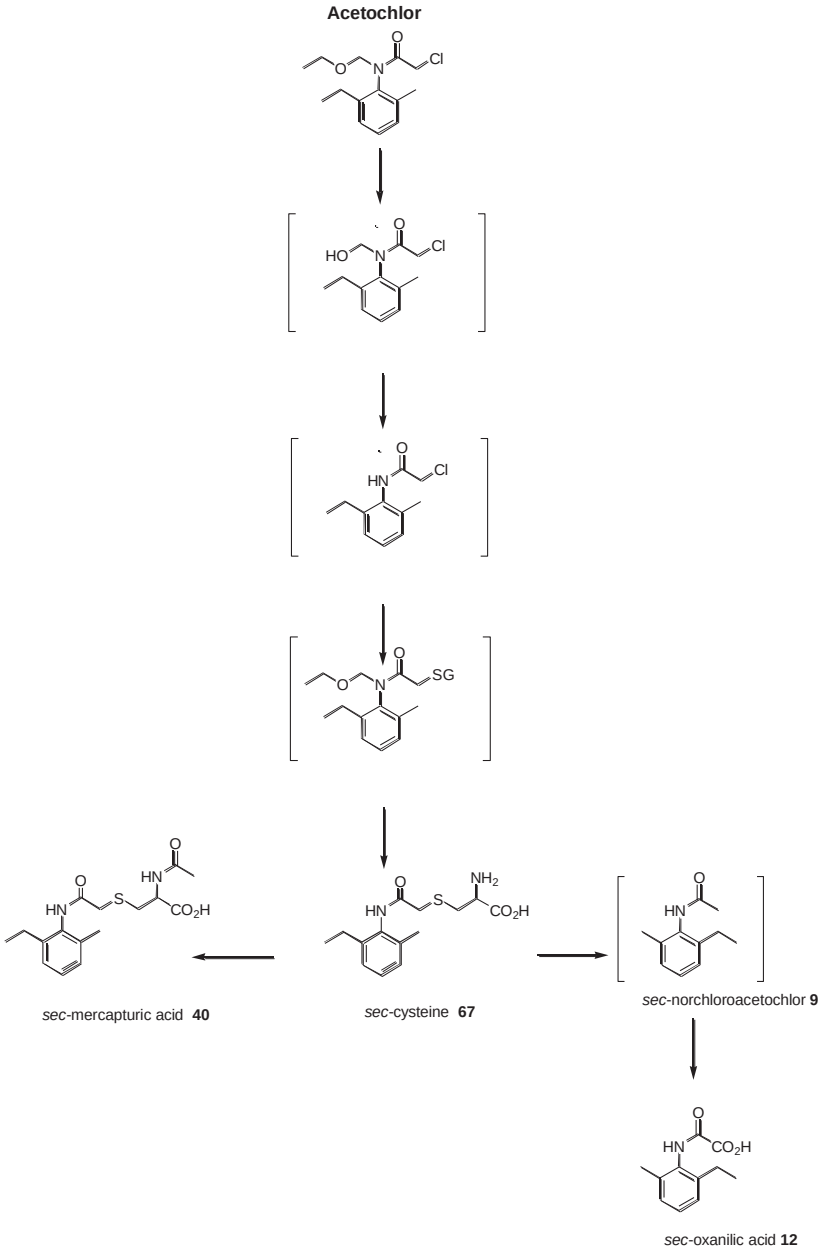

Figure 13 Metabolism of acetochlor in laying hens

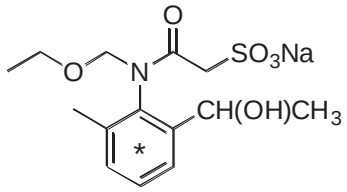
The metabolism of a number of plant metabolites was also studied in livestock.

Metabolism of 1-hydroxyethyl t-sulfonic acid (CP106070) in lactating goat

Cheng (1990 MSL-10472) studied the metabolism of the benzyl hydroxylated plant metabolite ^{14}C radiolabelled 1-hydroxyethyl-*tert*-sulfonic acid (24) in a lactating goat.



acetochlor 1-hydroxyethyl t-sulphonic acid (CP106070)

In a preliminary study, one lactating goat (Preliminary Phase, 53 kg bw) was dosed orally with capsules containing ^{14}C labelled 1-hydroxyethyl-*tert*-sulfonic acid (24) for 5 consecutive days at a daily dose of 10 mg. Daily feed consumption was 1.75 kg/d. The dose was equivalent to 5.7 ppm 1-hydroxyethyl-*tert*-sulfonic acid (24) in the diet. Total production of milk, urine, and faeces were collected daily and weighed. The animals were sacrificed approximately 6 hours after the last dose, and liver, kidneys, fat, muscle, urine, gastrointestinal tract and contents, and bile samples were collected and analysed for total radioactivity content.

The total recovery was 92.3%, with 68.7% eliminated in faeces, 3.65% in urine, and 18.5% remaining in the contents of the GI tract. Less than 0.01% of the total radioactivity was detected in the entire milk production, muscle, liver, kidneys, fat, and bile. The radioactivity concentration in tissues was very low, with 0.007 mg equiv/kg (1-hydroxyethyl-*tert*-sulfonic acid (24) equivalents) in kidney, 0.003 mg equiv/kg in liver, and < LOD (0.0003 mg equiv/kg) in blood, muscle, and fat. The low radioactivity concentration in bile and tissues indicated limited absorption of 1-hydroxyethyl-*tert*-sulfonic acid (24). The majority of the radioactivity detected in kidney and urine was 1-hydroxyethyl-*tert*-sulfonic acid (24).

Ten lactating goats (definitive phase, 51–65 kg bw) were dosed orally with capsules containing ^{14}C labelled or non-labelled 1-hydroxyethyl-*tert*-sulfonic acid 2 **(**24) for 28 consecutive days as follows: Three animals received a daily dose of 1 mg (0.4 ppm), with one animal receiving a ^{14}C-labelled dose (2.4 kg feed/d, 1.9 L/d) and two animals receiving a non-labelled dose, three animals received a daily dose of 3 mg (1.4 ppm), with one animal receiving a ^{14}C-labelled dose (2.1 kg feed/d, 1.2 L/d) and two animals receiving a non-labelled dose, and four animals received a daily dose of 10 mg (5.6 ppm), with two animals receiving a ^{14}C-labelled (1.8 kg feed/d, 1.0 L/d) and two animals receiving a non-labelled dose. These dose levels were equivalent to approximately 0.4, 1.4, or 5.6 ppm 1-hydroxyethyl-*tert*-sulfonic acid (24) in the diet. One of the animals, which received the 10 mg ^{14}C-labelled daily dose, were maintained for a

7-day depuration period following dosing and then sacrificed. The remaining nine animals were sacrificed within 24 hours after the 28th consecutive dose. Kidney, liver, fat, and muscle were collected from each animal for analysis.

The concentration in milk and tissues from animals that received the radiolabelled doses was either less than 0.001 mg equiv/kg or < LOD (0.0005 mg equiv/kg). The concentration in milk and tissues from animals that received the 10 mg non-radiolabelled doses was analysed by measuring the HEMA hydrolysis product of 1-hydroxyethyl-*tert*-sulfonic acid (24). Results indicated the residue concentration was < LOD (0.001 mg equiv/kg).

In conclusion, there was no accumulation of residues in milk and edible tissues of lactating goats after they received 28 consecutive daily oral dosings of 1-hydroxyethyl-*tert*-sulfonic acid (24) up to 10 mg/day.

Metabolism of four acetochlor metabolites co-administered to lactating goat

Leyes (1992, MSL-2280) studied the metabolic fate and nature of residues resulting from the metabolism of four acetochlor plant metabolites in lactating goats. Two lactating goats (Nubian, French Alpine, 49–54 kg bodyweight, 2.5 years old) were dosed with four ^{14}C-labelled synthetic plant metabolites of acetochlor twice a day for a period of five days. Milk production was 1.0–1.2 L/days. Average feed consumption was 0.6 to 0.8 kg concentrate and 2.6 to 3.4 kg hay per day. The metabolites were present in the following mass ratios: *tert*-sulfonic acid, sodium salt (7, sodium salt) (43.0%); *tert*-oxanilic acid, sodium salt (2) (33.0%); *tert*-hydroxyacetochlor (17) (22.3%); and *tert*-sulfinylacetic acid, sodium salt (3) (1.7%). The daily dose was 13.7 mg acetochlor equivalents/goat (3.2 and 4.3 ppm acetochlor equivalents for the two goats).

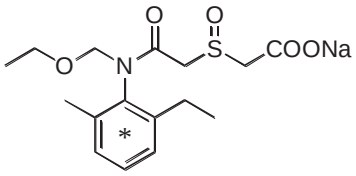
CP95200
acetochlor *t*-oxanilic acid (**2**), sodium salt



CP97290
acetochlor *t*-sulfinylacetic acid (**3**), sodium salt

Milk, urine and faeces were collected daily from each animal. On the sixth day the animals were sacrificed (12 hours after administration of the final dose) and liver, kidney, muscle, fat and blood samples were collected from each goat.

Most of the ^{14}C radioactivity was excreted (63–79% AD) with similar amounts recovered in urine (34–42% AD) and faeces (29–37% AD). Radioactivity in milk accounted for only 0.038–0.044% of the administered dose. The radioactivity present in tissues and organs was minimal.

Table 26 Distribution of ^{14}C on dosing lactating goats with a mixture containing *tert*-sulfonic acid (7), *tert*-oxanilic acid (2), *tert*-hydroxyacetochlor (17) and *tert*-sulfinylacetic acid (3)

Matrix/tissue	% AD	Mean residue
	(mean of two animals)	(mg acetochlor equivalents/kg)

milk	0.041	0.006
urine	38	–
faeces	33	–
total	71.1	

ND = not detected

Residues in milk reached a plateau by the fourth day of dosing.

Samples of raw urine and faecal extracts from each goat were profiled using reverse phase HPLC and for urine and faeces were found to be quite similar to that of the dosing solution.

To quantitate the total amount of dosing solution components or degradation products present, acid-pressure hydrolysis was performed. Hydrolyses were performed on raw urine and faecal extract samples from each of the dosed goats. In all samples subject to hydrolysis, EMA was the only aniline observed.

In conclusion, the very low levels of activity in tissues, organs, blood, and milk demonstrate that there is very little uptake of the acetochlor metabolites in the goat. The profiles of urine and faeces show that the metabolites passed through the animals with very little change. Finally, the results of this study show that the only identifiable aniline class of metabolites in the milk goat is the EMA class. This class of metabolites accounted for 83% and 77% of the recovered activity in urine and faeces, respectively, when corrected for the analytical recovery of the method.

Metabolism of four acetochlor metabolites co-administered to laying hen

Letendre *et al*. (1987 MSL-6941) studied the metabolic fate and nature of residues resulting from the metabolism of four acetochlor plant metabolites in laying hens. The dose mixture comprised an equal weight mixture of the metabolites *tert*-hydroxyacetochlor and the sodium salts *tert*-oxanilic acid, *tert*-sulfonic acid, and *tert*-sulfinylacetic acid. Each contained uniform ^{14}C labelling in the phenyl ring.

Four groups of White Leghorn hens (five per group) were dosed orally, via capsules, once a day for six consecutive days, with the acetochlor plant metabolites at an average dose of 13 ppm (acetochlor equivalents). Each metabolite used in this portion of the study was a mixture of ^{13}C-enriched and ^{14}C-labelled materials to aid in identifying metabolites. A separate group (Group 1) of five hens was dosed orally with placebo capsules for six days. Three of the four groups (Groups 2, 3, and 4), as well as the control group (Group 1) were sacrificed within 24 hours of the final dose; the fourth group (Group 5) of hens was sacrificed after a ten-day depuration period. Another group (Group 6) of three hens was dosed, via capsule, for six consecutive days at an exaggerated dose of 88 ppm (acetochlor equivalents) of the four ^{14}C-labelled metabolites and sacrificed within 24 hours of the final dose. Eggs and excreta were collected on a daily basis. The eggs were separated into egg whites (albumen) and yolk and each portion was radioassayed separately. Edible tissues were collected at the time of sacrifice and included liver, kidneys, breast muscle, thigh muscle, and abdominal fat.

The recovery of the administered dose for Groups 2–5 was 96.6–98.1%, with > 96% of the dose recovered in the excreta and cage washes. Recovery of the dose from the individual

hens from Group 6 was only slightly lower at 95.7–95.8% with the majority of the dose in the excreta and cage washes, which were pooled for the three hens to give a recovery of 95.5%.

The highest levels of ^{14}C residues were found in the gastrointestinal tract, with levels ranging from 0.211 to 0.246 mg equiv/kg for the three groups of hens (Groups 2–4) that were dosed at 13 ppm and sacrificed within 24 hours of the final dose administration. The next highest ^{14}C residues were observed in the crop and its contents, with levels ranging from 0.074 to 0.112 mg equiv/kg, respectively. The ^{14}C residue in the kidneys ranged from 0.018 to 0.020 mg equiv/kg, and for the liver ranged from 0.024 to 0.045 mg equiv/kg. The ^{14}C residue level in the gizzard ranged from 0.009 to 0.015 mg equiv/kg. The residue in the ovaries ranged from 0.021 to 0.027 mg equiv/kg. Egg whites and egg yolks collected at sacrifice had ^{14}C residue levels ranging from 0.004 to 0.007 mg equiv/kg and 0.025 to 0.033 mg equiv/kg, respectively. The ^{14}C levels in fat ranged from 0.006 to 0.011 mg equiv/kg, and the lowest levels of ^{14}C were observed in the muscle samples. Residue levels in the breast muscle ranged between < LOD and 0.010 mg equiv/kg and in thigh muscle the levels ranged from < 0.004 to 0.005 mg equiv/kg. The blood levels of ^{14}C residues taken approximately 24 hours after the final dose was administered ranged between 0.021 to 0.025 mg equiv/kg.

For the group of hens that underwent a ten-day depuration period after the last dose, the highest level of ^{14}C residues were observed in the crop at 0.044 mg equiv/kg. No residues were found in the liver and kidneys of the hens but breast and thigh muscle tissue were found to contain 0.010 and < 0.004 mg equiv/kg, respectively, and fat contained 0.006 mg equiv/kg.

The highest levels of ^{14}C found in the tissues of the hens dosed with 88 ppm (Group 6) gave similar results to the lower-dose groups. The highest levels of^{14}C were found in the gastrointestinal tract, ranging from 0.276 to 0.749 mg equiv/kg, and in the crop 0.209 to 1.03 mg equiv/kg. The ^{14}C residues in the kidneys ranged from 0.106 to 0.128 mg equiv/kg and in the liver 0.150 to 0.266 mg equiv/kg. The ^{14}C residue in the gizzard ranged from 0.031 to 0.080 mg equiv/kg. The ^{14}C content in the ovaries ranged from 0.153 to 0.162 mg equiv/kg. Egg whites and yolks collected at sacrifice had ^{14}C residue levels that ranged from 0.029 to 0.052 mg equiv/kg and from 0.192 to 0.198 mg equiv/kg, respectively. The ^{14}C residues in fat ranged from 0.049 to 0.061 mg equiv/kg. The lowest levels of ^{14}C were found in pooled breast muscle was 0.032 ppm and in thigh muscle, where the residue levels ranged from 0.024 to 0.028 mg equiv/kg.

Extractions of tissues with methanol:water (20:80) released 87% TRR in liver, 76% in kidney, 46% in breast muscle, 50% in thigh muscle, and with acetonitrile released 98% TRR in fat. Extractions conducted on eggs (90:10 CH_3CN/H_2O for whites; Bligh-Dyer method for yolks) resulted in the release of 80–97% TRR from egg whites and 31 to 63% TRR from yolks. Extracts were analysed by HPLC. In eggs, low levels of the dosing metabolites *tert*-oxanilic acid and *tert*-hydroxyacetochlor were present along with *sec*-oxanilic acid and two major unknowns. In tissues, the major component present was the dosing metabolite *tert*-hydroxyacetochlor, which represented 0 to 35% TRR in the various tissues. Small amounts of other dosing materials were also detected in some of the tissues. Analysis indicated that approximately 30 to 70% of the radioactivity contained within the tissues was associated with macromolecules. In excreta, four major components plus several minor compounds were observed. The major components were *tert*-oxanilic acid, *tert*-sulfonic acid, *tert*-hydroxyacetochlor, and *sec*-oxanilic acid; *tert*-sulfinylacetic acid was only present as a minor metabolite.

The nature of the residual metabolites was further characterised through acid hydrolysis (6 N HCl, 150 ºC, 3 hours). Acid hydrolysis of the radioactivity extracted from the liver, kidney, fat, and excreta indicates that these tissues contained one major class of metabolites that were derived from the EMA. Acid hydrolysis of breast and thigh muscle tissue produced evidence for the presence of acetochlor metabolites from the EMA, the HEMA, and HMEA aniline classes of metabolites.

Table 27 Distribution of ^{14}C residues in eggs and tissues from laying hens dosed at with four [^{14}C]-labelled acetochlor plant metabolites

Metabolism of oxamic acid in lactating cow

A metabolite of acetochlor in maize, 5-hydroxy-*sec*-oxanilic acid (68), uniformly labelled in the phenyl ring was used to dose a lactating cow (6 year old Friesian, 537 kg bw) at a nominal rate of 25 ppm (5-hydroxy-*sec*-oxanilic acid) in the diet for seven consecutive days (Corden *et al.* 1982 RJ1228B). Feed consumption averaged 13.7 kg/d while milk production averaged 8 L/d. Twenty-three hours after the final dose, the cow was sacrificed and the tissues collected.

Most of the administered dose was recovered from the excreta (faeces 82.5%, urine 8.4%). The majority of the urine ^{14}C was unmetabolised 5-hydroxy-*sec*-oxanilic acid (68). Four other minor components were found in the urine, each < 4.0%TRR. Two other components were found in the faeces at < 1.6%. 5-Hydroxy-*sec*-oxanilic acid (68) is rapidly excreted from cows, principally as unchanged acetochlor.

The residues in all tissues and milk were < 0.01 mg equiv/kg, except in the kidney which had a residue of 0.015 mg equiv/kg. Extraction of ^{14}C residues in kidney with $CH_3CN:H_2O$ released 70% of the TRR. Levels of ^{14}C in other tissues were too low to permit further characterisation. In the kidney 0.0068 mg equiv/kg (46.7%TRR) was unchanged 5-hydroxy-*sec*-oxanilic acid (68). The remainder of the residue was composed of unextracted material (24.5%, 0.0036 mg equiv/kg) and uncharacterized aqueous soluble material (15.0%, 0.0022 mg equiv/kg).

[b] TLC analysis of the fraction from the partition of a second subsample of the acetonitrile/water extract with ethyl acetate at neutral then acidic pH

[c] Consists of at least four components, the largest of which represents 4.0% of the total radioactive residue

[d] Consists of two fractions, 18.1 % (0.0027 mg equiv/kg) and 6.4% (0.0009 mg equiv/kg)

[e] Consists of at least four components, the largest of which represents 8% (0.0012 mg equiv/kg) of the TRR

[f] Consists of at least four components, the largest of which represents 7.3% (0.0011 mg equiv/kg) of the TRR

[g] Consists of at least three components, the largest of which represents 11.7% (0.0017 mg equiv/kg) of the TRR

ENVIRONMENTAL FATE

The FAO Manual on the Submission and Evaluation of Pesticide Residues Data for the Estimation of Maximum Residue Levels in Food and Feed (2009) explains the data requirements for studies of environmental fate. The focus should be on those aspects that are most relevant to MRL setting. For acetochlor, supervised residue trials data are available for numerous crops. Aerobic degradation in soil is relevant, as well as the normal requirements for hydrolysis, photolysis and rotational crop studies.

The Meeting received information on soil aerobic metabolism, hydrolysis and photolysis properties of acetochlor. Studies were also received on the behaviour of [^{14}C]acetochlor in a confined rotational crop situation.

Acetochlor residues are not persistent in soils however acetochlor residues in soils resulting from recommended uses could contribute to the residues in succeeding crops.

Confined rotational crop studies

A confined rotational crop study was conducted on a sandy loam soil (63.3% sand, 34.1% silt, 2.6% clay; pH 6.6; 2.5% organic matter; 48 meq/100 g CEC) treated with [^{14}C-U-phenyl]-acetochlor at either 2.24 or 3.36 kg ai/ha (O'Neal and Johnson 1992 MSL-12105). The lower application rate was used for rotations of 30 days while the high application rate was used with 120 and 365 day rotations. Radish (variety Red Devil B), lettuce (variety Royal Green) and wheat (variety Anza) were sown into the soil at 30, 120 and 365 (both treatment rates) days after application (DAA). Lettuce was also planted at 162 DAA. The treated boxes were maintained in a screened enclosure.

Analysis of soil extracts showed that acetochlor was metabolised to an array of metabolites, many of which were present at very low levels. In addition to acetochlor, four major soil degradates were identified as present in soil throughout the study: *tert*-oxanilic acid (2), *tert*-sulfonic acid (7), *tert*-sulfinylacetic acid (3) and hydroxyacetochlor (17). Unextracted radioactive residues in soil were characterized into soil organic components. The majority of this soil bound residue was found in the humin fraction (15–30% TRR), humic acid (10–18% TRR) and fulvic acid (5–12% TRR) of soil organic matter.

Analysis of extracts of plant matrices showed that many of the soil degradates were also observed at significant levels in plants. Five metabolites, which were consistently present in plant extracts from all three rotation intervals were: *sec*-oxanilic acid (12), *tert*-oxanilic acid (2), *sec*-sulfonic acid (13), *tert*-sulfonic acid (7), and 1-hydroxyethyl *tert*-oxanilic acid (30).

Unextracted radioactive residues in plant matrices were characterized by cell wall fractionation. The majority of this plant bound material was incorporated into hemicellulose (3–11% of bound ^{14}C) and cellulose (32–76% bound ^{14}C) and in the case of wheat grain with starch (19% bound ^{14}C).

36 = *sec*-methylsulfide
46 = *sec*-methylsulfoxide

The identified metabolites identified have are plotted according to their aniline metabolite class for various rotational crops from planting 120 days after application. The major aniline metabolite class in all crop types was EMA except wheat grain for which it was HMEA and HEMA.

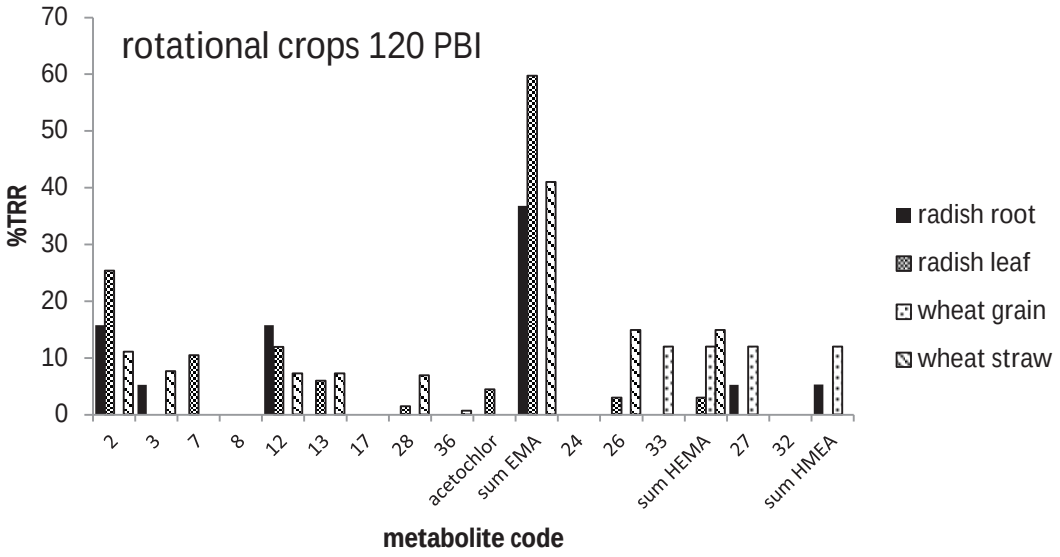

Figure 14 Aniline metabolite classes for rotational crops

In a separate study Weissler *et al.* (1995 RJ1306B) studied the residues in field confined rotational crops. [^{14}C]acetochlor was applied to the surface of a sandy loam soil at a nominal rate equivalent to 3.08 kg ai/ha. Crops typical of those rotated with corn and representative of a leafy crop, a root crop and a grain crop were planted approximately 30, 120 and 365 days after [^{14}C]acetochlor application. Soya beans were also planted approximately 30 and 365 days after application (DAA).

All crops were harvested at maturity. The grain and soya bean crops were also harvested at the immature stage (forage). Soil samples were taken at application and at each planting and harvest interval.

The radioactive residues dissipated rapidly in soil with only 22% AR remaining 30 days after application. The main identified soil metabolites were the same than those found in the laboratory aerobic soil metabolism studies, namely *tert*-oxanilic acid (2), *tert*-sulfinylacetic acid (3) and *tert*-sulfonic acid (7).

Analyses of the plant extracts showed that extensive metabolism occurred in all crops. Acetochlor was not found in any of the RACs analysed, except for day 30 turnip roots, where it accounted for 7.5% TRR (0.008 mg equiv/kg). The highest residue levels decreased from the 30 to the 365 days planting. The TRR was partially characterized and found to be comprised of up to nine different compounds, with no one above 0.01 mg equiv/kg in the edible portion of the root or cereal crop (turnip root, millet grain). The major metabolites identified in the 30 DAA rotational crops were *tert*-oxanilic acid (2), *sec*-methyl sulfone (10), *sec*-hydroxyacetochlor (11), and *tert*-methyl sulfone (16).

Further characterization of the extracted ^{14}C residue for all crops was achieved using the residue analytical methodology, and showed that the major class of metabolites was based on EMA in which no hydroxylation of the alkyl groups of the phenyl ring had occurred. A second class identified was based on HEMA and a third minor class based on HMEA.

Field Crop Rotational Studies

A number of field crop rotational studies were made available to the meeting. From the confined rotational crop studies, low levels of residues are expected in rotational crops.

Anderson *et al*. (1998 RJ2543B, 1998 RJ2567B) studied residue levels in potatoes planted as a follow crop to maize. A potato crop rotation residue study was carried out at 10 trial locations in the USA. Magnitude of acetochlor and HEMA and EMA class residues were determined in potatoes planted in fields that had previously contained maize treated pre-emergence or pre-plant, with acetochlor (EC formulation) at a rate of 3.36 kg ai/ha. At one site, maize was treated at an exaggerated rate of 16.8 kg ai/ha pre-emergence. Residues of acetochlor and its metabolites in the rotational crop (potatoes) planted 291 to 380 DAA were < 0.01 mg/kg for acetochlor and < 0.02 mg/kg acetochlor equivalents for its metabolites HEMA and EMA. Because no detectable residues of acetochlor or HEMA and EMA class metabolites were found in any of the unprocessed tubers analysed, none of the processed fractions were analysed.

Table 38 Residues of acetochlor in potato follow crops (Anderson *et al*. (1998 RJ2543B, 1998 RJ2567B). HEMA and EMA residues are expressed in acetochlor equivalents.

Anderson *et al.* (1998 RJ2560B, 1998 RJ2568B) studied residue levels in sunflowers planted as a follow crop to maize. A sunflower crop rotation residue study was carried out at nine

trial locations in the USA. Magnitude of acetochlor and HEMA and EMA residues were determined in sunflowers planted in fields that had previously contained maize treated pre-emergence or pre-plant with acetochlor (EC formulation) at a rate of 3.36 kg ai/ha. At one site, an exaggerated rate of 16.8 kg ai/ha pre-emergence was used to obtain samples for a processing study discussed later. Residues of acetochlor and its metabolites in the rotational crop (sunflowers) planted 350 to 3840 DAA were < LOQ in plots treated at 3.36 kg ai/ha (< 0.01 mg/kg for acetochlor and < 0.02 mg/kg acetochlor equivalents for its metabolites HEMA and EMA).

HEMA and EMA residues in sunflower seed harvested from sunflowers planted 338 DAT from the plot receiving the exaggerated application were 0.13–0.17 mg/kg for HEMA and 0.03 mg/kg for EMA, both expressed in acetochlor equivalents.

Table 39 Residues of acetochlor in sunflower follow crops (Anderson *et al.* 1998 RJ2560B, 1998 RJ2568B). HEMA and EMA residues are expressed in acetochlor equivalents.

Manning (1997 MSL-14117, 1997 MSL-14118) studied residues in oats grown as a follow crop to maize. This study determined residues of the HEMA and EMA classes of acetochlor metabolites in oats planted the season following pre-emergence or pre-plant incorporated treatment of sweet corn or maize with acetochlor (formulated as, an emulsifiable concentrate) at 17 sites in the USA. Magnitude of HEMA and EMA residues were determined in oats planted in fields that had previously contained maize treated pre-emergence or pre-plant with acetochlor (EC formulation) at a nominal rate of 3.36 kg ai/ha. At two sites, an exaggerated

rate of approximately 16.8 kg ai/ha pre-emergence was used to obtain samples for a processing study discussed later.

Total acetochlor residues (HEMA + EMA) in grain of crops planted 285–388 days after application to maize were < LOQ (0.035 mg/kg) in samples from all seventeen sites. The individual total acetochlor residues in the forage ranged from not detected to 0.126 mg/kg, in the hay from not detected to 0.196 mg/kg, and in the straw from not detected to 0.283 mg/kg.

Table 40 Residues of acetochlor in oat follow crops (Manning 1997 MSL-14117, 1997 MSL-14118). HEMA and EMA residues are expressed in acetochlor equivalents.

Total = EMA + HEMA

[a] = Grain sampled at processing facility

[b]=Grain before sending to processing facility

Planted DAA = follow crop planting/sowing days after application to primary maize crop

Harvest DAA = follow crop harvest days after application to primary maize crop

Schneider and Schneider (1996 MSL-14276) studied residues in alfalfa and clover grown as a follow crop to field corn. Acetochlor was applied to the primary crop (maize) at 3.2 to 3.7 kg ai/ha as a post-emergent application when the maize was 13–20 cm tall. Alfalfa and clover were sown after harvest of the maize (sowing 55–355 DAA for alfalfa and 130–358 DAA for clover).

Acetochlor residues were detected in all alfalfa and clover raw agricultural commodities (RACs). Total residue levels (HEMA + EMA) in alfalfa hay and the majority of the clover hay samples were higher than the residues in the corresponding forage samples. The highest alfalfa and clover RAC residues occurred in a first cutting of hay, and residue levels in both RACs for the rotational crops tended to decline in subsequent cuttings. Maximum acetochlor residues for alfalfa forage and hay were 0.540 and 1.870 mg/kg, respectively, and the maximum residues for clover forage and hay were 0.567 and 1.244 mg/kg, respectively. Method LOQs were 0.014 mg/kg for HEMA and 0.012 mg/kg for EMA.

Table 41 Residues of acetochlor in forage from alfalfa and clover follow crops, Schneider and Schneider (1996 MSL-14276). HEMA and EMA residues are expressed in acetochlor equivalents.

Method RES-074-93 v2

Total = EMA + HEMA

Planted DAA = follow crop planting/sowing days after application to primary maize crop

Harvest DAA = follow crop harvest days after application to primary maize crop

Sidhu (1992 MSL-11963) studied residues in winter wheat, soya bean and sorghum crops grown as follow crops after maize crops that had been treated with acetochlor. The primary maize crop was treated with acetochlor EC formulation at a target rate of 2.2 kg ai/ha with wheat planted 90–170 days after application to maize, soya beans 253–425 days and sorghum 253–425 days. At one site an exaggerated application rate of 16.8 kg ai/ha was used to generate material for use in a processing study if needed.

Table 43 Residues of acetochlor in wheat follow crops (Sidhu 1992 MSL-11963) HEMA and EMA residues are expressed in acetochlor equivalents

Total = EMA + HEMA

Planted DAA = follow crop planting/sowing days after application to primary maize crop

Harvest DAA = follow crop harvest days after application to primary maize crop

Veal and Spillner (1997a RJ2261B, 1997b RJ2262B) carried out trials on dried shelled peas and beans in the USA in which a primary crop, maize, was treated with one application of WF1301, an emulsifiable concentration of acetochlor at 3.4 kg ai/ha. The following year, beans (330–406 days after application) or peas (296–336 days after application) were planted in the plots previously treated with acetochlor and samples of dried shelled beans and peas taken at normal harvest to determine the magnitude of the residues of acetochlor and the EMA and HEMA class metabolites.

No residues of acetochlor at or above the limit of determination of 0.01 mg/kg were found in any of the samples analysed. No residues of EMA or HEMA class metabolites (LOQ 0.02 mg/kg acetochlor equivalents) were found, except for one residue of EMA at the LOQ in one sample of shelled beans and one of shelled peas.

Table 46 Residues of acetochlor in pulse (bean and pea) follow crops (Veal and Spillner 1997a RJ2261B, 1997b RJ2262B). HEMA and EMA residues are expressed in acetochlor equivalents.

Total = EMA + HEMA

Planted DAA = follow crop planting/sowing days after application to primary maize crop
Harvest DAA = follow crop harvest days after application to primary maize crop

In summary, residues in edible commodities (grain and tubers) of follow crops were < LOQ with the exception of soya beans. Residues were detected in livestock feeds such as forage, hay, straw and silage of alfalfa, clover and oats, wheat, sorghum and soya beans.

ENVIRONMENTAL FATE IN SOIL

Route of Degradation in Soil

Aerobic degradation in soil

A number of studies have investigated the aerobic degradation of [^{14}C]acetochlor in soil.

The rate and route of degradation of [^{14}C-U-phenyl]-acetochlor was investigated in a silty clay loam soil (Atterbury, USA, 2% sand, 67% silt, 31% clay, pH 6.9, 4.1% OM, CEC 23.6 meq/100g, % moisture holding capacity (saturation) 55.9%) under aerobic conditions by Hawkins *et al.* (1989 HRC/STR 19/881751; 1991 HRC/STR 19/901756). [^{14}C]acetochlor was applied at a nominal rate equivalent to a single application of 4.48 kg ai/ha (4.5 mg/kg soil) and 40.8 kg ai/ha (41 mg/kg soil). The soil samples were incubated under aerobic conditions in the laboratory and maintained under moist, dark conditions at 22 ± 1 °C for up to 365 days. Additional samples sterilised following autoclaving at 120 °C for 30 min were also studied at the 4.5 mg/kg soil concentration. Volatiles were collected in trapping solutions. Samples were sequentially extracted with CH3CN, CH3CN/H2O (7:3 v/v) at ambient temperature and then CH3CN/H2O under reflux using a Soxhlet apparatus.

The mean total recoveries of radioactivity for 0 to 30 DAA was 99.2% of applied radioactivity (AR) declining to 76.9% AR by 365 DAA. By 30 DAA 1.2% of the AR was mineralised to $^{14}CO_2$ with 71.9% AR extracted with the solvent systems used and 25.8 % remaining unextracted.

Acetochlor was rapidly degraded, accounting for less than 26% AR by 30 DAA. By day 365, acetochlor accounted for 1.7% AR. The only other products observed were *tert*-oxanilic acid (2), *tert*-sulfinylacetic acid (3), *tert*-sulfonic acid (7) which reached a maximum between days 30 and 180 accounting for 15.9–17.1, 4–6.5, 7.4–11.8% AR respectively and declining to 0.8–7.8% AR by day 365.

Table 47 Degradation of acetochlor (%AR) under aerobic conditions on silty clay loam soil (initial application of [^{14}C]acetochlor at 4.5 mg/kg)

NA = Not analysed

In sterile soils, acetochlor represented 73% of the ^{14}C present at 70 days of incubation and when compared to the approximately 19% for non-sterile, viable soils, the data indicate degradation is primarily due to microbial activity.

Table 48 Degradation of acetochlor under aerobic conditions on sterile silty clay loam soil (initial application of [^{14}C]acetochlor at 4.5 mg/kg)

Distribution of residues	Days after application	
	7	30
Volatiles	< 0.1	< 0.2
Acetochlor	94	73.2
Degradates	5.2	14.5
Unextracted	7.4	12.1
Total Recovered (as % AR)	106.6	99.8

The rate of degradation was estimated using single first-order (SFO) kinetics. The DT_{50} and DT_{90} values obtained are presented in Table 49. Degradation was slower in soils treated at the higher rate (Table 49).

Table 49 Summary of DT_{50} for acetochlor in Atterbury silty clay loam (22 °C in the dark) Hawkins *et al*. (1991, HRC/STR 19/901756)

Soil: Atterbury silty clay loam	DT_{50} (days)	DT_{90} (days)
0–60 days	13.5	44
41 ppm, 14–365 days	55	Not calculated

Hawkins *et al*. (1991, HRC/ISN 185/90535) studied the metabolism and degradation of [phenyl-U-^{14}C]acetochlor in sandy loam soil (East Jubilee Field, UK, 61.7% sand, 20.2% silt, 18.1% clay, pH 6.0, 2.9% OM, CEC 9.1 meq/100g, % moisture holding capacity (33 kPa) 17.4%, biomass 24.4 mg C/100g) under aerobic conditions. Soil samples were incubated in darkness, at an average temperature of 22.0 ± 1 °C, for periods of up to one year. Acetochlor was applied to soil at a rate equivalent to a field application rate of 3.0 kg ai/ha (sterile and non-sterile soil) and at 14 kg ai/ha (non-sterile soil). Volatiles were collected in trapping solutions. Samples were sequentially extracted with CH_3CN, CH_3CN/H_2O (7:3 v/v) at ambient temperature and for samples from 120 DAA also CH_3CN/H_2O under reflux using a Soxhlet apparatus. The 0 DAA samples were extracted with CH_3CN (4×) only.

Through the first 90 days of the study, acetochlor degraded with a half-life of 110 days; however, subsequent degradation of the remaining residue occurred more slowly. Four major metabolites of acetochlor were identified. The acetochlor degradates *tert*-oxanilic acid (**2**), *tert*-hydroxy (17), *tert*-sulfonic acid (7) and *tert*-sulfinylacetic acid (3) reached maximum levels of approximately 9%, 7%, 6% and 5% of the AR, respectively. No other single component of the extracted radioactivity (except acetochlor) accounted for more than 5% of the AR at any time. Unextracted radioactivity amounted to 14–19% of AR by 365 DAT of which $^{14}CO_2$ accounted for ca. 0.5% AR.

The fate of acetochlor was also investigated following application at an exaggerated (5×) rate. The half-life at this rate was approximately 300 days. The same metabolites were evident and unextracted and volatile components were produced in similar amounts to those found after application at the 'normal' rate.

Acetochlor was not appreciably degraded in the sterile soil over a 30-day period, indicating that the degradation of acetochlor in soil is primarily due to microbiological activity.

Campbell and Hamilton (1980, MSL-1255) studied the degradation of [carbonyl-^{14}C]acetochlor in three soils (silt loam, sandy loam, silty clay loam) maintained under aerobic conditions in the dark at a nominal temperature of 22 °C for 168 days. The moisture content of the soils was adjusted to between 40 and 60% maximum water holding capacity and as close as possible to 75% water holding capacity at 0.33 bar. Relevant properties of the soils used are presented in Table 51.

The aerobic degradation in sterile soils was also studied (22 °C for 28 days).

Table 51 Properties of soils used to study aerobic degradation of acetochlor Campbell and Hamilton (1980, MSL-1255)

Soil Name	Texture	%sand	%silt	%clay	%OM	pH	CEC meq/100 g	Water holding capacity (%)
Ray	Silt loam	4.6	84.2	10.0	1.2	8.1	10.4	23.9
Drummer	Silty clay loam	2.4	68.8	25.3	3.4	6.2	24.6	28.8
Spinks	Sandy loam	75.1	17.8	4.8	2.4	4.7	28.8	17.9

[Carbonyl-^{14}C]-Acetochlor was applied at a nominal rate of 3 mg/kg dry soil. Samples were analysed after 0, 7, 15, 30, 60, 90 and 120 days incubation. Soil samples were extracted with CH_3CN/H_2O (4×), once with aqueous 0.1 N ammonium hydroxide, and twice with water. The aqueous acetonitrile extracts were then partitioned with dichloromethane.

Extracted radioactivity recovered from samples declined from 98.2–102.9% at Day 0 to 63.9–67.3% at Day 56 and 50–55.3% at Day 168. Unextracted residues reached maximum levels of 64.4% at Day 56 in Ray soil, 40.6% at Day 84 in Drummer soil and 47.0% at Day 28 in Spinks soil and were 17.1–24.5% at the end of the test period. Volatile radioactivity identified as $^{14}CO_2$ represented 7.9–11.0 % AR at Day 56 and 16.5–24.5% at day 168. $^{14}CO_2$ production in sterile soils was lower than in the corresponding viable soil amounting to 0–4.4%AR after 28 days post treatment. The overall material balance ranged between *ca* 91 and 138% AR.

The amount of acetochlor recovered in the solvent extracts declined from 91, 94 and 92% AR at zero time to 0.4, 0.9 and 1.3% AR after 168 days in the Ray silt loam, Drummer silty clay loam and Spinks sandy loam soils, respectively. Three major metabolites were identified from the water soluble fraction. These metabolites reached their respective maximums between 21 and 56 days post treatment and then steadily declined through the end of the test. The *tert*-oxanilic acid (2) reached a maximum concentration of 15% AR, the *tert*-sulfinylacetic acid (3) was observed at a maximum concentration of 18% AR, and the *tert*-sulfonic acid (7) reached a maximum concentration of 11% AR. Fourteen other metabolites were identified, twelve organosoluble and two water soluble metabolites. One metabolite, the *sec*-sulfonic acid (13) exceeded 5% of AR in one soil and continued to increase at the end of the study in all soils, reaching a maximum of 9.8% AR in the Ray silt loam soil. The *tert*-hydroxy metabolite (17) exceeded 5% AR in only one soil at a single time point. No other metabolites exceeded 5% AR at any time during the study.

Parallel experiments using sterile soils at 22 °C indicated slower degradation of acetochlor, decreasing to 30.0–87.1 % AR at the end of the 28-day test period, compared to 8.8–19.7% AR in viable soils. The majority of the organosoluble fraction was acetochlor. Water

soluble and ammonia fractions contained less than 3% applied radioactivity, apart from the silt loam and silty clay loam soil on Day 28 when the water soluble fractions contained 29.6 and 45.8% AR, most likely due to experimental error. Metabolite identification was not conducted on these extracts.

Mason and Mills (1999 98JH113) studied the laboratory degradation of [^{14}C-U-phenyl]-acetochlor in surface and sub-soils collected from a site in Iowa, USA. Only soil from 10–20 cm below the uppermost end of each core was used in the incubation study. The 2 mm sieved samples were adjusted to their respective experimental moisture level and aliquots placed in incubation pots. These were equilibrated under the test conditions for 12 days at 20 °C (±2 °C). Following equilibration, soil pots were treated with ^{14}C-labelled acetochlor at application rates of 3.3 mg/kg for surface soil and 0.12 mg/kg for both sub-soils, equivalent to approximately 131% and 5% of the maximum agricultural application rate, of 3.5 kg ai/ha, respectively. The treated soil pots were placed back into the incubation columns, with a flow-through of moist CO_2-free air for up to 121 days. The soils, maintained at the approximately pF2 moisture level, were incubated at 20 °C (± 2°C) in the dark throughout the study.

During incubation, effluent gas from each incubation column was passed through a series of traps, including ethanolamine to trap evolved $^{14}CO_2$. At pre-determined intervals after treatment (0, 7, 14, 33, 64 days (all depths) and 92 days (mid and deep depths only) duplicate soil pots (triplicate soil pots at Day 0) were removed from each of the incubation columns. Of the duplicate pots, one was analysed for total radiochemical content, acetochlor and acetochlor metabolites.

Microbial biomass of the soils was determined at approximately the start and end of the post treatment incubation period. The microbial biomass carbon was 11.6 and 9.8 mg biomass C/100 g soil for surface soils, 7.8 and 10 for mid-depth soils, and 7.3 and 6.6 for deep soils, at the start and end of study, respectively.

Soil samples from all depths demonstrated the ability to degrade acetochlor. The rate of degradation was accurately described by the first order multi-compartment model. The DT_{50} values were 15.0 days for surface soil, 5.3 days for mid-depth soil, and 5.6 days for deep soil. Furthermore, CO_2 levels reached 1.9% AR for surface soil, 2.6% AR for mid-depth soil, and 1.9% AR for deep soil indicating some mineralisation of acetochlor had occurred in all soils. The acetochlor metabolite profile was similar to previously reported work.

This study has shown that acetochlor degradation and mineralisation can take place in both surface and sub-soils, despite the latter containing a relatively inactive microbial population.

Verity *et al.* (1999 RJ2749B) studied the degradation of acetochlor under laboratory conditions in surface and sub-soils collected from an untreated area in Wisconsin, USA. Surface soil from a 0–30 cm depth (sandy loam, 1.8% OM, pH 6.6) and two sub-soils from 30–76 cm and 260–305 cm (loamy sand, 0.7% OM, pH 6.7 and sand, 0.6% OM, pH 6.9, respectively) were collected and transported to the laboratory in 10 cm diameter schedule-40 plastic tubes under cool conditions (< 12 °C). The soil samples were treated with [^{14}C-U-phenyl]-acetochlor and incubated in the laboratory to determine the degradation rate of acetochlor under two different sets of temperature and moisture conditions.

The soil was stored at 4 °C for 6 weeks prior to use. Only soil from 10–20 cm below the surface of the soil in each core was used in the incubation study. The soil was passed through a 2 mm sieve and samples prepared at two moisture contents: as "received from the field", and at approximately pF2, and aliquots placed in incubation pots. These were equilibrated under the test conditions for 5–7 days at 20 ± 2 °C.

Following equilibration, soil pots were treated with ^{14}C-labelled acetochlor at application rates of 2.0 mg/kg for surface soil and 0.1 mg/kg for both sub-soils; equivalent to approximately 100% and 5% of the normal agricultural application rate, of 2.9 kg ai/ha, respectively. The treated soil pots were placed back into the incubation columns, with a flow-through of moist CO_2 -free air for up to 122 days.

The soils maintained at approximately pF2 moisture levels were incubated at 20 ± 2 °C throughout the study. Soils maintained at field moisture were incubated at temperatures similar to those recorded by temperature probes in the field. These soils were incubated, following treatment with acetochlor, at 20 °C for the first 23 days, 18 °C for the next 46 days, 16 °C for the next 37 days and 10 °C for the last 16 days.

Microbial biomass of the soils was determined at the start and end of the incubation period. The microbial biomass carbon, as a percentage of organic matter carbon, was 1.5 and 1.7

for surface soils, 1.0 and 0.6 for mid-depth soils, and 0.3 and 0.2 for deep soils, at the start and end of study, respectively. This results indicate that end of study mid-depth and deep soil throughout would not be considered to possess an active microbial population (i.e. < 1% of organic carbon is microbial biomass carbon).

Soil samples from all depths, under both sets of laboratory incubation conditions, demonstrated the ability to degrade acetochlor.

The DT_{50} values based on modelling were 13.2 and 7.2 days for surface soil, 2.9 and 2.3 days for mid-depth soil, and 29.9 and 10.3 days for deep soil under pF2 and 'field' incubation conditions, respectively. Furthermore, CO_2 levels reached 4.1 % (of applied radioactivity) and 4.5% for surface soil, 6.1% and 4.5% for mid-depth soil, and 9.5% and 3.5% for deep soil, under pF2 and 'field' incubation conditions, respectively, indicating complete mineralisation of some acetochlor had occurred in all soils. There was evidence for both aerobic and anaerobic degradation, although aerobic degradation predominated.

A proposed metabolic pathway for the aerobic degradation of acetochlor in soil is shown in Figure 16.

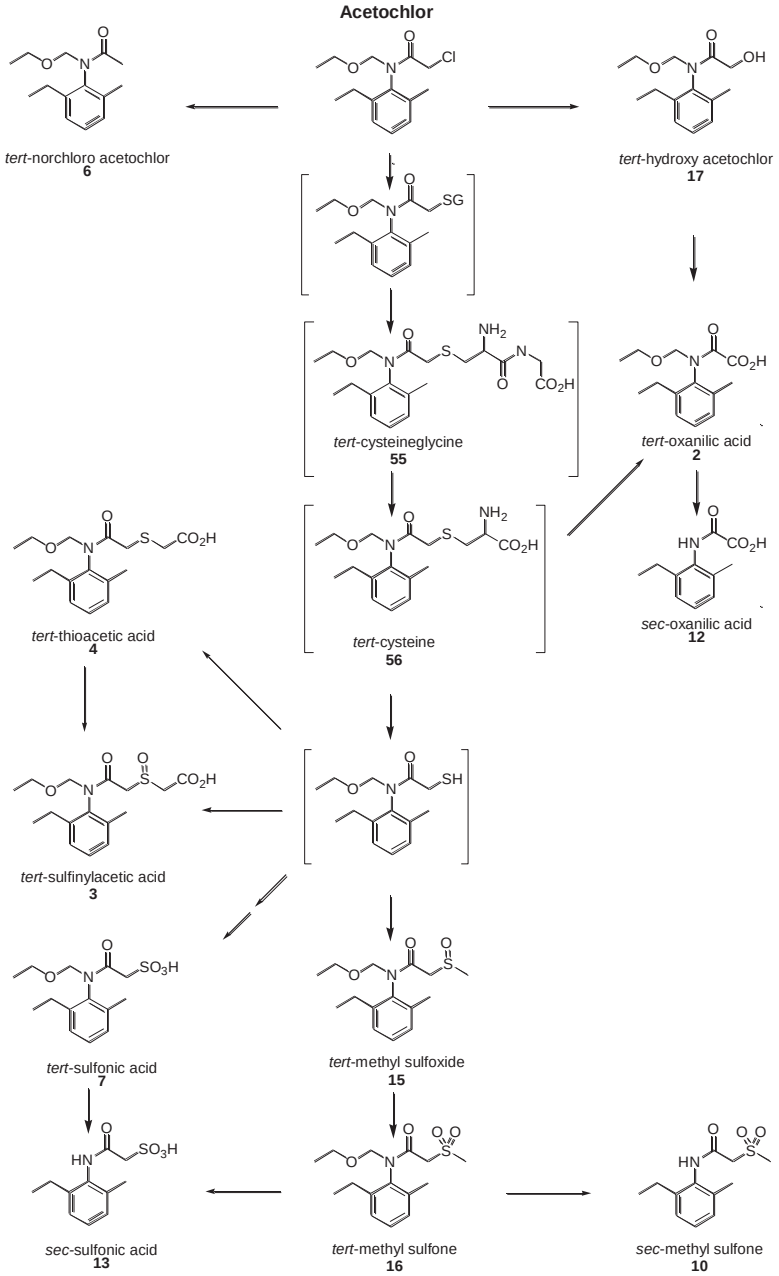

Figure 16 Proposed aerobic degradation pathway for acetochlor in soil

Rate of aerobic degradation

In a series of laboratory studies, the degradation of acetochlor was studied following a single application of [^{14}C-U-phenyl]-acetochlor to surface and subsurface soils obtained from a variety of sites in the USA Vaughan *et al.* (1999 RJ2151B) Tarry *et al*. (1998, RJ2396B). The results are summarized in Table 57 and indicate acetochlor residues *per se* should not be persistent in soil. No estimates have been calculated for acetochlor degradates and these may persist for longer periods than acetochlor.

Table 57 Summary of additional laboratory studies on the DT_{50} and DT_{90} values for aerobic degradation of acetochlor in soils (Vaughan *et al.* 1999 RJ2151B, Tarry *et al.* 1998, RJ2396B)

Field dissipation

Studies on the field dissipation of acetochlor residues were not made available to the Meeting; however, in a report in the scientific literature Oliveire *et al.* (2013) studied the persistence of acetochlor (parent compound) in Minnesota, USA where 38 locations with a wide range of soils from a single 16 ha watershed in Dakota County were sampled over a two year period (2000 and 2001). DT_{50} values ranged from 2.9 to 8.4 days (n = 74) and are in general agreement with those observed in laboratory studies.

Table 58 Descriptive statistics of soil properties and acetochlor dissipation from surface soils in the watershed study in 2000 and 2001 (Oliveire Jr RS, Koskinen WC, Graff CD, Anderson JL, Mulla DJ, Nater EA, Alonso DG (2013) Acetochlor persistence in surface and sub-surface soil samples. FATE AND BEHAVIOUR IN WATER

Hydrolysis

Myers (1989, WRC 88-70) studied the hydrolytic stability of acetochlor at 25 ± 0.5 °C for 31 days in dark, sterile, aqueous buffered solutions at pH 5, 7 and 9. Aqueous solutions of acetochlor showed less than 1% degradation at the end of the 31 day study period. Acetochlor is considered stable to hydrolysis at pH 5, 7 and 9 for at least 31 days.

A study to determine if hydrolysis would represent a significant degradation pathway for acetochlor in the environment was conducted (Campbell and Hamilton 1980 MSL-1255). This study showed that acetochlor was stable to hydrolysis in deionized water, in sterile buffers at pH 3, 6, and 9 and in sterilized lake water.

Hydrolysis of acetochlor is not expected to be a significant process under environmental conditions.

Aqueous photolysis

Chotalia and Weissler (1989 RJ0726B) studied the aqueous photolysis of [^{14}C]acetochlor at pH 7. Acetochlor accounted for 97.3% of the radioactivity at the start of the experiment and 88.8% after irradiation from a Xe arc lamp for a period equivalent to 30 days Florida summer sunlight. No degradation occurred in the dark controls. Acetochlor is considered to be essentially photolytically stable.

Environmental Fate Summary

Acetochlor degraded rapidly and extensively in soil under aerobic conditions with half-lives ranging from 3 to 30 days for soils treated at rates comparable to or lower than an equivalent maximum use rate of 3.36 kg ai/ha. The half-life from an application rate that was approximately 10-fold higher than the lower rate used in the study (4.5 mg/kg, which was equivalent to 4.48 kg ai/ha) was 55 days. Three major degradates exceeded 10% of applied radioactivity and were identified. Acetochlor *tert*-oxanilic acid (2), *tert*-sulfonic acid (7), and *tert* sulfinylacetic acid (3) reached maximum concentrations of 17, 13, and 18% of applied radioactivity, respectively, before declining by the end of the studies. No other components reached the 10% level at any time point. One metabolite, *sec*-sulfonic acid (13) reached 9.8% in one soil, and continued to increase towards the end of the incubation period. Under sterile conditions, degradation of acetochlor was significantly slower and no metabolites were observed at greater than 10% of the applied radioactivity. The results clearly indicate that degradation is principally microbially mediated.

Acetochlor is stable in sterile aqueous solutions at pH 5, 7, and 9.

Low levels of acetochlor residues are taken up by plants from soil following applications of acetochlor to soil. A confined rotational crop study conducted with radish, lettuce, and wheat resulted in TRRs of 0.05 2.88 mg/kg acetochlor equivalents at harvest of commodities from plantings 30 to 365 days after application of acetochlor to a sandy loam at 3.36 kg ai/ha. Analysis of commodities showed that residues comprised up to ten different compounds, with none exceeding 0.03 mg/kg in the edible portion of the crop (radish root and wheat grain). Five metabolites, which were consistently present in plant extracts from all three rotation intervals, were identified as *sec*-oxanilic acid (12), *tert*-oxanilic acid (2), *sec*-sulfonic acid (13), *tert*-sulfonic acid (7), and 1-hydroxyethyl *tert*-oxanilic acid (26). No acetochlor was detected in wheat or radish planted 30 and 365 days after application; however, it was detected at a level of 0.03 mg/kg in radish foliage from the 120-day planting.

A field confined rotational crop study was conducted with turnip, mustard, soya bean, millet, radish, and wheat. The study involved application of acetochlor to sandy loam soil at two different sites in the US at a rate equivalent to 3.32 kg ai/ha. Analyses of the plant extracts showed that extensive metabolism occurred in all crops. The TRR was characterised and found to be comprised of up to nine different compounds, with no one above 0.01 mg/kg in the edible portion of the root or cereal crop (turnip root, millet grain). The significant metabolites identified in the 30 DAA rotational crops were *tert*-oxanilic acid (2), *sec*-methylsulfone (10), *sec*-hydroxyacetochlor (11), and *tert*-methylsulfone (16) at 0.002–0.025 mg/kg. The 5-hydroxy-*sec*-oxanilic acid (68) appeared in the majority of crops analysed at noticeable concentrations of 0.005–0.018 mg equiv/kg. A significant percentage of TRR was not identified (e.g., in turnip tops 44.7% (0.18 mg equiv/kg), which contained at least 39 metabolites, the largest of which represented 0.016 mg equiv/kg. In the 120 DAA rotational interval, 5-hydroxy-*sec*-oxanilic acid (68) was also identified. Only *tert*-oxanilic acid (2, 0.14 mg equiv/kg), *sec*-methylsulfone (10, 0.005 mg equiv/kg), and 5-hydroxy-*sec*-oxanilic acid (68, 0.004 mg equiv/kg) were observed with levels higher than 0.002 mg equiv/kg in the 365 DAA rotational crops.

Field residue rotational crop studies involving a 3.36 kg ai/ha application of acetochlor in the previous season have been conducted on numerous crops that include the following: potatoes, sunflowers, oat, alfalfa, clover, wheat, soya bean, sorghum, dried shelled beans, and dried shelled peas. Total acetochlor residues (HEMA + EMA) were below the LOQ for potato tubers, all grain/seed commodities, beans, and peas except for soya bean seed, which reached a maximum of 0.12 mg/kg. Maximum residues in crop foliage (forage, hay, silage and straw) ranged from 0.06 to 1.19 mg/kg. Maximum residues in alfalfa and clover foliage (forage or hay) ranged from 0.54 to 1.87 mg/kg.

METHODS OF RESIDUE ANALYSIS

Analytical methods

The Meeting received descriptions and validation data for analytical methods for residues of acetochlor and metabolites in animal and plant matrices. The methods are suitable for analysis of acetochlor and metabolites in plant and animal matrices.

The metabolism of acetochlor in crops results in a complex mixture of metabolites that arise from initial glutathione (homoglutathione) conjugation. Subsequent catabolism of the glutathione conjugate via known routes along with oxidative processes and conjugation with natural products (e.g., glucose, malonic acid, etc.) or sulphite results in a wide variety of metabolites, most of which produce EMA or HEMA on base hydrolysis. The EMA-producing metabolites contain non-modified alkyl side-chains and phenyl rings and are converted to EMA upon hydrolysis. Any non-metabolised parent acetochlor that might be present would be converted to EMA. The HEMA-producing metabolites contain hydroxylation at the 1-position of the ethyl group attached directly to the phenyl ring, and a non-modified phenyl ring and are converted to HEMA upon hydrolysis. Metabolites that result from hydroxylation of the methyl group attached to the phenyl ring can also form, although generally not to a great extent. These metabolites are converted to HMEA upon hydrolysis.

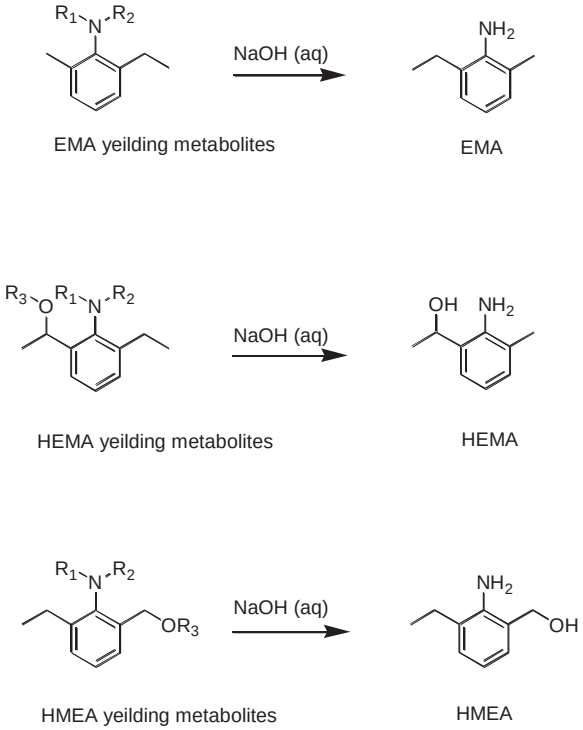

Figure 17 Aniline classes of metabolites obtained by base hydrolysis

Most of the methods developed to quantify acetochlor residues in plant commodities involve hydrolytic conversion of metabolites to the EMA and HEMA chemophores. These analytes are quantified in acetochlor equivalents and then may be summed to give total acetochlor residues. For samples from the rotational crop studies reported in MSL-11963 and the storage stability study reported in MSL-12139, residues of metabolites converted to HMEA on base hydrolysis, i.e. metabolites containing hydroxylation on the ring methyl group, were also quantified.

The methods all involve initial extraction of samples with an organic/aqueous solvent mixture, typically CH_3CN/H_2O, followed by hydrolysis of acetochlor residues with aqueous hydroxide solutions. The main differences between methods involve clean-up conditions, aniline derivatization (RES-074-93 and RAM 280 only), instrumentation for quantification, and scale.

In addition to the methods summarized for quantification of acetochlor residues in crops, a method is described for the determination of metabolites hydrolysable to EMA and HEMA in milk and animal tissues.

Representative compounds that generate EMA (*tert*-sulfonic acid) and HEMA (1-hydroxyethyl-*tert*-oxanilic acid) on hydrolysis were used as reference materials for fortification and method validation.

A method has been developed for determination of 5-hydroxy-*sec*-oxanilic acid (68) in corn and other crops that involves solvent extraction and derivatisation of (68) with N-methyl-N-(tert-butyldimethylsilyl)-trifluoroacetamide (MTBSTFA) for analysis by GC-MS.

Plant materials

RAM-280-01, RAM-280-02 (Robinson. 1996 RAM-280-01, Robinson 1998 RAM-280-02)

In summary, prepared crop samples are extracted by maceration with CH_3CN/H_2O (80:20 v/v). Samples are then filtered under vacuum or centrifuged depending on crop matrix and an aliquot is

evaporated to dryness under a stream of dry air. Saturated KOH solution and methanol are added to the samples and then the samples are refluxed for 30 minutes to 60 minutes to hydrolyse metabolites to EMA and HEMA. The hydrolysate is diluted with water and saturated NaCl and partitioned with toluene. An aliquot of the toluene extract is derivatised with heptafluorobutyric acid anhydride (HFAA) to acylate the EMA and HEMA. Excess derivatising agent is removed by partition of the derivatised samples with sodium hydrogen carbonate solution and the samples are analysed by GC-MS. The results are quantified against the acylated EMA and HEMA standards prepared in the relevant crop matrix.

Ion-monitoring for: 329, 314 amu for HEMA heptafluorobutyl derivative; 331. 162 amu for EMA heptafluorobutyl derivative. Representative compounds that generate EMA (*tert*-sulfonic acid) and HEMA (1-hydroxyethyl-*tert*-oxanilic acid) on hydrolysis are used as reference materials for fortification and method validation. The average recoveries for 1-hydroxyethyl-*tert*-oxanilic acid ranged from 65 to 120% and 73 to 115% for *tert*-sulfonic acid.

The LOQ is 0.01 mg/kg for both 1-hydroxyethyl-*tert*-oxanilic acid and *tert*-sulfonic acid, equivalent to 0.02 mg/kg acetochlor for each compound. The % RSD for 1-hydroxyethyl-*tert*-oxanilic acid at different fortification levels in different matrices ranged from 0.85 to 30%. The % RSD for *tert*-sulfonic acid at different fortification levels in different matrices ranged from 0.0 to 29.3%.

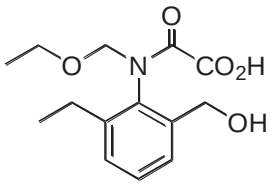
RES-004-90 (Autry and Steinmetz 1990 MSL-11963), RES-004-90 (Autry and Steinmetz 1990 MSL-12139), RES-004-90 (Kerregan and Lauer 1992 MSL-12091)

An analytical method was developed for determining acetochlor metabolites containing the EMA and HEMA moieties in wheat, sorghum and soya beans. The RAC sample is extracted with CH3CN/H2O (80:20 v/v), filtered, and concentrated on a rotary evaporator. The concentrated extract is then hydrolysed with 50% NaOH and the formed EMA and HEMA distilled into acid (2.5 N H2SO4). The distillate is partitioned with methylene chloride, made basic and partitioned again with methylene chloride. The sample is solvent exchanged from methylene chloride into the HPLC mobile phase, filtered through a 0.2 µm filter for analysis by HPLC on a SCX ion exchange column and quantitated using an electrochemical detector. Representative compounds that generate EMA (*tert*-sulfonic acid), HEMA (1-hydroxyethyl-*tert*-oxanilic acid) and HMEA (hydroxymethyl-*ter*t-oxanilic acid) on hydrolysis were used as reference materials for fortification and method validation.



HMEA (hydroxymethyl-*tert*-oxanilic acid)

Method recoveries were conducted in wheat (forage, straw, and grain), soya bean (forage, hay, and grain), and sorghum (forage, hay, silage, fodder, and grain). The average recoveries for 1-hydroxyethyl-*tert*-oxanilic acid ranged from 64.9 to 81.2%; 71.0 to 99.2% for *tert*-sulfonic acid and 62.2 to 84.7% for hydroxymethyl-*ter*t-oxanilic acid. The LOQ was 0.01 mg/kg for each analyte. The % RSD for 1-hydroxyethyl-*tert*-oxanilic acid ranged from 6.1 to 14.2%; for *tert*-sulfonic acid from 2.9 to 17.5% and for hydroxymethyl-*ter*t-oxanilic acid 1.1 to 14.4%.

ES-ME-1001-02 (Lauer et al. 2007 MSL-20269)

The method is a variation on earlier methods for metabolites hydrolysable to EMA and HEMA. Plant materials are cryogenically homogenized (dry ice). Residues in plant matrices are extracted with solvent (CH_3CN/H_2O 80:20 v/v), filtered, concentrated by rotary evaporation and the residue hydrolysed with base (50% NaOH) to form EMA and HEMA. The latter are steam distilled into dilute acid (2.5 N H_2SO_4) and the acid distillate partitioned with methylene chloride, discarding the organic (methylene chloride) layer. The pH of the aqueous layer is adjusted to be basic and the EMA and HEMA extracted with methylene chloride. The methylene chloride is dried over anhydrous Na_2SO_4 prior to addition of acetonitrile and rotary evaporation to remove methylene chloride. Additional

acetonitrile is added and the solution diluted with deionised water to give a solvent composition of approximately 10% acetonitrile/90% deionised water. Quantification is by LC-MS/MS using external standards (EMA 136→91 amu; HEMA 152→134 amu). Residues are converted to acetochlor equivalents using the following factors:

- Acetochlor equivalents = EMA × 1.995
- Acetochlor equivalents = HEMA × 1.784

Representative compounds that generate EMA (*tert*-sulfonic acid) and HEMA (1-hydroxyethyl-*tert*-oxanilic acid) on hydrolysis were used as reference materials for fortification and method validation.

The LOQs for 1-hydroxyethyl-*tert*-oxanilic acid are 0.002 mg/kg for sorghum grain, 0.003 mg/kg for sorghum forage, 0.01 mg/kg for sorghum stover, 0.001 mg/kg for maize grain, 0.009 mg/kg for maize forage and 0.01 mg/kg for maize stover. The LOQs for *tert*-sulfonic acid are 0.01 mg/kg for sorghum grain, 0.005 mg/kg for sorghum forage, 0.015 mg/kg for sorghum stover, 0.001 mg/kg for maize grain, 0.04 mg/kg for maize forage and 0.03 mg/kg for maize stover.

The maximum RSDs for 1-hydroxyethyl-*tert*-oxanilic acid in the different matrices was 20.25%, however, approximately two-thirds of the RSDs were < 10%. The maximum RSD for *tert*-sulfonic acid in the different matrices was 21.62%; again, approximately two-thirds of the RSDs were < 10%. The mean percent recovery values for 1-hydroxyethyl-*tert*-oxanilic acid ranged from 67.1 to 106.9%. The mean

ES-ME-1215-01 (Allan et al. 2008 MSL-20718), ES-ME-1215-02 (Allan et al. 2009 MSL-21172)

The method has been applied to cotton and soya bean commodities. Samples are cryogenically processed with dry ice (25% w/w). Storage of the homogenised sample in the freezer overnight allows the dry ice to sublime. For dry matrices, residues are extracted by blending with CH_3CN/H_2O (80:20 v/v) followed by filtration and the extract concentrated by rotary evaporation. For oily matrices, residues are extracted by shaking with CH_3CN/H_2O (80:20 v/v) followed by centrifugation to separate the phases. The CH_3CN/H_2O layer is retained and extraction process repeated on the oil layer. The combined CH_3CN/H_2O extracts are concentrated by rotary evaporation. For both dry and oily matrices, the concentrated residues are hydrolysed by adding 50% NaOH, heating and distilling the EMA and HEMA formed into 2.5 N H_2SO_4. The pH of the distillate is adjusted with $NaOH/NaHCO_3$ prior to analysis using on-line SPE (Oasis HLB) clean-up with LC-MS/MS. The following ions and transition ions are monitored:

- EMA parent ion 136 amu, product ion 91 amu
- HEMA parent ion 152 amu, product ion 134 amu.

LOQ 0.005 mg/kg (0.01 mg/kg for soy hay and forage). Range 0.005 to 5 mg/kg.

The % RSD for soya bean seed was less than 10% for both 1-hydroxyethyl-*tert*-oxanilic acid and *tert*-sulfonic acid, except for the 0.2 mg/kg *tert*-sulfonic acid fortification of seed, for which the % RSD for the two fortified samples was 22.8%. For soya bean forage and hay, maximum % RSDs were 14.4 and 14.8%, respectively, for both analytes except for *tert*-sulfonic acid in soya bean hay where levels were 29.1 and 24.6% at the 0.01 and 0.05 mg/kg fortification levels, respectively. In undelinted cotton seed, % RSDs were less than 10% for both 1-hydroxyethyl-*tert*-oxanilic acid and *tert*-sulfonic acid, except for *tert*-sulfonic acid at the 0.4 mg/kg fortification level where it was 11.9%. In gin by-products, % RSDs were less than 10% for 1-hydroxyethyl-*tert*-oxanilic acid; however, % RSDs ranged from 4.4 to 12.0% for *tert*-sulfonic acid at all levels except at the 0.005 fortification level where it was 49.6%. The mean percent recovery values for 1-hydroxyethyl-*tert*-oxanilic acid in RACs and processed fractions ranged from 71.9 to 109%. The mean percent recovery values for *tert*-sulfonic acid in the different matrices ranged from 72.6 to 96.5%.

AG-ME-1467 (MSL-24197), AG-ME-1467-01 (23-3.1.1-AG-ME-1467-01 Foster 2012)

Crop matrices are cryogenically milled (with dry ice) and samples extracted with methanol/water. The aqueous methanol is recovered by centrifugation and the residues hydrolysed by addition of NaOH. On completion of the hydrolysis the pH is quenched by addition of H_2SO_4. An aliquot is mixed with internal standard (^{13}C-EMA, ^{13}C-HEMA) and processed through an Oasis MCX SPE plate. The eluate is mixed with formic acid and analysed using LC-MS/MS with electrospray ionisation. The following ions and transition ions are monitored:

- EMA 136→91 amu; HEMA 152→134 amu.

Representative compounds that generate EMA (*tert*-sulfonic acid) and HEMA (1-hydroxyethyl-*tert*-oxanilic acid) on hydrolysis were used as reference materials for fortification and method validation.

Results obtained were within guideline requirements (60–120%). The LOQ for 1-hydroxyethyl-*tert*-oxanilic acid is 0.009 mg/kg for nutmeat, 0.003 mg/kg for peanut hay, 0.0015 mg/kg sugar beet roots and 0.001 mg/kg for tops. The LOQ for *tert*-sulfonic acid is 0.009 mg/kg for nutmeat, 0.003 mg/kg for peanut hay, 0.0016 mg/kg sugar beet roots and 0.004 mg/kg for tops. The %RSDs for 1-hydroxyethyl-*tert*-oxanilic acid ranged from 4.9 to 17.1% for raw agricultural commodities (RACs) and from 4.2 to 16.9% for processed fractions. The relative standard deviations for *tert*-sulfonic acid ranged from 3.4 to 16.5% for RACs and from 2.6 to 11.1% for processed fractions. The mean percent recovery values for 1-hydroxyethyl-*tert*-oxanilic acid ranged from 66.8 to 101.4% for RACs and from 80.7 to 109.3% for processed fractions. The mean percent recovery values for *tert*-sulfonic acid ranged from 66.3 to 100.7% for RACs and from 71.7 to 103.1% for processed fractions.

RES-074-93 (Arras 1995 MRL-14276), RES-074-93 (Arras and Schneider 1996 MRL-14117)

A method was developed for the analysis of metabolites hydrolysable to EMA and HEMA in crop commodities. For crop samples, the method consisted of extraction of the sample with CH_3CN/H_2O (80:20, v/v) followed by filtration and evaporation of the extract to a smaller volume. The concentrated extracts are hydrolysed with base (50% NaOH) and the resulting EMA and HEMA steam-distilled into dilute acid (2.5 N H_2SO_4). The pH of the distillate is adjusted to the basic pH range and the EMA and HEMA partitioned into methylene chloride and back-extracted into aqueous methanol/HCl. The HEMA is converted to its methoxy derivative with methanol in the presence of 4 N HCl (10:3 v/v) to form MEMA. The pH is adjusted and the residues quantified using HPLC-ECD. Residues are converted to acetochlor equivalents using the following factors:

- Acetochlor = 1.995 × EMA
- Acetochlor = 1.633 × MEMA

Representative compounds that generate EMA and HEMA on hydrolysis were used as reference materials for fortification and method validation. For plant commodities are *tert*-sulfonic acid (EMA) and 1-hydroxyethyl-*tert*-oxanilic acid (HEMA).

Method validations and recovery were conducted in oat raw agricultural commodities and processed oat fractions, alfalfa, clover and reported in MSL-14117 (oat commodities), MSL-14118 (oat processed fractions) and MSL-14276 and MSL-14134 (alfalfa and clover). The average recoveries for HEMA ranged from 71.4 to 101.8%; and 87.2 to 121.2% for *tert*- sulfonic acid. Recovery data obtained on numerous matrices from field residue studies were generally satisfactory.

The LOQ for HEMA and EMA in oat matrices was 0.018 mg/kg for HEMA and 0.017 mg/kg for EMA. For alfalfa and clover, LOQ for the HEMA were 0.014 mg/kg, and 0.012 mg/kg, respectively, for EMA.

Oat matrices

The method was validated at 0.01, 0.10, 0.50 and 1.00 mg/kg (acetochlor equivalent) for each of the two metabolite classes. Analytical recoveries from eight laboratory fortified samples of oats grain and oats straw averaged 88.2% with a standard deviation of 10.2% for *tert*-sulfonic acid; and 85.3% with a standard deviation of 9.2% for 1-hydroxyethyl-*tert*-oxanilic acid. For method recovery samples, average recoveries across all fortifications in grain, forage, straw, and processed fractions ranged from 81.6 to 101.8% for 1-hydroxyethyl-*tert*-oxanilic acid and from 102.3 to 116.8% for *tert*-sulfonic acid in all matrices except oat hulls, which had an average recovery of 121.2%. Relative standard deviations for both analytes across all matrices ranged from 1.0 to 17.7%.

Alfalfa and clover matrices

The method was validated at 0.01, 0.10, 0.20 and 0.50 mg/kg (acetochlor equivalent) for each of the two metabolite classes. Analytical recoveries from 16 laboratory fortified samples of alfalfa hay and clover forage averaged 101.0% with a standard deviation of 11.4% for *tert*- sulfonic acid; and 76.9% with a standard deviation of 8.0% for 1-hydroxyethyl-*tert*-oxanilic acid. For method recovery samples, average recoveries across all fortifications in alfalfa and clover forage and hay ranged from 69.1 to 85.5% for 1-hydroxyethyl-*tert*-oxanilic acid and from 84.2 to 108.4% for *tert*- sulfonic acid. Relative standard deviations for both analytes across all matrices ranged from 2.9 to 17.0%.

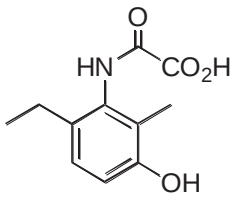
(Crook 1992 RJ1257B) 5-hydroxy-sec-oxanilic acid (68)



A method was developed for the analysis of 5-hydroxy-*sec*-oxanilic acid (68) in crops. Samples of crops are extracted by maceration with CH_3CN/H_2O (50:50, v/v), filtered under vacuum, and the filtrate concentrated by rotary evaporated to dryness and redissolved in CH_3CN/H_2O (50:50, v/v). In the case of oil process fractions, extraction involves dissolution in hexane and a water partition. In both cases, an aliquot is taken, diluted, then acidified and partitioned into ethyl acetate. Aqueous process fractions are acidified and partitioned directly into ethyl acetate. The organic layer is recovered, evaporated to dryness and reacted with isobutanol/3M HCl. Samples are again evaporated to dryness and then reacted with N-methyl-N-(tert-butyldimethylsilyl)-trifluoroacetamide (MTBSTFA) at 60–70 °C for one hour. The derivatives are then analysed by GC-MS. The LOQ was set as 0.01 mg/kg.

The % RSDs for 5-hydroxy-*sec*-oxanilic acid (68) at different fortification levels in corn commodities (grain, forage, and fodder) ranged from 7.6 to 23.9%. In all other matrices, RSDs ranged from 2.4% to 26.5%. The mean percent recovery values for 5-hydroxy-*sec*-oxanilic acid (68) at different fortification levels in corn commodities (grain, forage, and fodder) ranged from 71 to 118%. In all other matrices investigated, recoveries ranged from 55 to 120%.

Table 65 Recovery data for 5-hydroxy-*sec*-oxanilic acid in crops and processed maize fractions (Crook *et al.* 1992 RJ1257B)

Residues in food of animal origin

RES-074-93 (Arras 1995 MRL-14276), RES-074-93 (Arras and Schneider 1996 MRL-14117)

A method has been developed for the analysis of metabolites hydrolysable to EMA in animal commodities. The sample preparations for the different matrices is as follows:

- Milk—Homogenize the sample thoroughly extract residues with CH_3CN, centrifuge and concentrate the CH_3CN/H_2O phase by rotary evaporation
- Fat—Homogenise with hexane, and extract with CH_3CN/H_2O (80:20 v/v). Centrifuge and retain the aqueous acetonitrile phase, which is concentrated on a rotary evaporator.
- Muscle, Liver, Kidney—add CH_3CN/H_2O (80:20 v/v) and homogenise the partially frozen tissue, centrifuge and retain the supernatant which is concentrated by rotary evaporation.

The concentrated extracts are hydrolysed with base (50% NaOH) and the resulting EMA and HEMA steam-distilled into dilute acid (2.5 N H_2SO_4). The pH of the distillate is adjusted to the basic pH range and the EMA and HEMA partitioned into methylene chloride and back-extracted into aqueous methanol/HCl. The HEMA is methylated with methanol in the presence of 4 N HCl (10:3 v/v) to form MEMA. The pH is adjusted and the residues quantified using HPLC-ECD. Residues are converted to acetochlor equivalents using the following factors:

- Acetochlor = 1.995 × EMA
- Acetochlor = 1.633 × MEMA

Representative compounds that generate EMA and HEMA on hydrolysis were used as reference materials for fortification and method validation. For animal commodities these are *tert*-oxanilic acid (EMA) and 1-hydroxyethyl-*tert*-sulfonic acid (HEMA/MEMA).

The LOQ is 0.01 to 0.02 mg/kg for *tert*-oxanilic acid in milk, beef fat, muscle, liver and kidneys, eggs, chicken muscle, fat, liver and kidney.

Summarized recovery data were available for samples of milk, liver, kidney, muscle and fat fortified at 0.01 and 0.1 mg/kg. Average *tert*-oxanilic acid recoveries were 94 ± 3.7% for muscle, 88 ± 4.2% for fat, 79 ± 4.6 for kidney, 95 ± 16.8% for liver and 101 ± 14.7% for milk. Corresponding values for 1-hydroxyethyl-*tert*-sulfonic acid were 80 ± 2.4 (muscle), 77 ± 4.1

(fat), 74 ± 7 (kidney), 87 ± 5.2 (liver) and 95 ± 4.3% (milk). Recoveries reported by an independent laboratory for samples fortified at 0.01 and 0.05 mg/kg were *tert*-oxanilic acid: 86 ± 8 (muscle), 89 ± 9.5% (fat), 84 ± 4.6 (kidney), 89 ± 2.4 (liver), 91 ± 11.8 (milk); 1-hydroxyethyl-*tert*-sulfonic acid 77 ± 3.4 (muscle), 78 ± 5.7 (fat), 83 ± 4.6 (kidney), 75 ± 2.5 (liver) and 78 ± 5.6 (milk).

Method verification/validation and method recovery data were also obtained in numerous animal matrices and reported in MSL-2285 (beef muscle, liver, kidney and fat, and milk), MSL-2287 (chicken kidney, liver, fat, muscle, and eggs), and MSL-4537 (beef muscle, liver, kidney, fat, milk, chicken liver, eggs, and pig liver). Average method verification recoveries obtained from 0.02 or 0.20 mg/kg fortifications in the feeding studies, MSL-2285 and MSL-2287, ranged from 61.5 to 77.2%. Average method recoveries for samples fortified at multiple levels ranging from 0.02 to 0.2 mg/kg and analysed concurrently with treated samples in the feeding studies ranged from 69.4 to 82.1%; % RSDs ranged from 5.4 to 13.6%. Average method recoveries for beef liver, muscle, kidney, fat, and milk, and chicken liver and eggs, from fortifications at 0.10 mg/kg in the storage stability study on animal matrices (MSL-4537) ranged from 78.2 to 89.2%; and % RSDs ranged from 8.3 to 16.3%.

The mean relative standard deviations for method recovery samples fortified at levels ranging from 0.02 to 0.20 mg/kg in different animal matrices ranged from 5.4 to 16.3%. The mean percent recovery values for method recovery samples fortified at levels ranging from 0.02 to 0.20 mg/ ranged from 69.4 to 89.2%.

Applicability of multi-residue methods

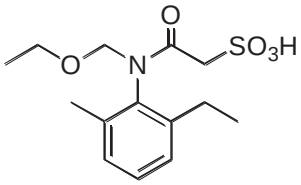
Acetochlor is not suitable for inclusion in multi-residue methods.

Stability of residues in stored analytical samples

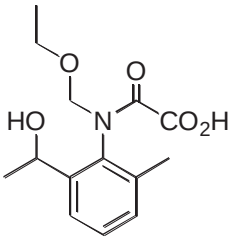
The freezer storage stability of acetochlor in homogenised plant, animal tissues, milk, and eggs samples fortified with acetochlor and/or metabolites was studied.

Stability of residues in plant products

Studies on the metabolism of acetochlor have shown that the parent compound is metabolised to a large number of compounds, none of which is the dominant contributor to residues. Methods of analysis have been developed that convert metabolites containing the ethylmethylaniline moiety to EMA and the hydroxyethylmethylaniline moiety to HEMA. To study the freezer storage stability of residues the metabolites *tert*-sulfonic acid [7] and 1-hydroxyethyl-*tert*-oxanilic acid [26] selected as representative as of the EMA and HEMA classes of acetochlor metabolites. The two compounds were mixed in equal proportions on the basis of acetochlor equivalents.



EMA-producing *tert*-sulfonic acid (7)



HEMA-producing 1-hydroxyethyl-*tert*-oxanilic acid (26)

Horton *et al.* (1996 MSL-14134) studied the stability of acetochlor residues in alfalfa forage and clover hay. Samples of ground alfalfa forage and clover hay were spiked with 1-hydroxyethyl-*tert*-oxanilic acid (HEMA class) and *tert*-sulfonic acid (EMA class) metabolites of acetochlor (94% and 95% purity, respectively) at a level of 0.10 mg/kg acetochlor equivalents each at approximately four-week intervals over 330 days (11 months). Samples were stored at approximately 20 °C. Samples were analysed using the same method as that employed in rotational alfalfa and clover crop residue studies (RES-074-93, v. 2). Results are expressed in terms of acetochlor equivalents.

Under the conditions of the study, total residues did not significantly decrease in alfalfa forage and clover hay. 1-hydroxyethyl-*tert*-oxanilic acid (HEMA-class) and *tert*-sulfonic acid (EMA class) residues on alfalfa forage and clover hay were stable at approximately –20 °C for 330 days.

Table 67 Stability of *tert*-sulfonic acid (EMA class) and 1-hydroxyethyl-*tert*-oxanilic acid (HEMA class) residues of acetochlor in alfalfa forage and clover hay on storage at approximately –20 °C

In a freezer storage stability study, Mannion and Steinmetz (1992 MSL-12139) spiked samples of ground soya bean forage, hay, and grain; wheat forage, straw, and grain; and sorghum silage and grain with three representative acetochlor metabolites: 1-hydroxyethyl-*tert*-oxanilic acid (HEMA class), *tert*-sulfonic acid (EMA class), and hydroxymethyl-*tert*-oxanilic acid (HMEA class) at a level of 0.05 mg/kg acetochlor equivalents each and stored for periods of up to 390 days (soya bean forage), 391 days (soya bean hay), 382 days (soya bean grain), 741 days (wheat forage), 741 days (wheat straw), 734 days (wheat grain), 739 days (sorghum silage), or 732 days (sorghum grain). Samples were stored at less than –17.8 °C. Samples were analysed at various time points using the same method as that employed in rotational soya bean, wheat, and sorghum crop residue studies (RES 004 90, v1 and v3). Results are expressed in terms of acetochlor equivalents.

Under the conditions of the study, total residues did not significantly decrease in soya bean forage, soya bean hay, and sorghum silage. A small but noticeable decreasing trend of residues with storage time was observed in soya bean grain, wheat forage, wheat straw, wheat grain, and sorghum grain. The average percent of residues remaining was 73% in soya bean grain after 382 days, 87% in wheat forage after 741 days, 78% in wheat straw after 741 days, 85% in wheat grain after 734 days, and 82% in sorghum grain after 732 days in frozen storage. The data reported indicate that 1-hydroxyethyl-*tert*-oxanilic acid, *tert*-sulfonic acid, and hydroxymethyl-*tert*-oxanilic acid residues on soya bean forage, soya bean hay, and sorghum silage were stable at less than –17.8 °C for 390, 391, and 739 days, respectively. Residues of 1-hydroxyethyl-*tert*-oxanilic acid, *tert*-sulfonic acid, and hydroxymethyl-*tert*-oxanilic acid on soya bean grain, wheat forage, wheat straw, wheat grain, and sorghum grain appear to degrade slowly with time, although the average percent remaining was still > 70% at the end of the storage periods.

Table 68 Stability of 1-hydroxyethyl-*tert*-oxanilic acid (HEMA class), *tert*-sulfonic acid (EMA class), and hydroxymethyl-*tert*-oxanilic acid (HMEA class) residues in soya bean forage, hay, and grain; wheat forage, straw, and grain; and sorghum silage and grain on storage at less than –17.8 °C

In a freezer storage stability study (White 2001 RJ3114B), samples of potato tubers and sugar beet tops were spiked with acetochlor (99.8% purity) as well as 1-hydroxyethyl-*tert*-oxanilic acid (HEMA class) and *tert*-sulfonic acid (EMA class) at a level of 0.2 mg/kg acetochlor equivalents each. Samples were stored at–18 °C for up to 295 days (9 months), and duplicate samples were analysed for acetochlor and HEMA and EMA metabolite class residues after 0, 3, 7 (acetochlor only), 8 (HEMA and EMA metabolite class only), and 9 months. Samples were analysed for HEMA and EMA metabolite class residues using analytical method RAM 280/02; parent acetochlor was analysed using RAM 244/02. Results were expressed as total acetochlor residues (HEMA + EMA) in acetochlor equivalents.

Under the conditions of the study, total residues did not significantly decrease in potato tubers or sugar beet tops, indicating that acetochlor and the HEMA and EMA metabolite class residues in these matrices were stable at–18 °C for up to 9 months.

Table 69 Stability of acetochlor, 1-hydroxyethyl-*tert*-oxanilic acid (HEMA class) and *tert*-sulfonic acid (EMA class) residues in potato tubers and sugar beet tops on storage at –18 °C

Procedural recoveries were 91% for acetochlor in potato day 295, 73% for 1-hydroxyethyl-*tert*-oxanilic acid (HEMA) day 286, 80% for *tert*-sulfonic acid (EMA) day 286 and for sugar beet tops 89% for acetochlor day 294, 65% for 1-hydroxyethyl-*tert*-oxanilic acid (HEMA) day 286 and 80% for *tert*-sulfonic acid (EMA) day 286.

Crook (1995 RJ1984B) studied the storage stability of 5-hydroxy-*sec*-oxanilic acid (68) in maize, soya bean, turnip and lettuce commodities. Samples were fortified with ^{14}C-phenyl-radiolabelled 5-hydroxy-*sec*-oxanilic acid at 0.09 mg/kg and then deep frozen at < –10 °C. Actual fortification levels were 0.09 mg/kg for maize fractions and lettuce and 0.1 mg/kg for turnip and soya bean fractions, except for 0 month samples that were all fortified at 0.09 mg/kg. Residues of 5-hydroxy-*sec*-oxanilic acid (68) were shown to be stable in deep frozen field maize grain forage and fodder for a storage period of at least 24 months.

Table 70 5-hydroxy-*sec*-oxanilic acid (68) residues in maize grain, forage and fodder samples fortified at 0.09 mg/kg and held in frozen storage

Hay and Wujcik (2009 MSL-21172) studied the frozen storage stability of 1-hydroxyethyl-*tert*-oxanilic acid (HEMA class) and *tert*-sulfonic acid (EMA class) in corn forage, grain and stover for a period of one year. Samples were stored at < –18 °C, which represents conditions typical of those used for frozen storage of residue samples. Samples were analysed using a common moiety method of analysis which converts metabolites in the EMA- and HEMA-classes to the analytes by base hydrolysis. Results are expressed in acetochlor equivalents.

Residues of the *tert*-sulfonic acid and 1-hydroxyethyl-*tert*-oxanilic acid were stable in forage, stover and grain after one year.

Table 71 Recovery of *tert*-sulfonic acid residues after fortification and frozen storage

Animal matrices

In a freezer storage stability study (Wilson 1986 MSL-4537), samples of ground or blended eggs, whole milk, chicken liver, pig liver, beef liver, muscle, fat, and kidneys were spiked with four metabolites of acetochlor (*tert*-hydroxyacetochlor, *tert*-oxanilic acid, *tert*-sulfonic acid and *tert*-sulfinylacetic acid, 99% purity each) at a level of 0.025 mg/kg each, for a total of 0.10 mg/kg, and stored at–23 °C for at least 130 weeks and up to 146 weeks. Samples were analysed at several time intervals using the same method as that employed in egg, milk, chicken tissue and beef tissue residue studies ("Analytical Residue Method for Four Metabolites of Acetochlor in Milk, Beef Tissues, Hog Liver and Chicken Liver"). Residues are measured as EMA and expressed in terms of acetochlor equivalents.

Under the conditions of the study, total residues did not significantly decrease in eggs, milk, chicken liver, pig liver, beef liver, muscle, fat, and kidneys. The data reported indicate that residues of the four acetochlor metabolites in eggs, milk, chicken liver, pig liver, beef liver, muscle, fat and kidneys were stable when samples are stored at–23 °C for at least 130 weeks and up to 146 weeks.

Introduction to Use Patterns

Acetochlor is an herbicide used to control annual grasses and broadleaf weeds. Acetochlor controls weeds by inhibiting growth of seedling shoots. It needs to be applied before weeds germinate to be effective; therefore, it is typically applied just before or after planting of the crop. Acetochlor is in the chloroacetanilide herbicide family. It is in herbicide Site of Action Group 15, known as long-chain fatty acid inhibitors. The product is mixed with water and applied as a ground broadcast spray prior to planting, after planting but pre-emergence to the crop, or post-emergence to the crop and pre-emergence to the weeds using ground equipment equipped for conventional spraying on crops.

Table 74 Selected registered uses of acetochlor

Crop	Country	Form g ai/L	GS	Rate kg ai/ha	Water L/ha	No	Interval (days)	PHI (days)
Sweet corn	USA	839 g/L EC	Apply pre-plant or pre-emergence only. Do not apply post emergence.	1.47–2.95 max 3.36 kg ai/ha per year	≥ 93.6	1		Not specified
Soya bean	USA	359 g/L CS	Apply pre-plant or pre-emergence or post-emergence but before R2 GS	1.05–1.68 max 3.36 kg ai/ha per year	≥ 93.6	1–2		Not specified
Sugar beet	USA	359 g/L CS	Apply pre-plant, at-planting, pre-emergence, or post emergence (2-leaf to the 8-leaf stage)	1.05–1.68 max 3.36 kg ai/ha per year	≥ 93.6	1–3	7	70
Field corn	USA	839 g/L EC	Apply pre-plant or pre-emergence or post-emergence (until corn reaches 28 cm in height)	1.47–2.95 max 3.36 kg ai/ha per year	≥ 93.6	1–2		Not specified
Field corn	USA	359 g/L CS	Apply pre-plant or pre-emergence or post-emergence (until corn reaches 76 cm in height)	1.26–2.52 max 3.36 kg ai/ha per year	≥ 93.6	1–2		Not specified
Sorghum	USA	359 g/L CS	Apply pre-plant incorporated, pre-emergence, or post-emergence before the crop exceeds 28 cm in height (generally 5–6 leaf)	1.26–2.52 max 3.36 kg ai/ha per year	≥ 93.6	1–2		Not specified

Crop	Country	Form g ai/L	GS	Rate kg ai/ha	Water L/ha	No	Interval (days)	PHI (days)
Cotton	USA	359 g/L CS	Apply pre-plant, at-planting, pre-emergence or post-emergence (but before first bloom)	1.05–1.68 max 3.36 kg ai/ha per year	≥ 93.6	1–2		Not specified
Peanut	USA	359 g/L CS	Apply pre-plant, at-planting, pre-emergence or post-emergence (but before flowering)	1.05–1.68 max 3.36 kg ai/ha per year	≥ 93.6	1–3	7	Not specified

Cotton—do not graze treated area or feed treated cotton forage to livestock following application

Maize—do not graze treated area or feed treated forage to livestock for 40 days following application

Do not use Warrant CS herbicide on sweet corn.

Peanut—allow a minimum of 90 days between last application and grazing or harvest and feeding of peanut hay to livestock.

Sorghum—do not graze treated area or feed treated sorghum forage to livestock for 60 days following application

If sorghum seed is not properly treated with seed protectant or safener, pre-plant and pre-emergence applications will severely injure the crop.

Soya bean post-emergence use—do not graze treated area or feed treated forage to livestock

Sugar beet allow a minimum of 70 days between last application and harvest of sugar beet, and grazing or harvest and feeding of sugar beet tops to livestock.

Rotational crops (CS formulation). Do not graze or harvest winter cover crops for food or animal feed for a minimum of 18 months following last application of acetochlor.

Rotational crops:

- If a treated crop is lost, corn (all types), cotton, soya beans, and milo (sorghum), may be replanted immediately, but could result in crop injury. When planting milo (sorghum), only use seed properly treated with seed protectant or safener. Do not exceed a total of 3.4 kg ai/ha/year if additional applications are made.
- Non grass animal feeds such as alfalfa, clover, kudzu, lespedeza, lupin, sainfoin, trefoil, velvet bean, and Vetch spp. may be planted 9 months after application. Wheat may be planted 4 months after application. .
- Rotate the next season to the following crops: soya beans, corn (all types), milo (sorghum), cotton, tobacco, sugar beets, sunflowers, potatoes, barley, buckwheat, millet (pearl and proso), oats, rye, teosinte, triticale, wild rice, dried shelled bean group Lupinus spp. (including grain lupin, sweet lupin and white lupin); Phaseolus spp. (includes field bean, kidney bean, lima bean (dry), navy bean, pinto bean, tepary bean); bean, Vigna spp. (includes adzuki bean, black-eyed pea, catjang, cowpea, Crowder pea, moth bean, mung bean, rice bean, southern pea and urd bean); broad bean (dry) chickpea, guar, lab lab bean, lentil, pea (Pisum spp., includes field pea); pigeon pea.

Residues studies

The Meeting received information on supervised field trials for acetochlor on the following crops or crop groups:

Crop	Table No.
Sweet corn	Table 76
Soya bean	Table 77
Sugar beet	Table 78
Maize	Table 79–82
Sorghum	Table 83
Cotton	Table 84
Peanut	Table 85

Trials were generally well documented with laboratory and field reports. Laboratory reports included method validation with procedural recoveries from spiking at residue levels similar to those occurring in samples from the supervised trials. Dates of analyses or duration of residue sample storage were also provided. Although trials included control plots, no control data are recorded in the tables except where residues in control samples exceeded the LOQ. Control

samples are indicated in the summary tables with a "c". Unless stated otherwise, residue data are recorded unadjusted for recovery.

Residues and application rates have generally been rounded to two significant figures or, for residues near the LOQ, to one significant figure. Residue values from the trials conducted according to maximum GAP have been used for the estimation of maximum residue levels. Those results included in the evaluation are underlined.

Conditions of the supervised residue trials were generally well reported in detailed field reports. Trial designs used non-replicated plots. Field reports provided data on the sprayers used, plot size, field sample size and sampling date.

Table 75 Summary of sprayers, plot sizes and field sample sizes in the supervised trials

Location	Year	Sprayer	Plot size	Sample size	Sample to analysis interval (days)
Sweet corn USA RJ2078B	1995	Tractor mounted boom sprayer, backpack sprayer, or all-terrain vehicle sprayer. The granular formulation was applied directly using a Gandy air flow granule applicator or a broadcast spreader	> 93–1115 m^2	Grain ≥ 12 ears > 5 lb Forage > 2.5 lb Stover 12 plts > 2.5 lb	≤ 182 d (6 mo)
Soya bean USA MSL20719	2007	Backpack, hand-held or tractor-mounted sprayers	93–557 m^2	Forage > 1.3 lb Hay > 1.1 lb 0.3 kg Seed > 1.2 lb	≤ 330 d (11 mo)
Sugar beet USA MSL-24198	2011	Backpack sprayer, tractor with boom	60–372 m^2	12 plants	≤ 210 d (7 mo)
Maize USA MSL-6843	1985	Bicycle sprayer, tractor with boom	> 93 m^2	Ns	Forage ≤ 669 d Fodder ≤ 624 d Grain ≤ 542 d
Maize USA RJ1337B	1991				< 11 mo
Maize USA MSL-11794	1990	Backpack sprayer, tractor with boom	181–2926 m^2		Silage 300 d (10 mo) Forage 240 d (8 mo) Fodder 240 d (8 mo) Grain 195 d (6.5 mo)
Maize USA MSL-20269	2006	Backpack sprayer, tractor with boom	70–149 m^2	Forage 1.1–4.1, 12 plants Grain 1.0–3.3 Stover 0.2–1.8, 12 plants	≤ 374 + 26 ≤ 175 + 11 ≤ 357 + 32
Sorghum USA MSL-18670	2003	backpack, ATV or tractor-mounted sprayers	93–248 m^2, 297 m^2 NE-1, 858 m^2 OK-2	Forage 1.5 kg Grain 1.07 kg Stover 12 plants, 0.16 kg (GA) else 0.57 kg	≤ 222 d forage ≤ 221 d stover ≤ 211 d grain
Cotton USA MSL-20718	2007	Backpack, hand-held or tractor-mounted sprayer	93–705 m^2	Seed > 1 kg Gin bp > 0.7 kg	Seed 112–209 d Gin byp 171–249 d
Peanut USA MSL-24197	2011	Backpack sprayer, tractor with boom	64–446 m^2	Nutmeat 0.2 to > 1 kg Hay 20–24 plants	≤ 240 d

Where duplicate field samples from an un-replicated plot were taken at each sampling time and were analysed separately, the mean of the two analytical results was taken as the best estimate of the residues in the plot and only the means are recorded in the tables. Similarly where

samples were collected from replicate plots the mean result is reported (see general consideration JMPR 2010).

Sweet corn

Crook and French (1996 RJ2078B) conducted fourteen trials in the USA during 1995, on the pre-emergence and pre-plant incorporated use of acetochlor formulations containing the safener dichlormid (R-25788) in sweet corn. Plots containing sweet corn were treated pre-emergence or pre-plant incorporated with either an emulsifiable concentrate (EC), a water dispersible micro-encapsulated suspension (CS) or a dry granular (GR) formulation of acetochlor at a rate of 3.4 kg ai/ha. The method used was RAM 280/01 for which the LOQ is 0.01 mg/kg for both EMA-class and HEMA-class compounds.

Table 76 Residues in sweet corn following a single application of an EC, CS or GR acetochlor formulation (kernels + cob with husk removed) (Crook and French 1996 RJ2078B) HEMA and EMA residues are expressed in acetochlor equivalents.

[a] Samples of kernels only and not kernels + cob with husk removed

[b] Replicate samples from same plot

Soya bean

Hay *et al.* (2008 MSL-20719) studied residues of acetochlor in soya beans following application of a micro-encapsulated formulation as a single post-emergent application at 3.4 kg ai/ha made at growth stage R1-R2 (beginning flowering–full flowering) or as three applications of 1.1 kg ai/ha each made pre-plant (45 d prior to planting), and post-emergent at growth stages V3 (3rd trifolate leaf) and at R1-R2. One composite sample was collected from each untreated control plot and two composite samples were collected from each of the treated plots. Hay was left in the field to dry for 1 to 7 days before sampling as this was needed to allow moisture levels to reach that of commercial hay. Residues were quantified using LC-MS/MS analytical method ES-ME-1215-01.

Table 77 Residues in soya bean following application of a CS acetochlor formulation (Hay *et al.* 2008 MSL-20719) HEMA and EMA residues are expressed in acetochlor equivalents. Replicate samples

Growth Stages

VE Emergence—cotyledons have been pulled through the soil surface

VC Unrolled unifoliolate leaves—unfolding of the unifoliolate leaves

V1 First trifoliolate—one set of unfolded trifoliolate leaves

V2 Second trifoliolate—two sets of unfolded trifoliolate leaves

V4 Fourth trifoliolate—four unfolded trifoliolate leaves

V(n) nth trifoliolate—V stages continue with the unfolding of trifoliolate leaves. The final number of trifoliolates depends on the soya bean variety and the environmental conditions

R1 Beginning flowering—plants have at least one flower on any node

R2 Full flowering—there is an open flower at one of the two uppermost nodes

R3 Beginning pod—pods are 5 mm at one of the four uppermost nodes

R4 Full pod—pods are 2 cm at one of the four uppermost nodes

R5 Beginning seed—seed is 3 mm long in the pod at one of the four uppermost nodes on the main stem

R6 Full seed—pod containing a green seed that fills the pod capacity at one of the four uppermost nodes on the main stem

R7 Beginning maturity—one normal pod on the main stem has reached its mature pod colour

R8 Full maturity—95% of the pods have reached their full mature colour

Sugar beet

Fifteen supervised residue trials were conducted on sugar beet in the USA and Canada in 2011. At each sites a plot was treated with CS formulations (Mueth and Foster 2012 MSL-24198). A non-ionic surfactant (0.5% v/v) and 2 kg ammonium sulphate/100L were added to the spray mixtures for all applications. One composite sample was collected from each untreated control plot and two composite samples were collected from each of the treated plots. Samples were analysed for residues of acetochlor using method AG-ME-1467. Roots EMA LOD 0.0005 mg/kg, LOQ 0.0016 mg/kg; HEMA 0.0005 mg/kg, LOQ 0.0015 mg/kg; Tops: EMA LOD 0.0012 mg/kg LOQ 0.0037 mg/kg HEMA LOD 0.00037 mg/kg, LOQ 0.0011 mg/kg.

Table 78 Residues in sugar beet following application of a CS acetochlor formulation (Mueth and Foster 2012 MSL-24198). HEMA and EMA residues are expressed in acetochlor equivalents. Replicate samples.

Maize

Oppenhuizen and Wilson (1989 MSL-6843) studied residues of acetochlor in corn (field and sweet) from 12 different trial sites in the USA. An EC formulation (MON-097 in tank mixed with MON-4666 ratio 1:10) was applied a single pre-emergence application at 1.7, 3.4 or 6.7 kg ai/ha. Forage samples (4.5 kg) were collected 8 weeks after application and fodder (4.5 kg) and grain (11 kg) at commercial harvest. The LOD for corn forage is 0.005 mg/kg for EMA-class metabolites and 0.006 mg/kg for HEMA-class metabolites. The LOQ is 0.017 mg/kg for EMA-class metabolites and

0.018 mg/kg for HEMA-class metabolites. Results are corrected for the average analytical recovery of the method.

Table 79 Residues in maize and sweet corn (two trials only) following application of an acetochlor EC formulation (Oppenhuizen and Wilson 1989 MSL-6843) HEMA and EMA residues are expressed in acetochlor equivalents. Results are for samples analysed in duplicate.

[a] Results are corrected for the average analytical recovery of the method

Ralph *et al.* (1992 RJ1337B) studied residues of 5-hydroxy *sec*-oxanilic acid (68) in 14 trials conducted in the USA where acetochlor, formulated as an EC formulation incorporating the safener R25788, was applied to the soil surface immediately after planting field corn. All treatments were made as a single application at a rate of 2.8 kg ai/ha, with the exception of one trial carried out in Colorado, which was mistakenly treated at 4.5 kg ai/ha. The analytical method used was reported in RJ1257B. Samples were analysed in duplicate.

Table 80 Residues of 5-hydroxy *sec*-oxanilic acid (68) in maize following application of an acetochlor EC formulation as a single pre-emergent application at 2.8 kg ai/ha (Ralph *et al.* 1992 RJ1337B) Single field samples analysed in duplicate.

[a] Application was 4.5 kg ai/ha

Lau (1992 MSL-11794) conducted 14 trials on maize in the USA. At each site, a CS formulation of acetochlor was applied to field corn as a pre-emergent application (all sites) or pre-plant incorporation (six sites) application at a nominal rate of 3.4 kg ai/ha. Pre-emergent applications were also done at 1.7 kg ai/ha at two sites. The CS formulation was applied as a tank-mix with MON 13900 (3-(dichloroacetyl)-5-(2-furyl)-2,2-dimethyloxazolidine, 2,2-dichloro-1-[5-(2-furyl)-2,2-dimethyl-oxazolidin-3-yl]ethanone = safener). Forage samples were collected six to twelve weeks after planting. Silage samples were taken at the dent stage, and grain and fodder collected at normal harvest.

Table 81 Residues in maize following application of a CS acetochlor formulation Lau (1992 MSL-11794) HEMA and EMA residues are expressed in acetochlor equivalents. Single field samples analysed in duplicate.

Values have been corrected for analytical method recoveries and expressed as acetochlor equivalents for either EMA (ethylmethylaniline producing) or HEMA (hydroxyethylrnethylaniline producing) residues

Maize

Twenty-one supervised residue trials were conducted on maize in the USA in 2006. At each sites a plot was treated with either CS (microencapsulated) or EC formulations (Maher 2007 MSL-20269). An herbicide safener, furilazole, was used in the spray mix for each application. A single control and duplicate treated samples of corn forage, grain, and stover were collected from each test plot. The interval between sampling and extraction for the acetochlor samples was 175 days for grain, 374 days for forage and 359 days for stover. Samples were analysed for residues of acetochlor using the LC-MS/MS method ES-ME-1001-02.

Table 82 Residues in maize following application of an EC or a CS acetochlor formulation (Maher 2007 MSL-20269). HEMA and EMA residues are expressed in acetochlor equivalents. Replicate samples.

PE = pre-emergent

PO = post-emegent

EMA LOD 0.0006 mg/kg, LOQ 0.0012 mg/kg

HEMA LOD 0.0007 mg/kg, LOQ 0.0012 mg/kg

Growth Stages

VE Corn emergence, coleoptiles break through soil surface

V1 First leaf fully emerged and leaf collar visible

V2 Second leaf fully emerged and leaf collar visible

V(n) n^{th} leaf fully emerged

VT last branch visible but silks not emerged

R1 Beginning silking—silk visible outside of husk

R2 Blister stage—kernel is white and shaped like a blister

R3 Milk stage—kernel is yellow with white milky inner liquid

R4 Dough stage—inner fluid begins to thicken due to stach accumulation

R5 Dent stage—kernels begin to dry down from the top of the kernel toward the cob. Each kernel will have a dent at the top.

R6 Full maturity—black layer forms where kernel attaches the cob. Kernel moisture is at 30–35%.

BBCH 18 leaf development: 18^{th} leaf unfolded

BBCH 33 stem elongation: 3 nodes detectable

Sorghum

Moran (2004 MSL-18670) studied residues in sorghum in 13 field trials conducted in 2003. Acetochlor as a CS formulation (controlled release suspension capsule) was applied in side-by-side tests at each trial site as either a Pre-emergence or an early post-emergence (plants $\leq$ 28 cm) application at a rate of 2.8 kg ai/ha. All applications were made using ground equipment in spray volumes of 94 to 188 L/ha. At two sites, food grade (white) sorghum was planted and used for processing while at the others typical animal feed sorghum varieties were used. Because sorghum is sensitive to acetochlor, the test substance included the safener furilazole at 0.50%. At crop maturity, single control and duplicate treated samples of grain (90 to 171 DAT) and stover (93 to 177 DAT) were collected from each test. Stover was left in the field to dry at four sites (Plains Georgia, York, Osceola and Grand Island Nebrasha) where the stover was too green and contained too much moisture at the appropriate grain harvest time. Samples were stored frozen for durations of up to 222 days prior to analysis of acetochlor residues. The LC/MS/MS Method ES-ME-1001-01 used to determine residues of EMA and HEMA class metabolites in sorghum forage, grain, and stover. The LOQs for EMA were 0.005 mg/kg in forage, 0.005 mg/kg in grain, and 0.015 mg/kg in stover, while the LOQs for HEMA were 0.003 mg/kg in forage, 0.003 mg/kg in grain, and 0.011 mg/kg in stover.

Table 83 Residues in sorghum following application of an EC or a CS acetochlor formulation Moran (2004 MSL-18670). HEMA and EMA residues are expressed in acetochlor equivalents. Replicate samples.

Cotton

Hay *et al.* 2008 (MSL-20718) studied residues in cotton seed following pre-plant/post-emergence or post-emergence applications of either CS (microencapsulated) or EC formulations of acetochlor. Both formulations contain a safener although this is not effective in the case of cotton. Applications were made as a single spray at 3.4 kg ai/ha late post-emergence (1st flower) or at the 8-leaf stage or as a split treatment with an application made pre-plant (about 30 days before planting) and another at the 8-leaf stage. Cotton was harvested by commercial-type equipment (stripper or mechanical picker) at all but two sites (Dill City and Tulare), where handheld clippers were used. A single control and duplicate treated samples of seed and gin by-products were collected from each test Samples were analysed for residues using LC-MS/MS method ES-ME-1215-01. The LOQs are 0.005 mg/kg for EMA and HEMA in seed and 0.06 mg/kg for EMA in forage and 0.014 mg/kg for HEMA in forage.

Table 84 Residues in cotton seed following application of a micro-encapsulated (CS) acetochlor formulation (Hay *et al.* 2008 MSL-20718). HEMA and EMA residues are expressed in acetochlor equivalents. Replicate samples.

BBCH 17 7th true leaf unfolded

BBCH 18 8th true leaf unfolded

BBCH 19 9th true leaf unfolded

BBCH 51 First floral buds detectable (“pin-head square”)

BBCH 52 First floral buds visible (“match-head square”)

BBCH 55 Floral buds distinctly enlarged

BBCH 59 Petals visible: floral buds still closed

BBCH 60 First flowers opened (sporadically within the population)

BBCH 61 Beginning of flowering (“Early bloom”): 5–6 blooms / 7.5 meter of row

BBCH 65 Full flowering: (“Mid bloom”): 11 and more blooms / 7.5 meter of row

Peanuts

Mueth and Foster (2012 MSL-0024197) studied residues in peanuts at 13 trial sites in the USA. Treatments included one pre-plant (10–15 days before planting) or one pre-emergence application and a post-emergence (about 40 days after planting but prior to flowering) applications or a single post-emergent application. The formulation used was a CS (microencapsulated, 359 g ai/L) formulation of acetochlor. The tank mix included a non-ionic surfactant (0.5% v/v) and in the case of the post-emergence applications 2 kg ammonium sulphate/100 L spray solution. One composite sample was collected from each untreated control plot and two composite samples were collected from each of the treated plots. The residues were quantified by LC-MS/MS, method AG-ME-1467. For nutmeat the LOD and LOQs were 0.003 and 0.009 mg/kg for EMA and 0.003 and 0.009 mg/kg for HEMA. For hay the LOD and LOQs were 0.001 and 0.003 mg/kg for EMA and 0.001 and 0.003 mg/kg for HEMA.

Table 85 Residues in nutmeat following application of a micro-encapsulated (CS) acetochlor formulation to peanuts Mueth and Foster (2012 MSL-0024197). HEMA and EMA residues are expressed in acetochlor equivalents. Replicate samples.

[a] Peanuts are typically dug (harvest date) and the field dried until they are ready for shelling and bagging (sampling date). Peanuts were sampled 3–16 days after harvesting. The pre-harvest intervals reported are the days between last application and the harvest date (digging date)

Values have been corrected for analytical method recoveries and expressed as acetochlor equivalents for either EMA (ethylmethylaniline producing) or HEMA (hydroxyethylrnethylaniline producing) residues

Table 98 Residues in maize fodder following post-emergent application of an EC or a CS acetochlor formulation (Maher 2007 MSL-20269). HEMA and EMA residues are expressed in acetochlor equivalents. Replicate samples.

Fate of residues in processing

Peanuts

Peanuts from two trial locations were processed. Following receipt and inventory, the peanuts were placed into frozen storage until preparation for processing. The untreated and treated peanuts were oven dried (54–71 °C) to 7–12% moisture, then cleaned by aspiration and screening. The unshelled peanuts were then fed into a huller to crack the hull and liberate the nutmeat. The nutmeat was separated from the hulls by aspiration. Fractions of hull material and nutmeat were collected and placed in frozen storage. If necessary, the nutmeat material for processing was oven dried (54–71 °C) to 7–10% moisture. Following drying the nutmeat was separated into two portions (dry roasted peanuts/peanut butter and peanut meal/peanut oil) for further processing.

Peanut oil and meal: Kernel moisture was adjusted to 12% and the material heated to 85–104 °C and pressed in an expeller to remove the majority of the oil. The press cake was milled and solvent extracted with hexane (49–60 °C) and after 30 minutes the miscella was drained and the process repeated (2×). Solvent was removed from the meal by forcing warm air through. Hexane was removed from the miscella by vacuum evaporation (91–96 °C) to obtain crude oil. The free fatty acid content of the crude oil was determined and an appropriate amount of NaOH added with mixing, initially at 20–24 °C and then at 60–67 °C after which the mixture was allowed to settle for one hour prior to refrigeration for 12 hours. The neutralised refined oil was decanted from the soapstock. The refined oil was bleached by adding activated bleaching earth,

heating to 85–100 °C for 10–15 minutes and filtering. The bleached oil was heated under vacuum to 220–230 °C for 30 minutes and cooled to 135–150 °C before addition of 0.5% citric acid. The oil was cooled and filtered to produce refined bleached deodorised oil.

Dry roasted nuts were prepared by heating raw shelled peanuts 160–171 °C for 2–7 minutes.

Oil roasting: raw shelled nuts were submerged in a deep fryer containing peanut oil heated to 171–182 °C for 2 minutes and drained.

Peanut butter: Skins were removed from dry roasted nuts, which were chopped and fed through a peanut butter machine. Peanut oil and salt were added to the material exiting the machine.

Table 105 Residues in peanut processed commodities (Mueth and Foster 2012 MSL-0024197). HEMA and EMA residues are expressed in acetochlor equivalents.

Soya bean

Harvested soya beans from one trial were processed into refined oil, soya bean meal, and hulls. Samples were processed to simulate commercial practice as closely as possible. Samples were dried in an oven at 54–71 °C until the moisture content was 7–10%. Light impurities were removed by aspiration and the samples screened to separate large and small foreign particles. The cleaned soya beans were fed into a roller mill to crack the hull and release the kernel. The hulls and kernels were separated by aspiration. The kernels were adjusted to a moisture content of 13.5% and heated to 71–79 °C, flaked (0.02–0.03 cm) and extruded into collets by direct steam injection and compression (exit temperature 93–121 °C). After extrusion the collects were dried at 66–82 °C for 30–40 minutes before being immersed in hexane 49–60 °C for 30 minutes, a process repeated a further 2×. The

solvent extracted meal was heated to 99–104 °C. The hexane was removed from the miscella under vacuum (91–96 °C) and filtered. An appropriate amount of NaOH was added and the oil mixed for 90 minutes at 20–24 °C and then 20 minutes at 63–67 °C. The neutralised oil was centrifuged to separate the refined oil from the soapstock.

Total HEMA and EMA residues in soya bean were reduced in refined oil and hulls relative to the unprocessed seeds by processing factors of 0.11 and 0.72, respectively. Total HEMA and EMA residues were slightly increased in meal relative to the unprocessed seeds with a processing factor of 1.2. The results show that no concentration occurred in soya bean refined oil or hulls, but a slight concentration of residues did occur in soya bean meal.

Table 106 Residues in soya bean processed commodities (Hay *et al.* 2008 MSL-20719). HEMA and EMA residues are expressed in acetochlor equivalents.

Sugar beet

Sugar beets from two trials were processed. Following receipt and inventory, the sugar beets were placed into frozen storage until preparation for processing. Samples were weighed and cleaned and a representative sample of the sugar beet RAC was collected. The cleaned beets were then chopped, diffused at 68–74 °C, and the raw juice was sieved to remove pieces of beet from the juice.

Diffused material was dewatered with a hydraulic press and beet pulp was dried to ≤ 15% moisture. The beet pulp fraction was then placed in freezer storage. Raw juice was mixed and heated, and the pH was adjusted to separate the mud and juice by centrifugation and filtration. After concentration, the thick juice was seeded with sugar to begin the crystallization process. Sugar and molasses were separated, centrifuged, and steam was added to facilitate separation. Sugar and molasses fractions were placed in freezer storage.

Sorghum

Harvested sorghum grain from two sites was processed into cleaned grain, flour, and bran. Samples were processed to simulate commercial practice as closely as possible.

Grain was dried to target moisture content, aspirated to remove light impurities, screened to clean the seed prior to decortication to produce decorticated grain, bran and grits (small grits and large grits). The decorticated grain was further processed to produce flour.

Grain sorghum was dried (if necessary) in an oven at 54–71 °C to a moisture content of 10–13%. The light impurities were separated using an aspirator. After aspiration, the sample was screened in a two screen cleaner to separate large and small foreign particles (screening) from the grain sorghum.

The cleaned grain was milled in an abrasion mill to remove most of the bran from the seed. Bran was separated using a sample sifter equipped with a 12 TMS screen. The grain was decorticated until approximately 15% or more of the bran passed through the 12 TMS screen. The material on top was again classified in the sample sifter utilizing 8 TMS and 10 TMS screens. The decorticated grain was collected from the top of the 8 TMS screen. Large grits passed through the 8 TMS and were collected on top of the 10 TMS screen. Small grits passed through the 8 and 10 TMS screens and were collected in the pan.

The decorticated grain was ground in a mill fitted with a 0.31 cm, 0.17 cm or similar size screen. The through product wais then reground in the mill with a 0.015 cm. Decorticated grain was milled into flour. Ground material was sifted with a sample sifter equipped with a US 34 screen.

Cotton

Undelinted seed were processed into hulls, cottonseed meal, and refined oil. Samples were processed to simulate commercial practice as closely as possible. Prior to ginning, the seed cotton was cleaned with an attached stick extractor to remove gin trash (gin by-products). Seed was saw-ginned to remove most of the lint (ginned cottonseed). With approximately 11–15% remaining lint, the undelinted cottonseed was saw delinted to produce delinted cottonseed (ca. 3% lint remaining). The delinted seed was mechanically cracked on a roller mill followed by screening to separate the hulls from the kernel. The kernel material was processed into meal and crude oil by heating kernels to 79–91 °C for 15–30 minutes, after which the kernel material was flaked (roll gap 0.02 cm) and the flaked material fed into a continuous processor (extruder). As material moved through the extruder steam was injected directly on the product. The maximum temperature of the exiting collets was 118 °C. Collets were dried in an oven at 65–82 °C for 30–40 minutes and then solvent extracted in batches (hexane 49–60 °C). After 30 minutes the hexane was drained, fresh hexane added and the extraction process repeated, three times in total. After final draining, the spent collets (meal) were heated to 99–104 °C to remove residual hexane. The miscella (crude oil + hexane) was passed through a vacuum evaporator (91–96 °C) to remove the hexane and filtered prior to refining. Crude oil and NaOH were mixed at 20–24 °C for 15 minutes, the temperature increased to 63–67 °C for a further 12 minutes. The neutralised oil was centrifuged to remove the solids (soapstock) and the refined oil decanted and vacuum filtered.

The processing factors range from 0.083 to 0.438, indicating that no concentration occurred in processed fractions.

[a] 1×EC pre-plant + 1×CS (1st flower)

Sunflower

The whole sunflower samples were dried in an oven at 54–71 °C until a final moisture content of 7–10% was reached. The light impurities were separated using an aspirator. After aspiration, the sample was screened in a two screen cleaner. Large and small foreign particles (screenings) were separated from the sunflower.

The whole sunflower was fed into a disc mill to crack the hull and liberate the kernel material. After hulling, the material was passed through the aspirator to separate the hull and kernel material (some whole-seed and kernel remain after separation).

Kernel material was moisture conditioned to 12%, heated to 88–104 °C and pressed in an expeller to liberate a portion of the crude oil. The press cake from the expeller was placed in stainless steel tanks and submerged in 49–60 °C solvent (hexane). After 30 minutes, the hexane was drained and fresh hexane added to repeat the cycle two more times. The final two washes

were for 15 minutes each. After the final draining, warm air was forced through the solvent extracted press cake (meal) to remove any residual hexane.

The miscella (crude oil and hexane) was passed through a recovery unit to separate the crude oil and hexane. Crude oil was heated to 73–90 °C for hexane removal.

Crude oil recovered from the expeller and solvent extraction was combined and refined. After refining, the refined oil and soap stock were separated.

A subsample of the seed was taken and processed into sunflower meal and oil. Samples were processed to simulate commercial practice as closely as possible. The processing factor was 1.44 for sunflower meal, indicating concentration may have occurred. The processing factor for sunflower oil was 0.22, indicating no concentration occurred

Table 110 Residues in sunflower processed commodities (Anderson 1996 RJ2568B). HEMA and EMA residues are expressed in acetochlor equivalents.

[a] Bulk pre-processing

Oats

The oat samples were dried in an oven with a temperature range of 85–93 °C to a moisture content of 7.4–9.9%. The light impurities were separated using an aspirator, after which the sample was screened in a two screen cleaner. Large and small screenings were separated from the oats. The cleaned oats were passed through a mill to dehull the oat sample. During dehulling, the groats (hulled oats) and hull were separated using the aspiration system on the mill. The groats and unhulled seed were separated using a gravity table until the amount of unhulled seed was less than 5% (visual inspection). The groats and fine material (oat feed) were separated with a sample sifter equipped with a US 24 screen. A fraction of the groats was ground in a mill and sifted in a sifter equipped with a US 34 screen. The groats were ground until 80–90% of the material passed through the screen. Resulting fractions were bran (top of the screen) and flour (through the screen).

There was no residue concentration in any of the processed commodities.

Table 111 Residues in oat processed commodities (Manning 1997 MSL-14118). HEMA and EMA residues are expressed in acetochlor equivalents.

PFs are based on combined EMA- and HEMA-class metabolites

PRIMARY FEED COMMODITIES OF PLANT ORIGIN

Fate on processing

Livestock feeding studies

Dairy cow feeding study

The transfer of acetochlor metabolites from feed to tissues and milk of dairy cows was studied by Wilson (1982, MSL-2285). A synthetic mixture representing the four classes of metabolites was used for dosing. The four metabolites were *tert*-hydroxy (17) and the sodium salts of *tert*-sulfonic acid (7), *tert*-oxanilic acid (2) and *tert*-sulfinylacetic acid (3) and were present in the dose material in equal parts by weight.

A mixture of the four acetochlor metabolites was administered orally to four groups of three Holstein cattle (1.9–5.8 years old; 441–598 kg bw) by gelatine capsule for 28 days. Mean daily feed consumption for the dose groups during the exposure period were 21.4–22.6 kg DM (hay, *ad libitum* and 6.3 kg/day protein concentrate). Mean daily milk yield for the dose groups during the exposure period were 15.6 to 17.3 kg/cow/day. Based on mean daily feed consumption, the exposure was equivalent to 5, 15 and 50 ppm in the feed. Milk was collected twice daily (pm sampling pooled with am sampling the next day) at 11 intervals through the 28 days of dosing. Selected samples were analysed for residues of acetochlor metabolites. Muscle, liver, kidney and fat samples were collected at sacrifice 22–24 hours after the last dose; or 28 days in the case of the depuration animals. The maximum frozen storage intervals were 65 days for milk, 30 days for skim milk and 59 days for cream. The maximum storage intervals for tissues were 44 and 36 days for muscle and fat, respectively. Liver and kidney samples were extracted on the day of collection with the exception of selected repeat samples. Samples were analysed using the analytical method "Analytical Residue Method for Four Metabolites of Acetochlor in Milk and Beef Tissues". Milk, muscle, liver, kidney, and fat were analysed for residues of acetochlor metabolites containing the EMA moiety.

The analytical method determines of compounds hydrolysable to EMA. The procedure consists of extraction of the beef matrix with solvents (90% CH_3CN/H_2O for milk, muscle, liver and kidney; hexane followed by 90% CH_3CN/H_2O), centrifugation, filtration, and evaporation. The extracted residue is digested first in acid (12 N H_2SO_4, reflux 20 min) to remove the

ethoxymethyl group, then in base (50% NaOH) followed by distillation to recover the liberated EMA. The recovered aniline is quantified by GC-NPD. Residues are expressed as acetochlor equivalents. The LOQ is 0.02 mg/kg for tissues and milk.

Milk samples taken throughout the 28-day dosing period and muscle and fat samples taken at sacrifice time showed residues < 0.02 mg/kg. Kidneys showed a maximum residue of 0.09 mg/kg at the 50 ppm dosing level, 0.04 mg/kg at the 15 ppm dosing level and < 0.02 mg/kg at the 5 ppm dosing level. Residues of 0.02 mg/kg in liver were seen only at the 50 ppm dosing level. All tissues and milk from animals allowed a 28-day withdrawal period were < 0.02 mg/kg.

Table 113 Concurrent recovery results for acetochlor metabolites for the dairy cow feeding study

Fortification (mg/kg)	Average EMA % recovery (number of replicates)				
	Milk	Muscle	Liver	Kidney	Fat
0.02	76.5 (36)	69.8 (4)	70.0 (6)	73.1 (8)	78.3 (4)
0.2	–	79.0 (1)	66.0 (1)	84.0 (1)	74.5 (1)
Average	76.5 (36)	71.6 (5)	69.5 (7)	73.7 (9)	77.5 (5)

Table 114 Residues of acetochlor metabolites in tissues of cows dosed with a mixture of four metabolites

	Dose group (ppm)	EMA (mg/kg), expressed as acetochlor	
		28 day dosing	28 day dosing + 28 day withdrawal
Milk (–1, 1, 4, 8, 14, 21, 28 d) [a]	50	< 0.02	< 0.02
Muscle	50	< 0.02 (< 0.02 (3))	< 0.02
Fat	50	< 0.02 (< 0.02 (3))	< 0.02
Liver	15	< 0.02 (< 0.02 (3))	NA
	50	0.02 (0.02 (3))	< 0.02
Kidney	5	< 0.02 (< 0.02 (3))	NA
	15	0.03 (0.02 0.04 0.04)	NA
	50	0.07 (0.09 0.06 0.06)	< 0.02

[a] Individual samples of milk from the days listed were analysed separately and were all < 0.02 mg/kg.

The method converts the metabolites to the common moiety EMA.

NA = not analysed

Laying hen feeding study

Wilson (1982 MSL-2287) studied the transfer of acetochlor metabolites to chicken tissues and eggs. A residue feeding study was conducted in laying hens (White Leghorn, 20–24 weeks old, 1.4–1.84 kg bw, lay efficiency 0.98, 0.96 and 0.96 eggs/d) with acetochlor metabolites to provide a basis for establishing tolerances for acetochlor in eggs and chicken tissues. Four representative metabolites of acetochlor, equal parts by weight, dissolved in absolute ethanol were fed by oral gavage to 100 laying hens in a single daily oral dose. The four metabolites were *tert*-hydroxy (17) and the sodium salts of *tert*-sulfonic acid (7), *tert*-oxanilic acid (2) and *tert*-sulfinylacetic acid (3). The 100 chickens were divided into four dosing groups (control, 5, 15, and 50 ppm) and dosed once daily for 28 days. Mean feed consumption was 110 g/d (actual dosing period, 117, 114, 115 g/d but 90% DM so 130, 128 128 g/d). Mean laying efficiency for the three dose groups were 98%, 96% and 96% respectively. After the dosing, one-half of the birds were sacrificed for tissue samples while the remaining hens were allowed a 28 day withdrawal period prior to sacrifice.

The analytical method, "Analytical Residue Method for Four Metabolites of Acetochlor in Eggs and Chicken Tissues" and is essentially the same method as used for the lactating cow transfer study. The residue method converts the metabolites to the common EMA moiety. Tissues from all three dose levels were analysed at one time. The tissues from all the birds in each treatment level group were composited. This was necessary to ensure a large enough analytical sample for some of the tissues.

Table 115 Concurrent recovery results for acetochlor metabolites for the laying hen feeding study

Matrix	Spiking level (mg/kg)	Average Recovery (%)	Standard Deviation	RSD (%)	Replicates
Egg	0.02	82.1	6.8	8.2	22
Muscle	0.02	75.8	5.4	7.1	4
Liver	0.02	72.8	4.5	6.2	4
Kidney	0.02	79.8	4.3	5.4	4
Fat	0.02	77	4.7	6.1	4

The LOQ was 0.02 mg/kg for all tissues except kidneys, for which the LOQ was 0.05 mg/kg due to the small sample size. Egg samples collected throughout the 28-day dosing period and muscle, liver, and fat samples taken at sacrifice time showed non-detectable residues (< 0.02 mg/kg) from all feeding levels. Kidney samples also showed non-detectable residues (< 0.05 mg/kg). All tissues and eggs from birds allowed a 28-day withdrawal period also had non-detectable residues from all feeding levels.

NATIONAL RESIDUE DEFINITIONS

Canada Acetochlor

China Acetochlor

Japan Acetochlor

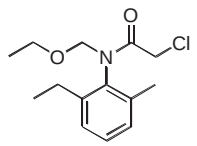
Korea Acetochlor

USA Acetochlor and its HEMA- and EMA-producing metabolites, calculated as parent equivalents

APPRAISAL

Acetochlor is a selective herbicide which, after application, is absorbed mainly by the shoots of germinating plants, and to some extent, by roots. Acetochlor is used as a pre-emergence or early post-emergence soil-applied herbicide. Acetochlor controls annual grasses and broadleaf weeds, germinating from seeds; however, its action against perennial weeds is very limited. At the Forty-sixth Session of the CCPR (2014), it was scheduled for the evaluation as a new compound by 2015 JMPR.

The Meeting received information on the metabolism of acetochlor in maize, soya beans and cotton, lactating goats and cows, laying hens, follow crops, methods of residue analysis, freezer storage stability, GAP information, supervised residue trials on maize (forage, grain, stover and silage), sweet corn (forage, kernels plus cob with husks removed, stover and silage), cotton (gin by-products and seed), sorghum (grain, forage and stover), soya bean (meal and seed), sugar beet (dried pulp, roots, tops, sugar and molasses), peanuts (hay and meal) and livestock transfer studies (lactating cows and laying hens).



Acetochlor is 2-chloro-*N*-(ethoxymethyl)-*N*-(2-ethyl-6-methylphenyl)acetamide

Metabolites referred to in the appraisal were addressed by their common names with the corresponding aniline metabolite class (EMA, HEMA, HMEA or OH) indicated in brackets.

2-ethyl-6-methyl aniline = EMA		2-(1-hydroxyethyl)-6-methyl aniline = HEMA	2-ethyl-6-hydroxymethyl aniline = HMEA			
1-hydroxyethyl *tert*-oxanilic acid (HEMA class)		*sec*-sulfinyllactic acid glucose conjugate (EMA class)	1-hydroxyethyl-*sec*-methylsulfone glucosylsulfate conjugate (HEMA class)	 R=glucose sulfate	*sec*-sulfonic acid (EMA class)	5-hydroxy-*sec*-oxanilic acid (OH class)		*tert*-cysteine (EMA class)	hydroxymethyl-*tert*-oxanilic acid (HMEA class)		*tert*-hydroxyacetochlor (EMA class)	sec-hydroxyacetochlor (EMA class)		*tert*-malonylcysteine (EMA class)	sec-methylsulfone (EMA class)		*tert*-malonylcysteine sulfoxide (EMA class)	sec-oxanilic acid (EMA class)		*tert*-methylsulfone (EMA class)	
sec-sulfinyllactic acid (EMA class)		*tert*-oxanilic acid (EMA class)	tert-sulfinyllactic acid (EMA class)		*tert*-sulfinylacetic acid (EMA class)	tert-sulfonic acid (EMA class)			

Plant metabolism

Acetochlor is typically used for three different situations:

- Incorporation into the soil prior to planting the crop (PP)
- As a broadcast spray to weeds and bare soil after seeding but prior to crop emergence (PE)
- As a broadcast spray to weeds and the growing crop, i.e. post-emergence (PO).

The Meeting received plant metabolism studies with acetochlor following pre-plant, pre- and post-emergent applications to maize (corn), cotton and soya bean.

Maize

The metabolism of [^{14}C-U-phenyl]-acetochlor in maize grown outdoors was studied following either a pre-emergence (PE) application immediately after seeding or post-emergence after allowing the corn plants to grow to a height of 66–71 cm (growth stage V6 to V7, i.e., 6–7 leaves fully emerged) before spraying. The effective treatment rates were 3.6 kg ai/ha for the PE application and 3.5 kg ai/ha for the PO application.

Total radioactive residues in PE forage, grain and stover were 0.67, 0.04 and 1.84 mg equiv/kg while those in PO forage, grain and stover were higher at 3.44, 0.022 and 6.41 mg equiv/kg respectively.

Solvent (CH_3CN/H_2O) extracted ≥ 79% of the TRR present in immature plants, forage and stover samples. Extraction of ^{14}C present in grain was lower at 58–63% TRR. The majority of the ^{14}C present in the solids after extraction were associated with natural products, especially starch, protein, lignin and hemicellulose. A large number of metabolites were detected in the solvent extracts but not unchanged acetochlor. There were notable differences in the pattern of metabolites observed following PE compared to PO application.

The metabolites identified in PO forage and stover primarily resulted from initial glutathione conjugation of acetochlor followed by oxidation to give sulfoxide-type metabolites. Only one compound exceeded 10% of TRR: *tert*-sulfinyllactic acid was observed at 12.6% TRR (0.43 mg equiv/kg) in forage and 11.3% of TRR (0.72 mg equiv/kg) in stover. Two other metabolites exceeded 0.1 mg equiv/kg: *sec*-sulfinyllactic acid and *sec*-sulfinyl lactic acid glucose conjugate.

In contrast, in PE maize the compounds detected resulted largely from the uptake of soil metabolites to give oxanilate-type metabolites. None of the individual components exceeded

10% of TRR in immature plant, forage or stover. The major component was 5-hydroxy *sec*-oxanilic acid present at levels of 8.4% (0.099 mg equiv/kg) 6.2% (0.042 mg equiv/kg) and 4.3% (0.080 mg equiv/kg) TRR in immature plants, forage and stover respectively.

In grain from PE or PO application, no individual compound exceeded 10% of TRR and no discrete component characterized by chromatography exceeded 0.001 mg equiv/kg.

Compounds containing an intact phenyl ring can be classified according to the aniline that would be generated on base hydrolysis. Non-hydroxylated metabolites give EMA, those hydroxylated at the 1-position of the ethyl side-chain give HEMA, those at the hydroxylated at the methyl side-chain HMEA and those hydroxylated at the 3, 4 or 5 positions of the phenyl ring could be classed as "OH" anilines. The major aniline metabolite class observed in maize (PE and PO) is EMA followed by OH.

Soya bean

The metabolism of [^{14}C-U-phenyl]-acetochlor in soya beans grown outdoors following either a pre-plant (PP) or post-emergence (PO) application was studied. The PP application was made to the soil (loamy sand) 45 days before seed planting while the PO application was made to a second group of plants 42 days after planting seed when the plants were approximately at the R1–R2 growth stage (beginning flowering to full flowering). The application rates were 3.5 kg ai/ha for the PP and 3.7 kg ai/ha for the PO application.

Levels of radioactivity were higher in PO treated plants compared to PP application. TRRs were 1.67 and 11.4 mg equiv/kg in PP and PO forage, respectively; 3.48 and 57.7 mg equiv/kg in PP and PO hay; and 0.175 and 0.192 mg equiv/kg in PP and PO seed.

Solvent (CH_3CN/H_2O) extracted ≥ 86% of the TRR present in forage and hay samples. Extraction of ^{14}C present in grain was lower at 59–80% TRR.

As was the case with maize, a large number of metabolites were detected in the solvent extracts but not unchanged acetochlor. There were also notable differences in the patterns of metabolites observed following PP compared to PO application.

Like maize, the metabolites identified in PO soya bean forage and hay primarily resulted from initial glutathione conjugation of acetochlor followed by oxidation to give sulfoxide-type metabolites. Five compounds exceeded 10% of TRR: *tert*-cysteine (forage 39% TRR, 4.45 mg equiv/kg), *tert*-malonylcysteine (forage and hay 18–23%TRR, 2.62–10.6 mg equiv/kg), *tert*-sulfinyllactic acid and *tert*-malonylcysteine sulfoxide (forage and hay; combined 24–30%TRR, 2.72–17.3 mg equiv/kg). A large number of other metabolites were present at levels in excess of 0.1 mg equiv/kg.

In contrast, in PP soya bean forage or hay the compounds detected resulted largely from the uptake of soil metabolites to give oxanilate-type metabolites. None of the individual components exceeded 10% of TRR in immature plant, forage or hay. The major metabolites were *tert*-oxanilic acid (> 9.5% TRR, > 0.158 mg equiv/kg) in forage and *tert*-oxanilic acid combined with *tert*-sulfonic acid present at levels of > 9.7% (0.34 mg equiv/kg) in hay.

Both PP and PO seed extracts contained numerous low-level metabolites (≥ 27), none of which exceeded 0.03 mg equiv/kg. PP seed metabolites were generally more polar than PO seed metabolites.

The major aniline metabolite classes in soya bean commodities are EMA and "other" for PP forage, HEMA and EMA for PP hay and EMA for PO hay.

Cotton

The metabolic fate of [^{14}C-U-phenyl]-acetochlor in cotton maintained outdoors was examined following either a pre-plant (PP) soil (sandy loam) application 30 days before seed planting or as a separate application (PO) made to plants 15 days after the majority of plants had reached their first white flower stage. The application rates were 3.6 kg ai/ha for the PP and for the PO application.

TRR in PO leaves/stems were 63.9 mg equiv/kg whilst the TRR in PP leaves/stems were much lower at 5.7 mg equiv/kg. The TRRs in seed from both treatments were similar at 0.13 mg equiv/kg for the PO treatment and 0.10 mg equiv/kg for the PP treatment.

Solvent (CH_3CN/H_2O) extracted $\geq$ 88% of the TRR present in leaf/stem samples. Extraction of ^{14}C present in seed was lower at 29–44% TRR.

In contrast to maize and soya bean, the metabolites identified following PP and PO applications were both from initial conjugation of acetochlor with glutathione, followed by subsequent loss of glutamate, then glycine. The resulting cysteinyl product underwent oxidation, deamination, dealkylation, and further conjugation with malonate or glucose to produce numerous metabolites. Only one compound exceeded 10% of TRR in PP leaves/stems: 1 hydroxyethyl-*sec*-methylsulfone glucosylsulfate conjugate (> 15%TRR, > 0.85 mg equiv/kg) and one following PO application: *sec*-sulfinyllactic acid (20% TRR, 12.5 mg equiv/kg). Levels of ^{14}C in cotton seed were too low to allow identification of the numerous metabolites present, none of which individually exceeded 5.3% TRR or 0.007 mg equiv/kg.

The major aniline metabolite classes in cotton leaves and stems are EMA and HEMA.

In summary, the metabolism of acetochlor by plants is well understood. Primary metabolic pathways of acetochlor in plants included:

1) hydrolytic/oxidative dechlorination to form the alcohol (and conjugates) and subsequent oxidation of the alcohol to the oxanilic acid

2) displacement of chlorine by glutathione (or homoglutathione) and further catabolism of the products to cysteine or lactic acid metabolites, and the S-oxides and conjugates, or to sulfonic acids and methyl sulfones

3) ethyl/methyl side-chain or ring hydroxylation; and 4) N dealkylation. Oxanilate, sulfonic acid, and sulfone metabolites were more prevalent in PP and PE matrices. Glutathione/homoglutathione conjugation followed by catabolism to cysteine and lactic acid metabolites, and their oxidized derivatives and conjugates, was the primary metabolic pathway for acetochlor after PO treatment.

Animal metabolism

The plant metabolism studies show that livestock are unlikely to be exposed to parent acetochlor. Rather, animals will be exposed to a range of metabolites, none of which is considered likely to be a major component of the residue. A range of livestock metabolism studies were made available to the meeting including the metabolism of acetochlor in lactating goats and laying hens as well as the metabolism of a range of plant metabolites administered individually or as a combination to lactating animals (goats and cows) or laying hens.

Acetochlor

Lactating goats were orally dosed twice daily for four consecutive days with [^{14}C-U-phenyl]-acetochlor at a dose equivalent to 8.1 to 11 ppm in the feed. The majority of the ^{14}C residues was recovered in the excreta (urine 58–71%AD, faeces 20–29% AD). For tissues, ^{14}C residues were highest in liver, (0.277–0.588 mg equiv/kg), followed by the kidney (0.247–0.479 mg equiv/kg), muscle TRR ranged from (0.012 to 0.024 mg equiv/kg) and fat (0.002–0.003 mg equiv/kg). TRR in milk reached 0.016 mg equiv/kg after two days of dosing. No intact acetochlor was detected in tissues or milk. The majority of the residues were not recovered by mild extraction techniques using organic solvents or water at ambient temperatures. Cell fractionation confirmed the ^{14}C in the solids had been incorporated into natural products, principally proteins.

Laying hens were orally dosed once a day for seven consecutive days with [^{14}C-U-phenyl]-acetochlor at a dose equivalent to 10 ppm in the feed. The majority of the ^{14}C residues was recovered in the excreta (68–72.3%AD). Radioactivity reached its highest level in eggs on Day 7 from the start of dosing, with average concentrations of 0.072 mg equiv/kg for yolk and

0.007 mg equiv/kg for egg whites. Mean levels of TRR were 0.337 mg equiv/kg in liver, 0.054 mg equiv/kg in breast muscle, 0.072 mg equiv/kg in leg muscle, 0.019 mg equiv/kg in peritoneal fat, and 0.041 mg equiv/kg in skin plus subcutaneous fat. No intact acetochlor was detected in tissues or eggs. The majority of the residue was associated with natural products; proteins, glycan, and lipid fractions.

Metabolism of selected acetochlor plant metabolites by livestock

1-hydroxyethyl-tert-sulfonic acid

Groups of lactating goats were dosed orally with ^{14}C-[1-hydroxyethyl-*tert*-sulfonic acid] for five or 28 consecutive days at a dose equivalent to 0.4 to 5.7 ppm in the feed. In an animal dosed at the equivalent of 5.7 ppm for five days, most of the ^{14}C was recovered in the excreta (faeces 68.7%AD, and urine 3.65% AD). TRR in tissues was very low, with 0.007 mg equiv/kg (1-hydroxyethyl-*tert*-sulfonic acid equivalents) in kidney, 0.003 mg equiv/kg in liver, and < 0.0003 mg equiv/kg in muscle and fat. For animals dosed for 28 days, ^{14}C residues in milk and tissues were < 0.001 mg equiv/kg.

Metabolism of four acetochlor plant metabolites co-administered to lactating goat

Two lactating goats were orally dosed with a mixture of metabolites (*tert*-sulfonic acid, *tert*-oxanilic acid, *tert*-hydroxyacetochlor and *tert*-sulfinylacetic acid ratio 25:19:13:1 based on weight) uniformly labelled in the phenyl ring at 13.7 mg acetochlor equivalents/goat twice daily for five days equivalent to 3.2 and 4.3 ppm (acetochlor equivalents) in the feed. Most of the ^{14}C was excreted (63–79% AD) with similar amounts recovered in urine (34–42% AD) and faeces (29–37% AD). Residues in milk reached a plateau by the fourth day of dosing. Levels of ^{14}C were highest in kidney (0.034 mg acetochlor equiv/kg) followed by liver (0.022 mg equiv/kg) with levels in muscle and fat below the limit of detection. Levels of ^{14}C in milk were 0.006 mg equiv/kg. The HPLC profile of urine and faeces was similar to the dosing solution suggesting limited transformation occurs. Due to the low levels of ^{14}C present in tissue, analysis was by high pressure acid hydrolysis to form anilines. The only aniline metabolite class observed was EMA, the same as the dosing compounds.

Laying hens were dosed with the same mixture of metabolites (but in ratios 1:1:1:1 based on weight) for five to six days at doses equivalent to 13 to 88 ppm (acetochlor equivalents) in the feed. Excreta and cage wash accounted for ≥ 96% AD. The highest levels of ^{14}C found in the tissues of the hens dosed with 88 ppm were in liver (0.150–0.266 mg equiv/kg) followed by kidneys (0.106–0.128 mg equiv/kg) with much lower levels found in fat (0.049–0.061 mg equiv/kg) and muscle (0.024–0.032 mg equiv/kg). Egg whites and yolks collected at sacrifice had ^{14}C residue levels that ranged from 0.029 to 0.052 mg equiv/kg and from 0.192 to 0.198 mg equiv/kg, respectively.

The main components of ^{14}C detected in tissues and eggs were unchanged *tert*-hydroxyacetochlor (2.9–26%TRR) and *tert*-oxanilic acid 1.2–20.4% TRR) as well as *sec*-oxanilic acid (6.3% TRR yolk).

Metabolism of 5-hydroxy-sec-oxanilic acid in lactating cow

A metabolite of acetochlor in maize, 5-hydroxy-*sec*-oxanilic acid, uniformly labelled in the phenyl ring was used to dose a lactating cow at a nominal rate of 25 ppm (30 ppm if expressed in acetochlor equivalents) in the diet for seven consecutive days. Most of the administered dose was recovered from the excreta (faeces 82.5% and urine 8.4%).

The residues in all tissues and milk were < 0.01 mg 5-hydroxy-sec-oxanilic acid equiv/kg, except in the kidney which had a residue of 0.015 mg equiv/kg. Extraction of ^{14}C residues in kidney with CH_3CN:H_2O released 70% of the TRR. In kidney unchanged 5-hydroxy-*sec*-oxanilic acid accounted for 46.7%TRR with the remainder composed of unextracted material (24.5%TRR) and uncharacterized aqueous soluble residues (15.0%TRR).

The metabolism of acetochlor and selected plant metabolites (*tert*-oxanilic acid, *tert*-sulfonic acid, *tert*-sulfinylacetic acid, *sec*-sulfonic acid, *tert*-norchloroacteochlor, 5-hydroxy-*sec*-

oxanilic acid?) in laboratory animals (rats) was summarized and evaluated by the WHO panel of the JMPR in the present meeting.

In summary, the metabolism of acetochlor in goats is similar to metabolism in laboratory animals. Studies on a limited number of plant metabolites suggests, at least for these plant metabolites, that following oral dosing they remain the major component of the ^{14}C residues.

Environmental fate

The Meeting received information on soil aerobic metabolism, aqueous photolysis and aqueous hydrolysis properties of [^{14}C]acetochlor. Studies were also received on the behaviour of [^{14}C]acetochlor in a rotational crop situation.

The degradation of acetochlor in soil maintained under aerobic conditions is rapid with four major degradates identified; *tert*-oxanilic acid, *tert*-hydroxy, *tert*-sulfonic acid and *tert*-sulfinylacetic acid. While parent acetochlor is degraded relatively quickly in soils the degradates formed are moderately persistent. In the laboratory studies, soil DT_{50} values for parent acetochlor ranged from 3.3 to 55 days while for field dissipation studies DT_{50} values ranged from 2.9 to 12.6 days.

Acetochlor was stable to hydrolysis in aqueous solutions at pH 5, 7 and 9 (25 °C) suggesting hydrolysis plays a negligible role in its degradation. Similarly negligible degradation was observed in an aqueous photolysis study suggesting photolysis is not a major route of degradation.

In a confined rotational crop study with lettuce, radish and wheat, a plot of sandy loam soil was treated with [^{14}C-U-phenyl]-acetochlor at the equivalent of 2.24 or 3.36 kg ai/ha and crops sown 30, 120 and 365 days after the soil application. Analysis of soil extracts prior to planting showed that acetochlor was degraded to an array of compounds, many of which were present at very low levels. In addition to acetochlor, four major soil degradates were identified as present in soil throughout the study: *tert*-oxanilic acid, *tert*-sulfonic acid, *tert*-sulfinylacetic acid and *tert*-hydroxyacetochlor.

Five compounds, which were consistently present in plant extracts from all three rotation intervals were: *sec*-oxanilic acid (0–11%TRR; < LOD–0.075 mg equiv/kg; not observed in grain), *tert*-oxanilic acid (0–25%TRR; < LOD–0.17 mg equiv/kg; up to 0.003 mg equiv/kg in grain), *sec*-sulfonic acid (0–27%TRR; < LOD–0.21 mg equiv/kg; not observed in grain), *tert*-sulfonic acid (0–16%TRR; < LOD–0.072 mg equiv/kg; up to 0.0045 mg equiv/kg in grain), and 1-hydroxyethyl *tert*-oxanilic acid (0–15%TRR; < LOD–0.43 mg equiv/kg; up to 0.0017 mg equiv/kg in grain). Unextracted radioactive residues in plant matrices were characterized by cell wall fractionation. The majority of this plant bound material was incorporated into hemicellulose and cellulose and in the case of wheat grain into starch.

The major aniline metabolite class in rotational crop types was EMA except in wheat grain for which it was HMEA and HEMA.

In a separate study [^{14}C-U-phenyl]-acetochlor was applied to the surface of a sandy loam soil at a nominal rate equivalent to 3.08 kg ai/ha. Mustard, turnip and millet were planted approximately 30, 120 and 365 days after [^{14}C]acetochlor application. Soya beans were planted approximately 30 and 365 days after treatment. The radioactive residues dissipated rapidly in soil with only 22% AR remaining 30 days after application. The main identified soil degradates were *tert*-oxanilic acid, *tert*-sulfinylacetic acid and *tert*-sulfonic acid.

Analyses of the plant extracts showed that extensive metabolism occurred in all crops. Acetochlor was not found in any of the RACs analysed, With the exception of Day 30 turnip roots, acetochlor was not found in RACs. The ^{14}C residue levels decreased in crops from the 30 day compared to the 365 days planting. The TRR was partially characterized and found to be comprised of up to nine different compounds, with not one above 0.01 mg equiv/kg in the edible portion of the root or cereal crop (turnip root and millet grain). The major metabolites identified

in crops planted 30 DAA were *tert*-oxanilic acid, *sec*-methyl sulfone, *sec*-hydroxyacetochlor, and *tert*-methyl sulfone.

The major aniline class of metabolites was EMA in which no hydroxylation of the alkyl groups of the phenyl ring had occurred with HEMA class metabolites was also significant.

In summary, acetochlor related residues in soil may contribute to residues observed in rotational and primary crops.

Methods of Analysis

The metabolism of acetochlor in crops results in a complex mixture of metabolites, most of which produce EMA or HEMA on base hydrolysis. Any non-metabolised parent acetochlor that might be present would be converted to EMA upon hydrolysis.

Consequently most of the methods developed to quantify acetochlor residues in animal and plant commodities involve hydrolytic conversion of metabolites to the EMA and HEMA chemophores. These analytes are quantified and expressed in acetochlor equivalents and then may be added to give total acetochlor residues. LOQs are typically 0.01 mg/kg each for EMA and HEMA.

The methods all involve initial extraction of samples with an organic/aqueous solvent mixture, typically CH_3CN/H_2O, followed by hydrolysis of residues with aqueous hydroxide solutions. The main differences between methods involve clean-up conditions and instrumentation for quantification, LC-MS/MS in more recent versions.

Representative compounds that generate EMA (*tert*-sulfonic acid) and HEMA (1-hydroxyethyl-*tert*-oxanilic acid) on base hydrolysis are used as reference materials for fortification and method validation.

The methods are suitable for analysis of acetochlor and related metabolites in plant and animal matrices.

Multi-residue methods are currently not validated for acetochlor and its metabolites.

Stability of pesticide residues in stored analytical samples

The Meeting received information on the stability of acetochlor and example metabolites hydrolysable to EMA (*tert*-sulfonic acid) and HEMA (1-hydroxyethyl-*tert*-oxanilic acid) and for some matrices HMEA (hydroxymethyl-*tert*-oxanilic acid) and OH-class (5-hydroxy-*sec*-oxanilic acid) in various matrices on freezer storage (–18 °C).

Residues of parent acetochlor were stable in potato tubers for at least 295 days and sugar beet tops for at least 294 days storage.

Residues of *tert*-sulfonic acid (EMA-class) and 1-hydroxyethyl-*tert*-oxanilic acid (HEMA class) measured using a common moiety method, were stable in alfalfa forage and clover hay for at least 330 days freezer storage, soya bean forage for 390 days, soya bean hay for 391 days, soya bean grain for 382 days, wheat forage for 741 days, wheat straw for 741 days, wheat grain for 734 days, sorghum silage for 739 days, sorghum grain for 732 days, potato tubers for 286 days, sugar beet tops for 286 days, maize grain for 356 days, maize forage for 357 days and maize stover for 351 days.

Residues of hydroxymethyl-*tert*-oxanilic acid (HMEA class) measured using a common moiety method, were stable in sorghum grain, silage for at least 732 days, soya bean grain, forage and hay for at least 380 days and wheat grain, forage and straw for at least 734 days.

Residues of 5-hydroxy-*sec*-oxanilic acid (OH-class) measured using a common moiety method, were stable in maize grain, forage and stover, lettuce, turnip roots and leaves and soya bean seed and hay for at least 730 days.

Residues of a mixture of *tert*-hydroxyacetochlor, *tert*-oxanilic acid, *tert*-sulfonic acid and *tert*-sulfinylacetic acid (EMA-class) in equal proportions measured using a common moiety method, were stable in eggs, milk, chicken liver, pig liver, beef liver, muscle, fat, and kidneys for at least 910 days.

The periods of demonstrated stability cover the frozen storage intervals used in the residue studies.

Definition of the residue

Following application of acetochlor to crops (maize, soya bean and cotton) a large number of metabolites were detected, but not unchanged acetochlor. There were notable differences in the pattern of metabolites observed following applications (PP and PE) to soil prior to crop emergence compared to applications made when the crop is present (PO).

The metabolites identified in forage, stover and hay following PO application to maize and soya beans are mainly sulfoxide-type metabolites. Significant metabolites (> 10%TRR) were *tert*-sulfinyllactic acid (13% TRR 0.43 mg equiv/kg maize forage; 11% TRR 0.72 mg equiv/kg maize stover), *tert*-cysteine (39% TRR soya hay), *tert*-malonylcysteine (18–23%TRR soya bean forage and hay), *tert*-sulfinyllactic acid and *tert*-malonylcysteine sulfoxide (combined 24–30%TRR soya bean forage and hay).

In contrast, in PE maize and PP soya beans the compounds detected resulted largely from the uptake of soil metabolites to give oxanilate-type metabolites. None of the individual components exceeded 10% of TRR in immature plant, forage, stover or hay. The major metabolite in PE maize was 5-hydroxy *sec*-oxanilic acid present at levels of 8.4% (0.099 mg equiv/kg) 6.2% (0.042 mg equiv/kg) and 4.3% (0.080 mg equiv/kg) TRR in immature plants, forage and stover respectively. The major metabolites in soya bean were *tert*-oxanilic acid (> 9.5% TRR) in forage and combined with *tert*-sulfonic acid present at levels of > 9.7% (0.34 mg equiv/kg) in hay.

Metabolism of acetochlor in cotton differed compared to maize and soya bean in that the metabolites identified following both PP and PO applications were from initial conjugation of acetochlor with glutathione, followed by subsequent loss of glutamate, then glycine. Only one compound exceeded 10% of TRR in PP leaves/stems: 1 hydroxyethyl-*sec*-methylsulfone glucosylsulfate conjugate (14.8%TRR) and one following PO application: *sec*-sulfinyllactic acid (20% TRR).

Negligible residues were detected in seeds and grain. Metabolites detected in maize were individually present at < 0.001 mg/kg. Identification of individual metabolites was not achieved in soya bean grain and cotton seed. In both cases extracts contained numerous metabolites, each present at < 0.03 mg equiv/kg (soya bean grain) or < 0.01 mg equiv/kg (cotton seed).

There is no obvious candidate compound for use as a residue definition for compliance, nor is there a small group of compounds that combined could usefully be used to monitor compliance. It is noted that the majority of the residue in crops can be classified according to the aniline class formed on base hydrolysis. As such a common moiety residue definition would allow residues to be monitored in all crops and derived commodities.

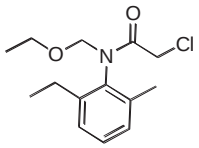
The major aniline metabolite class observed in maize (PE and PO) is EMA followed by OH, in soya bean commodities EMA and “other” for PE soya bean forage, HEMA and EMA for PE soya bean hay and EMA for PO soya bean hay and in cotton leaves and stems EMA and HEMA.

Validated analytical methods are available for the determination of compounds hydrolysable with base to EMA and HEMA in crop matrices.

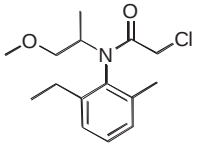
Residues derived from acetochlor may also occur in rotational (follow) crops. Five metabolites, which were consistently present in plant extracts from all rotation intervals studied were: *sec*-oxanilic acid, *tert*-oxanilic acid, *sec*-sulfonic acid, *tert*-sulfonic acid, and 1-

hydroxyethyl *tert*-oxanilic acid. The major aniline metabolite class in rotational crop types studied was EMA except wheat grain for which it was HMEA and HEMA.

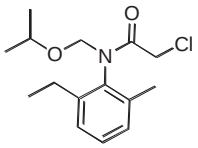
The Meeting also noted that acetochlor is a member of the chloroacetamide herbicides, a group that also includes metolachlor and propisochlor. The structures of these herbicides are similar to acetochlor and they are expected to share a number of common metabolites on cleavage of the ether side-chain.



Acetochlor

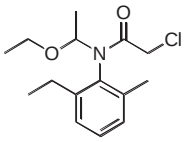


Metolachlor



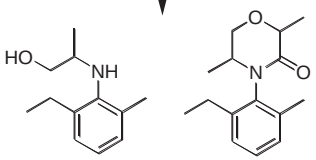
Propisochlor

A common moiety method of analysis has been developed for metolachlor that involves hydrolysis in 6N HCl. The resulting compounds differ from those produced by acetochlor and where required re-analysis of samples using the metolachlor method could be used to distinguish acetochlor from metolachlor residues.



metolachlor

6N HCl



CGA-37913 CGA-49751

No naturally occurring compounds hydrolysable to EMA and HEMA have been identified in crops likely to be treated or grown as follow crops.

The Meeting decided the residue definition for compliance with MRLs and estimation of dietary intake in plants should be the sum of compounds converted to EMA and HEMA, expressed in terms of acetochlor

Livestock may be exposed to acetochlor-derived residues present in feeds. Due to the extensive metabolism of acetochlor in plants, exposure to unchanged parent compound is not expected. Additionally the extensive metabolism combined with metabolite profiles that differ with application type (pre-emergence or post-emergence) and also crops complicate the choice of metabolite mixtures that might usefully typify the metabolite profiles present in feed, and therefore the nature of residues in livestock commodities. Available studies involving a limited number of plant metabolites suggest the major components of the residues in livestock commodities are the dosing compounds. Therefore, as for plant commodities, it is proposed the residue definition for compliance in animals be compounds converted to EMA and HEMA. Analytical methods are available for animal matrices.

Residues hydrolysable to EMA and HEMA and captured by the residue definition are comprised of a range of hydroxylated acetochlor-derived compounds as well as conjugates, all reactions that are expected to increase water solubility. Taken as a whole, the Meeting considered that residues encompassed by the residue definition for acetochlor are not fat soluble.

Based on the above the Meeting decided the residue definition for compliance with MRLs and estimation of dietary intake should be as follows:

Definition of the residue for compliance with MRL and estimation of dietary intake (for animal and plant commodities):

Sum of compounds converted to EMA and HEMA, expressed in terms of acetochlor.

The residue is not fat soluble.

Results of supervised residue trials on crops

Supervised residue trial data for were available for acetochlor on maize, sweet corn, cotton, sorghum, soya bean, sugar beet and peanuts. With the exception of one series of trials on maize where 5-hydroxy *sec*-oxanilic acid was analysed, residues were measured as compounds hydrolysable with base to EMA and HEMA. Residues listed below are for the sum of compounds hydrolysed to EMA and HEMA expressed in acetochlor equivalents.

The following indicates how the residues were combined when residues were reported as < LOQ for one or both of the components.

EMA	HEMA	Total residues (EMA+HEMA)
< 0.05	< 0.05	< 0.1
0.1	< 0.05	< 0.15
0.1	0.06	0.16

Sweet corn

The Meeting received supervised residue trial data for acetochlor on sweet corn from the USA. GAP in the USA is applications pre-plant or pre-emergence at up to 3.0 kg ai/ha with a PHI not required. The maximum rate per year is 3.4 kg ai/ha. In trials approximating critical GAP in the USA residues in sweet corn were (n=14): < 0.04 (14) mg/kg (kernels with husks removed).

The Meeting estimated a maximum residue level, STMR and HR or 0.04 (*), 0.04 and 0.04 mg/kg respectively for sweet corn (corn-on-the-cob).

Soya bean

In the USA acetochlor is approved for use on soya beans. GAP in the USA is applications pre-plant, pre-emergence or post-emergence but before the R2 growth stage (full flowering) at up to 1.7 kg ai/ha with a PHI not required. The maximum rate per year is 3.4 kg ai/ha. None of the trials matched critical GAP (2× 1.7 kg ai/ha post-emergence applications) and none were suitable for applying the proportionality approach.

Sugar beet

Supervised residue trial data for acetochlor on sugar beet were made available. GAP in the USA is applications pre-plant, pre-emergence or post-emergence (2 to 8 leaf stage) at up to 1.7 kg ai/ha with a PHI of 70 days. The maximum rate per year is 3.4 kg ai/ha. In trials approximating critical GAP in the USA residues in sugar beet roots were (n=15): < 0.008, < 0.009, 0.011, 0.011, 0.015, 0.016, 0.017, 0.018, 0.019, 0.021, 0.021, 0.025, 0.045, 0.051 and 0.086 mg/kg.

The Meeting estimated a maximum residue level and STMR of 0.15 and 0.018 mg/kg respectively for sugar beet roots.

Maize

The Meeting received supervised residue trial data for acetochlor on maize. GAP in the USA is applications pre-plant, pre-emergence or post-emergence (28 cm height) at up to 3.0 kg ai/ha with a PHI not specified for the EC formulation and pre-plant, pre-emergence or post-emergence (76 cm height) at up to 2.5 kg ai/ha for the CS formulation. The maximum rate per year is 3.4 kg ai/ha. The

Meeting considered trials with the CS formulation where the last application can be made closer to harvest but at a lower rate compared to the EC trials where applications are made earlier but at a higher rate to give rise to higher residues and represent critical GAP. Critical GAP was considered to be pre-emergent application at 0.9 kg ai/ha followed by post-emergence application at 2.5 kg ai/ha. In trials with the CS formulation, maize was treated with a single post-emergence application rate at approximately 3.2 kg ai/ha (1.28× the maximum label rate). The Meeting agreed to utilise the proportionality approach to estimate residues matching *c*GAP noting that residues from pre-emergence applications do not contribute to final residues and that a single post-emergence application at 2.5 kg ai/ha should be targeted for use in estimating maximum residue levels. The following scaled residues (n=21) matched *c*GAP:

Trial application rate (kg ai/ha)	Scaling factor = 2.5/trial application rate	Trial residue (mg/kg)	Scaled residue =scaling factor × trial residue (mg/kg) [a]
3.31	0.755	< 0.002	< 0.002
3.19	0.784	< 0.002	< 0.002
3.19	0.784	< 0.002	< 0.002
3.22	0.776	< 0.002	< 0.002
3.15	0.794	0.003	< 0.002
3.19	0.784	0.003	< 0.002
3.18	0.786	0.003	< 0.002
3.16	0.791	0.003	< 0.002
3.26	0.767	0.003	< 0.002
3.17	0.789	0.003	< 0.002
3.09	0.809	0.003	< 0.002
3.18	0.786	0.004	< 0.003
3.19	0.784	0.004	< 0.003
3.14	0.796	0.006	0.005
3.33	0.751	0.006	0.005
3.33	0.751	0.008	0.006
3.13	0.799	0.008	0.006
3.17	0.789	0.009	0.007
3.27	0.765	0.009	0.007
3.24	0.772	0.009	0.007
3.32	0.753	0.019	0.014

[a] LOQ for combined residues is 0.002 mg/kg.

The Meeting estimated a maximum residue level, STMR and HR of 0.02 and 0.002 mg/kg respectively for maize.

Sorghum

Acetochlor is approved in the USA for use on sorghum. GAP in the USA is applications pre-plant, pre-emergence or post-emergence (28 cm height) at up to 2.5 kg ai/ha with a PHI not specified. The maximum rate per year is 3.4 kg ai/ha. No trials matched cGAP (2× 1.7 kg ai/ha POST) and the data were not suitable for use of the proportionality approach.

Cotton

The Meeting received supervised residue trial data for acetochlor on cotton. GAP in the USA is applications pre-plant, pre-emergence or post-emergence (before 1st bloom) at up to 1.7 kg ai/ha with a PHI not specified. The maximum rate per year is 3.4 kg ai/ha. Two-post-emergence applications made closest to the latest growth stage permitted lead to highest residues. No trials utilising post-emergence application matched critical GAP in the USA.

Peanut

Supervised residue trial data for acetochlor on peanuts were available. GAP in the USA is applications pre-plant, pre-emergence or post-emergence (before flowering) at up to 1.7 kg ai/ha with a PHI not specified. The maximum rate per year is 3.4 kg ai/ha. In trials conducted in the USA plots

were treated pre-plant and post-emergence (1.7 PP + 1.7 PO kg ai/ha), pre-emergent and post-emergent (1.7 PE + 1.7 POST kg ai/ha) or post-emergent (3.4 PO kg ai/ha). No trials matched cGAP (2× 1.7 PO kg ai/ha) and the data were not suitable for use of the proportionality approach.

Animal feeds

Peanut fodder

GAP in the USA is applications pre-plant, pre-emergence or post-emergence (before flowering) at up to 1.7 kg ai/ha with a PHI not specified. The maximum rate per year is 3.4 kg ai/ha. GAP in the USA is to allow a minimum of 90 days between last application and grazing or harvest and feeding of peanut hay to livestock. No trials matched *c*GAP (2× 1.7 POST kg ai/ha).

Soya bean forage

In the USA there are restraints on the grazing and feeding of post-emergence treated soya bean forage to livestock.

Soya bean fodder

In the USA acetochlor is approved for use on soya beans. GAP in the USA is applications pre-plant, pre-emergence or post-emergence but before the R2 growth stage (full flowering) at up to 1.7 kg ai/ha with a PHI not required. None of the trials matched *c*GAP and none were suitable for use of the proportionality approach.

Corn and maize forage

GAP in the USA is applications pre-plant, pre-emergence or post-emergence (28 cm height) at up to 3.0 kg ai/ha with a PHI not specified for the EC formulation and pre-plant, pre-emergence or post-emergence (76 cm height) at up to 2.5 kg ai/ha for the CS formulation. The maximum rate per year is 3.4 kg ai/ha. GAP for maize (field corn) in the USA requires that treated areas are not grazed and treated forage not fed to livestock for 40 days following application. No trials matched *c*GAP.

GAP in the USA for sweet corn is applications of an EC formulation pre-plant or pre-emergence at up to 3.0 kg ai/ha with a PHI not required. The maximum rate per year is 3.4 kg ai/ha. Residues in sweet corn forage from field trials performed in the USA approximating cGAP in the USA were (n=13): < 0.04, < 0.06, < 0.08, 0.08, < 0.09, 0.1, < 0.12, 0.14, 0.22, 0.24, 0.29, 0.44 and 0.97 mg/kg (on an as received basis). Sweet corn forage contains approximately 48% DM.

The Meeting estimated median and highest residues of 0.25 and 2.02 mg/kg for sweet corn forage (on a dry matter basis).

Corn and maize fodder

For maize (field corn), GAP in the USA is applications pre-plant, pre-emergence or post-emergence (28 cm height) at up to 3.0 kg ai/ha with a PHI not specified for the EC formulation and pre-plant, pre-emergence or post-emergence (76 cm height) at up to 2.5 kg ai/ha for the CS formulation. The maximum rate per year is 3.36 kg ai/ha. The Meeting considered trials with the CS formulation where the last application can be made closer to harvest but at a lower rate compared to the EC trials where applications are made earlier but at a higher rate to give rise to higher residues and represent critical GAP. Critical GAP was considered to be pre-emergent application at 0.9 kg ai/ha followed by post-emergence application at 2.5 kg ai/ha. No trials matched cGAP.

Residues in sweet corn fodder from field trials performed in the USA approximating cGAP in the USA were (n=14): < 0.04, < 0.04, < 0.04, < 0.04, 0.04, < 0.05, < 0.06, 0.08, 0.09, 0.10, 0.13, 0.13, 0.42 and 0.91 mg/kg (on an as received basis). Sweet corn fodder contains approximately 83% DM.

The Meeting estimated a maximum residue level and median and highest residues of 1.5, 0.07 and 0.91 mg/kg for sweet corn fodder (on as received matter basis) or 1.5, 0.084 and 1.096 mg/kg (dry matter basis) assuming 83% dry matter (DM).

Sorghum forage

GAP in the USA requires that treated areas are not grazed and treated forage not fed to livestock for 60 days following application. In the USA applications are made pre-plant, pre-emergence or post-emergence (28 cm height) at up to 2.5 kg ai/ha. No trials matched *c*GAP.

Sorghum fodder (stover)

GAP in the USA is applications pre-plant, pre-emergence or post-emergence (28 cm height) at up to 2.5 kg ai/ha with a PHI not specified. No trials matched cGAP.

Cotton gin by-products

No trials on cotton matched GAP in the USA.

Sugar beet tops

GAP in the USA is applications pre-plant, pre-emergence or post-emergence (2 to 8 leaf stage) at up to 1.7 kg ai/ha with a 70 day interval between the last application and grazing or harvest of sugar beet tops. The maximum seasonal application is 3.4 kg ai/ha/year. Residues in sugar beet tops from field trials performed in the USA approximating cGAP in the USA were (n=15): 0.009, 0.014, 0.019, 0.028, 0.028, 0.030, 0.035, 0.041, 0.043, 0.050, 0.051, 0.056, 0.063, 0.147 and 0.554 mg/kg (on an as received basis). Sugar beet tops contain approximately 23% DM.

The Meeting estimated a maximum residue level and median residues of 3 and 0.178 mg/kg for sugar beet tops (on dry matter basis).

Rotational crop residues

Soil residues of acetochlor related compounds are moderately persistent. The use-pattern (USA GAP) specifies plant-back intervals for certain follow-crops as well as crops that may be rotated following application:

- Non-grass animal feeds such as alfalfa, clover, kudzu, lespedeza, lupin, sainfoin, trefoil, velvet bean, and Vetch spp. may be planted 9 months (270 days) after application.
- Wheat may be planted 4 months (120 days) after application.
- Rotate the next season to the following crops—soya beans, corn (all types), milo (sorghum), cotton, sugar beets, sunflowers, potatoes, barley, buckwheat, millet (pearl and proso), oats, rye, teosinte, triticale, wild rice, dried shelled bean group Lupinus spp. (including grain lupin, sweet lupin and white lupin), Phaseolus spp. (includes field beans, kidney beans, lima beans (dry), navy beans, pinto bean and tepary beans), bean Vigna spp. (includes adzuki beans, black-eyed peas, catjang, cowpeas, Crowder peas, moth beans, mung beans, rice beans, southern peas and urd beans), broad beans (dry), chickpeas, guar, lab lab beans, lentils, peas (Pisum spp., includes field peas) and pigeon peas.

Field crop rotation residue trials are available for representative crops that may be rotated. In these trials follow crops were planted after harvesting of maize that had been treated with acetochlor as a pre-plant, pre-emergence or seed treatment at 3.4 kg ai/ha equivalent to the maximal seasonal rate in the USA. The Meeting considered these trials reflect likely residues in crops grown in rotation following application at the maximum seasonal rate (3.4 kg ai/ha/year).

Legume animal feed as a follow crop

Residues in follow crops of alfalfa and clover as representative legume feed commodities were made available to the Meeting. Alfalfa was sown 274–355 days after pre-emergent application to maize. Clover was sown 274–355 days after pre-emergent application to maize. Residues are listed below:

Alfalfa forage (n=17): < 0.04, 0.04, 0.06, 0.07, 0.08, 0.08, 0.08, 0.09, 0.11, 0.14, 0.14, 0.16, 0.20, 0.29, 0.35, 0.47 and 0.54 mg/kg (fresh weight basis).

Clover forage (n=18): < 0.03, < 0.04, < 0.04, 0.04, < 0.05, < 0.05, 0.05, 0.06, 0.10, 0.10, 0.10, 0.10, 0.11, 0.16, 0.17, 0.17, 0.35 and 0.57 mg/kg (fresh weight basis).

The Meeting estimated median and highest residues in legume forage of 0.10 and 0.57 mg/kg (as received basis) or 0.333 and 1.9 mg/kg when expressed on a dry matter basis (assuming 35%DM for alfalfa and 30%DM for clover).

Alfalfa hay (n=16): 0.11, 0.14, 0.15, 0.16, 0.18, 0.19, 0.20, 0.24, 0.28, 0.29, 0.33, 0.34, 0.73, 0.82, 0.97, and 1.87 mg/kg (fresh weight basis).

Clover hay (n=17): < 0.02, < 0.02, < 0.04, 0.08, 0.08, 0.08, 0.12, 0.13, 0.13, 0.15, 0.24, 0.30, 0.41, 0.44, 0.48, 0.76 and 1.24 mg/kg (fresh weight basis).

The median residues in the clover and alfalfa hay datasets differed by less than a factor of five and the Meeting decided to recommend a group maximum residue level for legume animal feeds. In deciding which data set to use for the recommendation, as a Mann Whitney U-test indicated that the residue populations were not different it was decided to combine the data sets.

Residues in alfalfa and clover fodder (hay) of follow crops ranged from < 0.02 to 1.87 mg/kg (as received basis). Alfalfa and clover hay contains approximately 89%DM.

The Meeting estimated maximum residue levels, median and highest residues of [2, 0.20 and 1.87 mg/kg fresh weight basis] 3, 0.225, and 2.101 mg/kg (dry matter basis) for legume animal feeds.

Wheat (forage, straw, grain)

Wheat may be planted as a follow crop four months after application. Residues (as received basis) in follow wheat crops planted 90–176 days after pre-emergent application to maize were:

- Forage (n=18): < 0.02, < 0.02, < 0.02, < 0.03, < 0.03, 0.03, 0.04, < 0.05, 0.06, 0.06, 0.11, 0.13, 0.14, 0.18, 0.19, 0.27, 0.41 and 0.47 mg/kg (fresh weight basis).

The Meeting estimated median and highest residues in wheat forage of 0.06 and 0.47 mg/kg (fresh weight basis) or 0.24 and 1.88 mg/kg when expressed on a dry matter basis (assuming 25%DM).

- Straw (n=18): < 0.02, < 0.02, < 0.02, < 0.02, < 0.02, < 0.02, < 0.02, 0.03, 0.03, 0.03, 0.04, 0.07, 0.07, 0.07, 0.07, 0.08, 0.09 and 0.10 mg/kg.

The Meeting estimated maximum residue levels, median and highest residues of 0.2, 0.034, and 0.114 mg/kg for wheat straw and fodder (dry matter basis) assuming wheat straw contains 88% dry matter.

- Grain (n=18): < 0.02 (18) mg/kg.

The Meeting estimated maximum residue levels and median residues of 0.02 (*) and 0.02 mg/kg for wheat grain.

Other cereals (forage, hay, straw, grain)

In the USA, a number of cereal and grass-like crops (other than wheat, maize, sorghum) may be planted approximately one year after last application. Residues (on an as received basis) in follow oat crops planted the next season after pre-emergent application to maize:

- Forage (n=18): < 0.035 (7), < 0.038, < 0.038, < 0.042, 0.048, 0.056, 0.057, 0.063, 0.066, 0.085 and 0.121 mg/kg (fresh weight basis).

The Meeting estimated median and highest residues in oat forage of 0.04 and 0.121 mg/kg (as received basis) or 0.13 and 0.40 mg/kg when expressed on a dry matter basis (assuming 30%DM).

- Hay (n=16): < 0.035 (6), < 0.036, < 0.036, < 0.042, 0.042, 0.060, 0.068, 0.074, 0.091, < 0.098 and 0.156 mg/kg (fresh weight basis).

The Meeting estimated median and highest residues of 0.039, and 0.173 mg/kg for oat hay (dry matter basis).

- Straw (n=17): < 0.035 (11), < 0.036, < 0.036, 0.044, 0.044, 0.070, and 0.254 mg/kg (fresh weight basis).

The Meeting estimated maximum residue levels, median and highest residues of 0.3, 0.039, and 0.282 mg/kg for oat straw (dry matter basis) assuming straw contains 90% dry matter.

- Grain (n=17): < 0.035 (16) and < 0.036 mg/kg.

The Meeting estimated a maximum residue level and STMR of 0.04 (*) and 0.035 mg/kg for oat grain.

The Meeting agreed to extrapolate the results for oats to other cereals that are permitted in the USA as follow crops and not treated directly—barley, buckwheat, millet (pearl and proso), rye, teosinte, triticale and wild rice commodities. The Meeting decided not to extrapolate the results to follow rice crops as the cultivation practices for rice differ from those of other cereal crops and this may impact on residues.

Sunflowers

Sunflowers are a permitted follow crop when planted the following year. Residues in seed of follow sunflower crops planted 350–384 days after pre-emergent application to maize were all < 0.04 (8) mg/kg. The Meeting estimated a maximum residue level and STMR of 0.04 (*) and 0.04 mg/kg for sunflower seed.

Potato

Potatoes are a permitted follow crop when planted the following year. Residues in tubers of follow potato crops (planted 291–380 days after pre-emergent application to maize) were all < 0.04 (10) mg/kg. The Meeting estimated a maximum residue level, STMR and HR of 0.04 (*), 0.04, and 0.04 mg/kg for potatoes.

Beans (dry), Peas (dry)

A number of legume grains are permitted follow crops to be planted the next season (about one year after the last application). Residues in grain of follow bean and pea crops were all < 0.02 mg/kg, nine bean trials and five pea trials. The Meeting estimated maximum residue levels of 0.02 (*) for beans and peas (dry) and STMRs or 0.02 mg/kg. The two maximum residue levels would cover residues in follow *Phaseolus* spp as well as *Vigna* spp and *Pisum* spp.

Rotational crop trials were available for follow soya beans. The observed residues are higher than reported for beans and peas (dry) and residues in follow soya beans could be used as a representative crop for the remaining pulses permitted to be rotated in the USA—*Lupinus* spp., broad beans, chickpeas, Hyacinth beans (lab lab beans), lentils, and pigeon peas.

Residues in seed of follow soya beans were (n=16): < 0.02 (8), 0.02, < 0.03, 0.03, 0.03, 0.04, 0.04, 0.06 and 0.10 mg/kg.

The Meeting agreed to extrapolate to residues in seed of follow soya bean to *Lupinus* spp., broad beans (dry), chickpeas, Hyacinth beans, dry (lab lab beans), lentils, and pigeon peas and estimated maximum residue limits of 0.15 and STMRs of 0.02 mg/kg for these seeds.

Fate of residues during processing

The Meeting received information on the fate of incurred residues of acetochlor during the processing of soya beans, sugar beets, sorghum, cotton, peanuts and sunflower seeds. A study of the nature of the residue of acetochlor under simulated processing conditions (pasteurization, baking/brewing/boiling, sterilization) showed acetochlor, if present, is stable.

Summaries of relevant acetochlor processing factors are provided below.

	Processed Fraction	Processing Factor	Best estimate PF	RAC STMR or median	STMR × PF = STMR-P	RAC HR or highest	HR × PF = HR-P
Sugar beet	Dried pulp	2.3, 0.9	1.6	0.018	0.029	0.086	0.138
	Molasses	4.2, 1.1	2.65		0.048		0.228
	Refined sugar	0.5, < 0.25	0.375		0.0068		0.032
Sunflower	Meal	1.4	1.4	0.04	0.056	0.04	0.056
	Oil	0.22	0.22		0.0088		0.0088

PFs are based on combined EMA and HEMA aniline class metabolites: PFs calculated as EMA + HEMA, expressed as acetochlor in processed commodity divided by EMA + HEMA in the RAC

The Meeting recommended a maximum residue level of 0.3 mg/kg for sugar beet molasses and a median residue of 0.048 mg/kg. For sugar beet pulp (dry) the Meeting recommended a maximum residue level of 0.3 mg/kg and a median residue of 0.029 mg/kg.

Residues in animal commodities

Farm animal feeding studies

The Meeting received information on the residue levels in tissues and milk of dairy cows dosed with a mixture of four EMA class acetochlor plant metabolites (*tert*-hydroxy and the sodium salts of *tert*-sulfonic acid, *tert*-oxanilic acid and *tert*-sulfinylacetic acid and present in equal proportions) at the equivalent of 5, 15 and 50 ppm acetochlor equivalents in the feed for 28 consecutive days. Based on HPLC retention times for extracts in plant metabolism studies, it is concluded that the properties of the dosing compounds encompass the range of polarities of the majority of compounds observed in the plant metabolism studies (log K_{ow} of dosing compounds ranged from –3.2 to 2.2). The studies are considered to cover the likely transfer of acetochlor-related residues, including those from different aniline metabolite classes, from feed to livestock.

Residues in milk were < 0.02 mg/kg (acetochlor equivalents) for the 50 ppm dose group for all sample intervals.

In kidney mean residues were < 0.02, 0.03, and 0.07 mg/kg (acetochlor equivalents) for the 5, 15, and 50 ppm dose groups respectively. Mean residues liver residues were < 0.02 and 0.02 mg/kg for the 15 and 50 ppm dose groups while mean residues in fat and muscle were < 0.02 mg/kg for all samples in the 50 ppm dose group. As no residues were observed at the highest dose level samples muscle and fat from other dose groups were not analysed.

Laying hens dosed at the equivalent of 5, 15 and 50 ppm acetochlor with a mixture of *tert*-hydroxy and the sodium salts of *tert*-sulfonic acid, *tert*-oxanilic acid and *tert*-sulfinylacetic acid for 28 days. No residues above the LOQ were detected in any tissues or eggs, LOQ 0.05 mg/kg for kidney and LOQ 0.02 mg/kg for other tissues and eggs.

Estimation of livestock dietary burdens

Dietary burden calculations for beef cattle, dairy cattle and poultry are provided below. The dietary burdens were estimated using the OECD diets listed in Appendix IX of the 2009 edition of the FAO Manual.

Potential cattle feed items include legume fodder, cereal forage and fodder, sugar beet tops and various grains.

Summary of livestock dietary burden (ppm acetochlor equivalents of dry matter diet)

	US-Canada		EU		Australia		Japan	
	max	mean	Max	mean	max	Mean	max	Mean
Beef cattle	0.4	0.1	2.0	0.3	2.1	0.3	0.2	0.03
Dairy cattle	1.4	0.2	1.6	0.2	2.1 [a, b]	0.3 [c, d]	0.6	0.09
Broilers	0.03	0.02	0.05	0.04	0.02	0.02	0.1	0.03
Layers	0.03	0.02	0.54 [e]	0.10 [f]	0.02	0.02	0.01	0.01

[a] Highest maximum beef or dairy cattle dietary burden suitable for MRL estimates for mammalian meat

[b] Highest maximum dairy cattle dietary burden suitable for MRL estimates for mammalian milk

[c] Highest mean beef or dairy cattle dietary burden suitable for STMR estimates for mammalian meat

[d] Highest mean dairy cattle dietary burden suitable for STMR estimates for milk

[e] Highest maximum poultry dietary burden suitable for MRL estimates for poultry meat and eggs

[f] Highest mean poultry dietary burden suitable for STMR estimates for poultry meat and eggs

Animal commodity maximum residue levels

The calculations used to estimate highest total residues for use in estimating maximum residue levels, STMR and HR values are shown below.

	Feed level	Residues	Feed level	Residues (mg/kg) in			
	(ppm) for milk residues	(mg/kg) in milk	(ppm) for tissue residues	Muscle	Liver	Kidney	Fat
MRL beef or dairy cattle							
Feeding study [a]	5	< 0.02	15	< 0.02	< 0.02	0.04	< 0.02
Dietary burden and high residue	2.1	< 0.008	2.1	< 0.003	< 0.003	0.0056	< 0.003
STMR beef or dairy cattle							
Feeding study [b]	5	< 0.02	15	< 0.02	< 0.02	0.03	< 0.02
Dietary burden and median residue estimate	0.3	< 0.0012	0.3	< 0.0004	< 0.0004	0.0006	< 0.0004

[a] Highest residues for tissues and mean residues for milk

[b] Mean residues for tissues and mean residues for milk

The Meeting estimated the following maximum residue levels: milk 0.02* mg/kg; meat (mammalian except marine mammals) 0.02* mg/kg, mammalian fat (except milk fat) 0.02* mg/kg andedible offal 0.02* mg/kg.

For poultry no residues were observed in eggs and tissues on dosing laying hens at up to 50 ppm in the diet for 28 days. The Meeting estimated the following maximum residue levels for poultry commodities: poultry meat 0.02* mg/kg; poultry edible offal 0.02* mg/kg and eggs 0.02* mg/kg. The Meeting estimated the following STMR and HR values: poultry meat 0 mg/kg; poultry fat 0 mg/kg; poultry edible offal 0 mg/kg and eggs 0 mg/kg.

RECOMMENDATIONS FURTHER WORK OR INFORMATION

On the basis of the data obtained from supervised residue trials the Meeting concluded that the residue levels listed in Annex 1 are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of the residue for compliance with MRL and estimation of dietary intake (for animal and plant commodities):

Sum of compounds hydrolysable with base to 2-ethyl-6-methylaniline (EMA) and 2-(1-hydroxyethyl)-6-methylaniline (HEMA), expressed in terms of acetochlor.

The residue is not fat soluble.

DIETARY RISK ASSESSMENT

Long-term intake

The 2015 JMPR established an Acceptable Daily Intake (ADI) of 0–0.01 mg/kg bw for acetochlor.

The evaluation of acetochlor resulted in recommendations for MRLs and STMR values for raw and processed commodities. Where data on consumption were available for the listed food commodities, dietary intakes were calculated for the 17 GEMS/Food Consumption Cluster Diets. The results are shown in Annex 3 to the 2015 Report.

The IEDIs in the seventeen Cluster Diets, based on the estimated STMRs were 0–4% of the maximum ADI (0.01 mg/kg bw). The Meeting concluded that the long-term intake of residues of acetochlor from uses that have been considered by the JMPR is unlikely to present a public health concern.

Short-term intake

The 2015 JMPR established an Acute Reference Dose (ARfD) of 1 mg/kg bw for acetochlor. The IESTI of acetochlor for the commodities for which STMR, HR and maximum residue levels were estimated by the current Meeting are shown in Annex 4 to the 2015 Report. The IESTI represented 0–0% of the ARfD.

The Meeting concluded that the short-term intake of residues of acetochlor resulting from uses that have been considered by the JMPR is unlikely to present a public health concern.

BIFENTHRIN (178)

The first draft was prepared by Professor Mi-Gyung Lee, Andong National University, Republic of Korea

EXPLANATION

Bifenthrin is a pyrethroid insecticide and miticide. It was first evaluated for residues and toxicology by the JMPR in 1992 and re-evaluated in 2009 (T) and 2010 (R). The 46th Session of the CCPR (2014) listed bifenthrin for the evaluation of additional MRLs.

Currently, an ADI of 0–0.01 mg/kg bw and an ARfD of 0.01 mg/kg bw are established. The residue definition for compliance with the MRL and for estimation of dietary intake (for animal and plant commodities) is bifenthrin (sum of isomers). The residue is fat-soluble.

The Meeting received information on supervised residue trials for blueberries, grapes, head lettuce, spinach, celery, peas, snap beans and lima beans.

Analytical methods

Grape, Head lettuce (IR-4 trial), Spinach (manufacturer), Celery, Peas, Snap bean, Lima bean

Analytical methods used for analysis of bifenthrin residues involved an extraction with acetone, an aqueous/acetone partition, a clean-up using florisil and analysis by GC-ECD (Ref. method, Ridler 1989, Report P-2132M; evaluated acceptable for recoveries of the residue in maize samples by 2010 JMPR). For spinach, 4'-hydroxy bifenthrin was analysed as well as bifenthrin using the analytical method. For lima bean (seed), methylene chloride was used instead of hexane in the partition step. The limit of quantification (LOQ) of bifenthrin was 0.05 mg/kg in all matrices. The recoveries and CV (%) values at various fortification levels were in an acceptable range of 70–120% and 20%, respectively, with exceptions of head lettuce 23% CV and celery 25% CV at a fortification level of 0.05 mg/kg. The LOQ of 4'-hydroxy bifenthrin in spinach was 0.05 mg/kg and recoveries at fortification levels of 0.05–2.0 mg/kg were in a range of 79–100% (in total, n=9).

Blueberry, Spinach (IR-4 trial)

Bifenthrin residues were extracted with hexane in an automated extraction unit. The extract was cleaned up on a florisil column and subjected to GC-ECD for analysis. For spinach, the hexane extract was subjected to GC-ECD, omitting the florisil clean-up step. The LOQ was 0.05 mg/kg in the matrices. Recoveries at fortification levels of 0.05, 0.5 and 2.0 or 5.0 mg/kg were in a range of 80–100% (CV, < 5.3%).

Head lettuce (manufacturer)

Bifenthrin residues in head lettuce were extracted with acetone after adding sodium chloride. The extract was partitioned with hexane and cleaned up using an aminopropyl SPE cartridge. GC-MSD was used for determination of the analyte and the LOQ was 0.05 mg/kg. At four fortification levels in the range of 0.05–1.0 mg/kg, recoveries of bifenthrin were 90–120% (in total, n=6; CV, 16%).

A summary of recovery data with the methods used for residue trial samples in this submission are shown in Table 1.

Table 1 Analytical recoveries of bifenthrin in some plant commodities

[a] Including concurrent recoveries

[b] Concurrent recoveries

[c] Recoveries underlined are for 4'-hydroxy bifenthrin. The value in parenthesis is from a repeat analysis.

[d] In the study report, P-2715 was mentioned as a reference method, however, the used method was very similar to the P-2132M.

Stability of residues in stored analytical samples

The 2010 JMPR evaluated that bifenthrin residues were stable for the period of at least 18 months in oranges, 49 months in apples, 7 months in strawberries, 24 months in bananas, 36 months in lettuce, potatoes and pecans, 15 months in peas, dry, 34 months in maize grain and up to 24 months in cotton seed.

In this Meeting, additional information was available that showed the residues were stable for at least 176 days in grapes, 300 days in head lettuce, 561 days in celery, 210 days in peas with pods, 142 days in snap beans and up to 196 days in lima beans. In these storage stability tests, zero-day residues were not determined, except for lima beans.

Based on the available information, it is considered that residues in all samples relevant to this submission were stable under frozen conditions until extraction and analysis. Table 2 includes results of storage stability tests and actual storage days for field trial samples.

Table 2 Storage stability of bifenthrin in some plant matrices

Matrix	Fortification level, mg/kg	Tested storage days	Residue in fortified samples, mg/kg	Procedural recoveries, %	Actual max. storage days
Blueberry	–	–	–	–	81
Grape	0.10	176	0.080	110	172
	10	176	8.7	121% at 12 ppm	
Head lettuce	0.05	300	0.062	152	280 days or 11 months
	0.1	300	0.11	104	
	0.5	300	0.55	97% at ca. 1 ppm	
Spinach	–	–	–	–	57 days or 4 months
Celery	0.5	561	0.38, 0.38, 0.30 (60%)	69, 76, 109% at 0.05 ppm	229 or 349
Peas with pods	0.05	192	0.030 (58%), 0.049	88	178
	0.5	192	0.34 (68%), 0.39	106	
	0.16 [a]	210	0.17	[b]	
	0.17 [a]	210	0.15	[b]	
Snap bean	0.5	142	0.38, 0.47, 0.36	98% at 0.6 ppm	135 or 150
Lima bean, seed	0.5	1	0.52, 0.53, 0.54	81% at 0.05 ppm	61
		35	0.54, 0.54	81% at 0.05 ppm	
		68	0.49, 0.50, 0.50	87% at 0.05 ppm	
		98	0.42, 0.46, 0.46	61% at 0.05 ppm	

Matrix	Fortification level, mg/kg	Tested storage days	Residue in fortified samples, mg/kg	Procedural recoveries, %	Actual max. storage days
		117	0.48, 0.48, 0.48	195 at 0.05 ppm	
		196	0.40, 0.43, 0.46	120% at 0.05 ppm	

[a] Pea samples from a field residue trial were analysed again seven months after the initial analysis. The initial residue concentrations were 0.16 mg/kg and 0.17 mg/kg, with overall concurrent recoveries of 79–91% at fortification levels of 0.05, 0.5 and 2.0 mg/kg.

[b] Mean procedural recoveries were 88% and 106% at fortification levels of 0.05 mg/kg and 0.5 mg/kg, respectively. At the same date, fortified sample at 192 days and field trial sample at 210 days were analysed.

USE PATTERNS

Bifenthrin is registered in many countries for control of insect pests on fruit, vegetables, cereals, oilseeds and forage crops. This Meeting received information on registered uses from the USA regarding the submitted residue trial, which is summarized in the Table 3.

Table 3 Registered uses of bifenthrin in the USA on crops relevant to this submission

Crop	Form.	Method	Application			
			Rate, kg ai/ha	Max. no.	Interval days	PHI, days
Bushberries (blueberry)	WSB, 2EC	Foliar, G or A [a]	0.11 (0.56 kg ai/ha/season)		7	1
Grapes	WSB, 2EC	Foliar, G or A	0.11 (0.11 kg ai/ha/season)			30
Leafy petiole vegetables (celery)	WSB, 2EC	Foliar, G or A	0.11 (0.56 kg ai/ha/season)		7	7
Lettuce, head	WSB, 2EC	Foliar, G or A	0.11 (0.56 kg ai/ha/season)		7	7
Spinach	WSB, 2EC	Soil at planting; foliar, G or A	0.11 (0.45 kg ai/ha/season)	4	7	40
Succulent peas and beans (pea, snap bean, lima bean)	WSB, 2EC	At planting time [b]; foliar use, G or A [b]	0.11 (0.22 kg ai/ha/season)			3

Succulent peas and beans include as follows: pea (Pisum spp.: dwarf pea, English pea, garden pea, etc.), bean (Phaseolus spp.: broadbean, succulent, lima bean, green, snap bean, etc.), bean (Vigna spp.: asparagus bean, cowpea, moth bean, etc.), jackbean, soybean, immature seed and sword bean.

Bushberries include blueberry, high-bush and low-bush, currant, elderberry, gooseberry and huckleberry.

Leafy petiole vegetables include celery, cardoon, Chinese celery, celtuce, Florence fennel, rhubarb, Swiss chard.

The formulation, WSB (water soluble bags; ai, 10%) is a type of wettable powder. The formulation 2EC is a type of emulsifiable concentrate (ai, 25.1%).

[b] Apply in-furrow with the seed or transplant

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

Supervised residue trials were conducted in the USA for the following crops: blueberry, grape, head lettuce, spinach, celery, peas, snap bean and lima bean. The results of these residue trials are summarized in the following tables.

Crop group	Commodity	Table No.
Berries and other small fruits	Blueberry	4
	Grape	5
Leafy vegetables	Head lettuce	6
	Spinach	7

Crop group	Commodity	Table No.
Stalk and stem vegetables	Celery	8
Legume vegetables	Peas	9, 10
	Snap bean	11
	Lima bean	12

In all trials, there were no residues detected above the LOQ, 0.05 mg/kg, in control samples. Procedural recoveries of bifenthrin residues were satisfactory in all analytical sets. Bifenthrin residues were demonstrated to be stable for the period of frozen storage for all samples (See section of stability of residue in stored analytical samples).

For estimation of a maximum residue level, residue values from the trials conducted according to the maximum GAP were used. In cases where multiple samples were taken from a single plot, the mean residue from that plot was selected. In cases where separate plots were found not to be independent, the highest residue value was selected for estimating a maximum residue level. Those selected values are underlined in the tables.

Berries and Other Small Fruit

Bushberries—Blueberry

Nine trials were conducted in the USA (CA, ME, MI, NC, NJ and OR) in 2004. At each trial, five foliar applications, 6–8 days apart, were made with the 2 EC formulation (emulsifiable concentrate, 240 g/L), except in Trial ID, NJ10 (in which two of the applications were made at 4-day intervals because the crop was maturing rapidly). In four of the trials (ME01, MI06, NC10, and OR06), separate plots received treatments with the 10 WP formulation (10% wettable powder) as five foliar applications, 6–8 days apart. In all treatments, the application rate was 0.11–0.12 kg ai/ha (0.55–0.57 kg ai/ha/season). Samples of blueberries were collected 1 day after the last application.

2 EC (emulsifiable concentrate; ai, 25.1%), 10 WP (wettable powder, 10%)

Duplicate sampling in each trial was made.

[a, b] The trials were conducted at the same site and on the same dates of application.

Small fruit vine climbing—Grapes

Seven trials on grapes were conducted in the USA (NC, MI, WA, NJ, NY and OH) from 1994 to 1996. One foliar application (2 EC) was made at the rate of 0.10 or 0.11 kg ai/ha. Grape samples were harvested 28 to 32 days after the application.

Table 5 Residues resulting from bifenthrin application to grapes in USA (Report: IR-4 PR No. 05335)

Location (Variety) Year	Application		DALA	Residue, mg/kg [a]			Trial ID
	kg ai/ha	No.		Repl.1	Repl. 2	Mean

[a] 2 EC was applied and duplicate sampling in each trial was made.

Leafy vegetables

Lettuce, head

Six residue trials were conducted in the USA (CA, OH, NJ, FL and TX) in 1993 and 1994. At each trial, five applications (six at TX*25) timed 5–11 days apart were made with the 2 EC formulation.

The rate of application was approximately 0.11 kg ai/ha (0.55 kg ai/ha/season; 0.66 kg ai/ha/season for TX*25 trial). Head lettuce samples with and without wrapper leaves were taken 7–8 days after the last treatment.

The 'Mesa' variety used in Trial NJ17 has a 'frilled' morphology, which suggests that the leaf edges may not stay as close to the head as in other varieties, perhaps resulting in water and residues being retained.

In 2004, four additional trials were conducted in California and Arizona. At each trial, five foliar applications were made at a rate of 0.11 kg ai/ha (0.55 kg ai/ha/season), 5–10 days apart, with the 2 EC formulation. Samples with and without wrapper leaves were collected 6–8 days after the last treatment. In Trial 04, additional samples were collected at 1, 3 and 14 days after the last application to determine the residue decline pattern of bifenthrin.

				14	w/ w. leaves	0.070	0.080	0.075	
					wo/ w. leaves	0.070	0.080	0.075	

2 EC formulation was used and duplicate sampling in each trial was made.

Residues were analysed for heads with wrapper leaves and heads without wrapper leaves.

[a] Variety with a “frilled” appearance

[b] Higher residue value was selected.

Spinach

Five trials were conducted in the USA (MD, NJ and TX) in 1999. At each trial, foliar spray was made once at a rate of 0.45–0.47 kg ai/ha with the 2 EC formulation. A single treatment was made because spinach in some areas developed too rapidly to accommodate a use pattern of four applications and a 40-day PHI. Spinach samples were taken 36–41 days after the application.

Three additional trials were conducted in California and Arizona in 1999. The 2 EC formulation was applied to spinach as four foliar sprays (aerial or ground spray) 4–13 days apart. Each application was at 0.11 kg ai/ha (0.55 kg ai/ha/season), and spinach samples were collected 20, 39 or 40 days after the last application. In these three trials, the metabolite 4'-hydroxy bifenthrin was also analysed along with bifenthrin.

Table 7 Residues resulting from bifenthrin application to spinach in the USA (Report: IR-4 PR No.07088; P-2839)

Location (Variety) Year	Application			DALA	Residue, mg/kg			Trial ID
	kg ai/ha	No.	Inter. days		Repl.1	Repl. 2	Mean

Yuma, AZ (St. Helens) 1999	0.11	4	7–13	20	0.89	1.4	1.1	01

Location (Variety) Year	Application			DALA	Residue, mg/kg			Trial ID
	kg ai/ha	No.	Inter. days		Repl.1	Repl. 2	Mean	
			4–10	40	0.14	0.16	0.15	
Imperial, CA (St. Helens) 1999	0.11 aerial spray	4	5–8	20	0.44	0.50	0.47	02
Imperial, CA (St. Helens) 1999	0.11 ground spray	4	5–8	20	1.0	1.1	1.0	03
			4–7	39	0.040	0.060	0.050	

2 EC formulation was used and duplicate sampling in each trial was made.

For Trial ID, 01, 02 and 03, the metabolite, 4'-hydroxy bifenthrin was analysed as well as bifenthrin. The metabolite was not determined in any samples, i.e., less than LOQ, 0.05 mg/kg.

Stalk and stem vegetables

Celery

Four trials were conducted in the USA (Florida and California) in 1997 and 1998. Celery plots were treated five times with the 2 EC formulation 6–8 days apart. Foliar application was made at a rate of 0.11–0.12 kg ai/ha (0.55–0.57 kg ai/ha/season). Samples were taken 6–8 days after the last treatment. In one trial (CA*03), additional samples were taken 1, 5, 9 and 14 days after the last treatment.

In 2004, four additional trials were conducted in California, Florida and Ohio. Each trial included two treated plots treated with the 2EC or 10 WP formulation. Five foliar applications, 6–8 days apart, were made at the rate of 0.11–0.12 kg ai/ha (0.56–0.58 kg ai/ha/season). Samples were harvested 6–7 days after the last application.

2 EC (emulsifiable concentrate, 240 g/L), 10 WP (wettable powder, 10%)

Two sampling in each trial was made and duplicate sampling in each trial was made.

Residues in stalks and leaves were analysed.

Legume vegetables

Peas

Six trials were conducted in the USA (MN, WI, MD, NY and WA) from 1992 to 1994. At each trial, two foliar applications (2 EC) were made with a 7-day retreatment interval at a rate of 0.11 kg ai/ha (0.22 kg ai/ha/season). Peas and shelled pea samples were collected 3 days after the second application. In three of the six trials, forage samples were collected (one trial for hay), however, residues were not analysed.

Snap bean

Six residue trials on snap beans (beans with pods) conducted in the USA (1996 and 1997), previously evaluated by the 2010 JMPR were re-submitted for evaluation by this Meeting. The 2010 JMPR did not estimate a maximum residue level as the trials submitted were not in accordance with the GAP.

At each trial, three foliar applications (2EC) were made, with 7-day intervals, at a rate of 0.090, 0.090, and 0.045 kg ai/ha for the 1st, 2nd and 3rd applications, respectively. The total rate was 0.23 kg ai/ha during growing the season. The bean samples were harvested 2-4 days after the last application.

(Bush Blue Lake) 1997								

Re-submitted data to this Meeting.

2 EC formulation was used and duplicate sampling in each trial was made.

Residues in snap bean with pods were analysed.

Lima bean

Seven residue trials on lima beans, without pods, conducted in the USA (1997), previously evaluated by the 2010 JMPR, were re-submitted for evaluation by this Meeting. The 2010 JMPR did not estimate a maximum residue level as the trials submitted were not in accordance with the GAP.

At each trial, three foliar applications (2EC) were made with 6–7 day intervals at the rate of 0.087–0.091, 0.089–0.092, 0.043–0.047 kg ai/ha for the 1st, 2nd and 3rd applications, respectively. The total rate was 0.22–0.23 kg ai/ha during the growing season. The bean samples were harvested 2–4 days after the last application.

Re-submitted data to this Meeting

2 EC formulation was used and duplicate sampling in each trial was made.

The 3rd application rate was 0.045 kg ai/ha in all trials.

Residues in lima bean without pods, were analysed.

APPRAISAL

Bifenthrin is a pyrethroid insecticide and miticide. It was first evaluated for residues and toxicology by the JMPR in 1992 and re-evaluated in 2009 (T) and 2010 (R) under the periodic review

programme of the CCPR. The forty-sixth Session of the CCPR (2014) listed bifenthrin for the evaluation of additional maximum residue levels by the 2015 JMPR.

Currently, an ADI of 0–0.01 mg/kg bw and an ARfD of 0.01 mg/kg bw are established. The residue definition for compliance with the MRL and for estimation of dietary intake (for animal and plant commodities) is bifenthrin (sum of isomers). The residue is fat-soluble.

The Meeting received information on supervised residue trials for blueberry, grape, head lettuce, spinach, celery, peas, snap bean and lima bean.

Methods of analysis

Acceptable analytical methods were developed and validated for determination of bifenthrin in residue trial samples. All methods involved an analysis by GC-ECD, except one method using GC-MSD. The limit of quantification (LOQ) of bifenthrin was 0.05 mg/kg in all matrices.

Stability of residues in stored analytical samples

At the 2010 JMPR, bifenthrin was shown to be stable in lettuce under frozen storage condition for at least 36 months. This Meeting received additional storage stability studies on grape, head lettuce, celery, peas, snap bean and lima bean, showing that bifenthrin was stable for the period of storage of the supervised trial samples. Bifenthrin residues in blueberry (81 days) and spinach (4 months) were considered to be stable for the storage period based on all available information.

Results of supervised residue trials on crops

Berries and Other Small Fruit

Bushberries-Blueberry

Nine trials were conducted in the USA in 2004, matching the US GAP on bushberries (0.11 kg ai/ha with 7-day intervals and a PHI of 1 day; 0.56 kg ai/ha/season). Six independent trials matched the GAP.

Bifenthrin residues in blueberry were (n=6): 0.43, 0.48, 0.50, 0.84, 1.2 and 1.4 mg/kg.

The Meeting estimated a maximum residue level of 3 mg/kg, an STMR of 0.67 mg/kg and an HR of 1.6 mg/kg (based on a highest single sample) for blueberries. The Meeting noted that an extrapolation to the group of bushberries was not possible because of a high acute intake resulting from the consumption of currents.

Small fruit vine climbing-Grapes

Seven trials were conducted in the USA from 1994 to 1996 that matched the US GAP on grapes (0.11 kg ai/ha with a PHI of 30 days; 0.11 kg ai/ha/season).

Bifenthrin residues in grapes were (n=7): < 0.05, 0.050, 0.060, 0.060, 0.070, 0.12 and 0.13 mg/kg.

The Meeting estimated a maximum residue level of 0.3 mg/kg, an STMR of 0.060 mg/kg and an HR of 0.14 mg/kg (based on a highest single sample) for grapes.

Leafy vegetables

Lettuce, head

Ten trials were conducted in the USA in 1993–1994 (six trials) and 2003 (four trials), matching the US GAP on lettuce, head (0.11 kg ai/ha with 7-day intervals and a PHI of 7 days; 0.56 kg ai/ha/season).

Bifenthrin residues in head lettuce with wrapper leaves were (n=10): < 0.05, 0.14, 0.23, 0.33, 0.45, 0.56, 0.71, 0.81, 1.7 and 1.8 mg/kg.

The Meeting estimated a maximum residue level of 4 mg/kg for lettuce, head, an STMR of 0.51 mg/kg and an HR of 1.9 mg/kg (based on a highest single sample). However, this would result in an exceedance of the ARfD and an alternative GAP for head lettuce was not identified.

Spinach

Eight trials were conducted in the USA in 1999, two trials of which matched the US GAP on spinach (by ground or aerial spray, a rate of 0.11 kg ai/ha with 7-day intervals and a PHI of 40 days; 0.45 kg ai/ha/season).

Bifenthrin residues were 0.05 and 0.15 mg/kg.

The Meeting did not estimate a maximum residue level as the number of trials was not sufficient.

Stalk and stem vegetables

Celery

Eight trials, including one decline trial, were conducted in 1997 (3 trials), 1998 (one trial) and 2004 (four trials) matching the US GAP on leafy petiole vegetables (0.11 kg ai/ha with 7-day intervals and a PHI of 7 days; 0.56 kg ai/ha/season).

Bifenthrin residues were (n=8): 0.13, 0.17, 0.29, 0.68, 0.71, 0.89, 1.1 and 1.5 mg/kg.

The Meeting estimated a maximum residue level of 3 mg/kg, an STMR of 0.70 mg/kg and an HR of 1.8 mg/kg (based on a highest single sample). However, this would result in an exceedance of the ARfD and an alternative GAP for celery was not identified.

Legume vegetables

Peas

Six trials were conducted in the USA from 1992 to 1994 that matched the US GAP on succulent peas and beans (0.11 kg ai/ha with a PHI of 3 days; 0.22 kg ai/ha/season).

Bifenthrin residues in peas with pods were (n=6): 0.17, 0.17, 0.20, 0.25, 0.34 and 0.49 mg/kg.

The Meeting estimated a maximum residue level of 0.9 mg/kg, an STMR of 0.23 mg/kg and an HR of 0.50 mg/kg (based on a highest single sample) for peas (pods and succulent=immature seed).

Bifenthrin residues in peas without pods were (n=6): < 0.05 (6) mg/kg.

The Meeting estimated a maximum residue level of 0.05* mg/kg and an STMR of 0 mg/kg for peas, shelled (succulent seeds).

Beans

Data from six trials on snap bean (beans with pods) were re-submitted. The 2010 JMPR did not estimate a maximum residue level as the trials were not conducted in accordance with the US GAP (0.11 kg ai/ha with a PHI of 3 days; 0.22 kg ai/ha/season). The trials were conducted in the USA in 1996 and 1997 with three applications 7 days apart, 0.090 kg ai/ha (1st), 0.090 kg ai/ha (2nd) and 0.045 kg ai/ha (3rd) and with a 3-day PHI. Residue values in snap beans with pods were < 0.05, 0.050, 0.050, 0.055, 0.11 and 0.14 mg/kg.

None of the data matched the GAP and the data were not suitable for application of the proportionality approach.

Data from seven trials on lima bean, without pods (conducted in the USA in 1997) were re-submitted. The 2010 JMPR did not estimate a maximum residue level as the trials were not conducted in accordance with the US GAP. The trials were conducted with three applications (approximately 0.090 kg ai/ha at the 1st and 2nd application, and 0.045 kg ai/ha at the 3rd application), 6–7 days apart, and a 2 to 4-day PHI. Residue concentrations in lima bean, shelled (succulent seeds) were all less than 0.05* mg/kg (n=7).

None of the data matched the GAP and the data were not suitable for application of the proportionality approach.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed in Annex I are appropriate for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of the residue (for compliance with the MRL and for estimation of dietary intake) for plant and animal commodities: *bifenthrin (sum of isomers).*

The residue is fat-soluble.

CCN	Commodity	Recommended Maximum residue level (mg/kg)		STMR or STMR-P mg/kg	HR or HR-P mg/kg
		New	Previous		
FB 0020	Blueberries	3		0.67	1.6
FB 0269	Grapes	0.3		0.06	0.14
VL 0482	Lettuce, Head	4 [a]		0.51	1.9
VS 0624	Celery	3 [a]		0.7	1.8
VP 0063	Peas (pods and succulent=immature seed)	0.9		0.23	0.5
VP 0064	Peas, shelled	0.05*		0	

[a] On the basis of information provided to the JMPR it was concluded that the estimated short-term intake of bifenthrin for the consumption of head lettuce and celery may present a public health concern

DIETARY RISK ASSESSMENT

Long-term intake

The 2009 JMPR established an ADI of 0–0.01 mg/kg bw for bifenthrin.

The International Estimated Daily Intakes (IEDIs) of bifenthrin were calculated for the 17 GEMS/Food cluster diets using STMRs/STMR-Ps estimated by the current and previous Meeting. The results are shown in Annex 3 to the 2015 JMPR Report.

The calculated IEDIs were 9–30% of the maximum ADI. The Meeting concluded that the long-term intake of residues of bifenthrin from uses that have been considered by the JMPR is unlikely to present a public health concern.

Short-term intake

The 2009 JMPR established an ARfD of 0.01 mg/kg bw for bifenthrin. The International Estimated Short Term Intakes (IESTIs) for bifenthrin were calculated for the food commodities using HRs/STMRs estimated by the current Meeting. The results are shown in Annex 4 to the 2015 JMPR Report.

For celery the IESTI represented 600% and 360% of the ARfD for children and general population, respectively. For head lettuce the IESTI represented 430% and 190% of the ARfD for children and general population, respectively. No alternative GAP for celery and head lettuce was available. On the basis of information provided to the JMPR, the Meeting concluded that the short-term intake of residues of bifenthrin from consumption of celery and head lettuce may present a public health concern.

Estimates of intake for the other commodities considered by the 2015 JMPR were within 0-100% ARfD. The Meeting concluded that the short-term intake of bifenthrin for the other commodities is unlikely to present a public health concern when bifenthrin is used in ways that were considered by the Meeting.

CHLOROTHALONIL (081)

The first draft was prepared by Mr Christian Sieke, Federal Institute for Risk Assessment, Berlin, Germany

EXPLANATION

Chlorothalonil is a non-systemic fungicide first evaluated by JMPR in 1974 and a number of times subsequently. It was recently reviewed for toxicology by the 2009 and 2010 JMPR within the periodic review program of the CCPR. For the parent substance an ADI of 0-0.02 mg/kg bw and an ARfD of 0.6 mg/kg bw were established. In addition to the parent substance an ADI of 0-0.008 mg/kg bw and an ARfD of 0.03 mg/kg bw were established for the metabolite SDS-3701. In 2010 the JMPR also considered the toxicity of the soil metabolite R611965, however due to the lower toxicity compared to the parent compound, estimation of a separate ADI and ARfD was considered unnecessary.

The 2010 JMPR recommended the following residue definition for chlorothalonil:

Definition of the residue for compliance with MRL for plant commodities: *chlorothalonil*

Definition of the residue for estimation of dietary intake for plant commodities: *chlorothalonil*

SDS-3701 (2,5,6-trichloro-4-hydroxyisophthalonitrile), all considered separately.

Definition of the residue for compliance with MRL and for estimation of dietary intake for animal commodities: *SDS-3701 (2,5,6-trichloro-4-hydroxyisophthalonitrile)*.

In 2012 the JMPR evaluated additional uses for chlorothalonil in banana, chard, chicory, endive, spring onion, spinach, and peas.

The current Meeting received new information on use patterns for chlorothalonil in multiple crops supported by additional analytical methods, storage stability data and supervised field trials.

RESIDUE ANALYSIS

Analytical methods

For chlorothalonil and its metabolite SDS-3701 two additional analytical methods were provided for plant matrices.

Method GRM005.01A (Chaggar, 2006, CLTA10_269 & CLTA10_270)
Crop samples are extracted by homogenisation with acetone; 5M sulphuric acid solution (95:5 v/v) and then centrifuged. For chlorothalonil determination, aliquots were diluted with water followed by solid phase extraction (SPE) clean-up. Chlorothalonil was analysed by gas chromatography with mass selective detection (GC-MSD). For the determination of R182281, aliquots were diluted with acetonitrile:water and quantified by high performance liquid chromatography with triple-quadrupole mass spectrometric detection (LC-MS/MS). Target markers are m/z: 266 → 264 and m/z: 266 → 268 for chlorothalonil and m/z: 245 → 182 and m/z: 245 → 175 for SDS-3701.

Method "Cornell Laboratory" (Thompson, 2007, CLTA10_277 & CLTA10_278)
Crop samples are ground whilst frozen, then extracted with acidified acetone. Extracts are partitioned against petroleum ether, the organic phase containing chlorothalonil and the aqueous SDS-3701. The organic phase is evaporated and the residue cleaned up on a Florisil column, eluting with dichloromethane/hexane and dichloromethane/hexane/acetonitrile. The aqueous phase is adjusted to a pH below 2 and extracted with ether. The sample is then methylated with diazomethane and cleaned up on an alumina column, eluting with dichloromethane. The organic and aqueous extracts were analysed by GC/EC to determine residues of chlorothalonil and SDS-3701 respectively.

Table 2 Recovery data for method "Cornell Laboratory" in plant matrices by GC-ECD

Stability of pesticides in stored analytical samples

Plant matrices

Two additional studies on the storage stability of chlorothalonil and SDS-3701 in stored plant commodities were submitted for incurred residues and fortified residues in cranberries.

Anderson (2007, CLTA10_271)

A study was conducted to investigate the storage stability of field-incurred residues of chlorothalonil and its metabolite SDS-3701 in a wide range of crops (tomato, cucumber, whole melon, whole orange, carrot leaves, carrots, barley straw, barley grain and soya bean) when prepared without acidification or the addition of dry ice and stored deep frozen for up to 24 months.

In this study, all field treated crops were prepared by chopping large quantities of semi-frozen crop without acidification or the addition of dry ice. Untreated samples of these matrices were acidified and chopped semi-frozen without the addition of dry ice and used as control samples and procedural recoveries. Field treated and untreated barley grain and soya bean samples were stored frozen and dispensed into sample pots with no preparation; frozen barley straw was chopped into small pieces and finally prepared in a knife mill. The 0 month samples were analysed immediately after preparation and samples for the 3, 6 12 and 24 month storage intervals were stored deep frozen for the appropriate period up to 24 months.

Samples were analysed by method GRM005.01A, using LC-MS/MS.

Table 3 Recovered chlorothalonil and SDS-3701 incurred residues in stored plant commodities after storage up to 24 months (Anderson, 2007, CLTA10_271)

Interval (days)	Chlorothalonil			SDS-3701

Corley (2013, CLTA10_272)

Samples of cranberries were fortified with either chlorothalonil or the metabolite SDS-3701 at a concentration of 0.2 mg/kg and stored under the same conditions as those used for the residues trials samples, i.e. -20 °C in the dark. Samples were analysed after 295 days of storage. Analysis of the samples was performed according to the method GRM005.01A.

Table 4 Recovered residues in cranberries fortified with chlorothalonil or SDS-3701 at 0.2 mg/kg after storage for 295 days

Analyte	Storage Period (days)	Recovered residue (%)	Mean storage stability recovery (%)	Procedural Recoveries (%)
Chlorothalonil	295	55, 64, 70	63	58-64
SDS-3701		38, 38, 39	38	66-74

USE PATTERN

Chlorothalonil is a non-systemic protectant fungicide. The Meeting received numerous uses involving foliar spray applications mainly before harvest in 2010, amended by additional uses in 2015. The following table lists all additional GAPs only; however the labels provided cover a broader spectrum of uses.

Table 5 List of additional uses of chlorothalonil submitted in 2015

Crop	Country	Application detail					
		Indoor/ Outdoor	Type	kg ai/ha	Growth stage at last treatment	No	PHI
Pome fruit							
Pear	KR	Outdoor	Foliar	0.04 kg ai/hL	At infestation	4	14
Stone fruit

Asparagus	CA	Outdoor	Foliar	1.7	After harvest, to the fern	3	190
Asparagus	US	Outdoor	Foliar	3.4	After harvest, to the fern	3	190
Rhubarb	US	Outdoor	Foliar	2.5	At infestation	6	30
Tree nuts							
Pistachios	US	Outdoor	Foliar	5.0	Full bloom (BBCH 65)	5	14

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

Residue levels were reported as measured. Application rates were always reported as chlorothalonil equivalents. When residues were not detected they are shown as below the LOQ, e.g., < 0.01 mg/kg. Application rates, spray concentrations and mean residue results have generally been rounded to two

significant figures. HR and STMR values from the trials conducted according to maximum GAP have been used for the estimation of maximum residue levels. These results are underlined.

Laboratory reports included method validation including batch recoveries with spiking at residue levels similar to those occurring in samples from the supervised trials. Dates of analyses or duration of residue sample storage were also provided. Field reports provided data on the sprayers used and their calibration, plot size, residue sample size and sampling date. Although trials included control plots, no control data are recorded in the tables except where residues in control samples exceeded the LOQ. Residue data are recorded unadjusted for % recovery.

Chlorothalonil - supervised residue trials

APPRAISAL

Chlorothalonil is a non-systemic fungicide first evaluated by JMPR in 1974 and a number of times subsequently. It was recently reviewed for toxicology by the 2009 and 2010 JMPR within the periodic review program of the CCPR. For the parent substance an ADI of 0–0.02 mg/kg bw and an ARfD of 0.6 mg/kg bw were established. In addition to the parent substance, an ADI of 0–0.008 mg/kg bw and an ARfD of 0.03 mg/kg bw were established for the metabolite SDS-3701.

The 2010 JMPR recommended the following residue definition for chlorothalonil:

Definition of the residue for compliance with MRL for plant commodities: *chlorothalonil*

Definition of the residue for estimation of dietary intake for plant commodities: *chlorothalonil*

SDS-3701 (2,5,6-trichloro-4-hydroxyisophthalonitrile), all considered separately.

Definition of the residue for compliance with MRL and for estimation of dietary intake for animal commodities: *SDS-3701 (2,5,6-trichloro-4-hydroxyisophthalonitrile)*.

In 2012 the JMPR evaluated additional uses for chlorothalonil in banana, chard, chicory, endive, spring onion, spinach, and peas.

The current Meeting received new information on use patterns for chlorothalonil in multiple crops supported by additional analytical methods, storage stability data and supervised field trials.

Methods of analysis

The Meeting received two analytical methods for chlorothalonil not previously evaluated by the Meeting. Both methods were used in the supervised field trials newly submitted and are not intended for monitoring purposes.

Method GRM005.01A is applicable to plant matrices and used homogenisation with acetone and 5M sulphuric acid solution (95:5 v/v). Following solid phase extraction (SPE) clean-up, chlorothalonil was analysed by gas chromatography with mass selective detection (GC-MSD). The metabolite R182281 was quantified by high performance liquid chromatography with triple-quadrupole mass spectrometric detection. The method was successfully validated (70–110% recovery, RSD < 20%) for both analytes for matrices with high water, high acid, high oil and high starch content.

The second method (“Cornell-Method”) is an in-house method using acidified acetone and partitioning against petroleum ether. The organic phase contains chlorothalonil and the aqueous, its metabolite SDS-3701. The sample is then methylated with diazomethane and cleaned up on an alumina column, eluting with dichloromethane. The organic and aqueous extracts were analysed by GC/ECD to determine residues of chlorothalonil and SDS-3701 respectively. The method was successfully validated (70–110% recovery, RSD < 20%) for both analytes for matrices with high water and high acid content.

Stability of residues in stored analytical samples

The Meeting received two additional studies on the storage stability to support the newly submitted supervised field trials not previously evaluated.

In the first study chlorothalonil and its metabolite SDS-3701 were proven to be stable for at least 24 months in stored samples of tomato, cucumber, melon, oranges, carrots (roots and tops), barley (grain and straw) and soya bean seeds.

In a second study cranberries fortified with chlorothalonil and SDS-3701 were analysed after 10 months. The stored triplicate samples indicated a significant decline with average recoveries of 63% of chlorothalonil and 38% of SDS-3701 remaining. The Meeting concluded that both analytes may degrade in cranberries. Since no intermediate samples were analysed, no acceptable storage interval above one month could be identified by the Meeting.

Results of supervised residue trials on crops

The Meeting received supervised trial data for applications of chlorothalonil on various fruit and vegetable crops conducted in Brazil, Europe, Rep. of Korea and the USA.

Residues of SDS-3701 may potentially be taken up by succeeding crops after application of chlorothalonil in the previous year. For annual crops considered by this year, JMPR only estimated median and highest residue values following primary treatment, as these are intermediate values in the establishment of the final STMR and HR values which need to take into account the additional contribution by soil uptake; refer to the rotational crop section.

Pear

Chlorothalonil is registered in Rep. of Korea on pears at a rate of 4×0.04 kg ai/hL with a PHI of 14 days. Six supervised field trials from Rep. of Korea matching this GAP were submitted.

In the trials submitted samples were prepared for analysis by removal of the stem and the core, which were discarded before homogenisation. The Meeting concluded the sample preparation did not comply with the Codex Sampling Guideline, and would have had a significant influence on the residue concentration, making these trials unsuitable for the estimation of maximum residue levels or STMR and HR values.

Cherries

Chlorothalonil is registered in Canada on cherries with a rate of 3×4.5 kg ai/ha with a PHI of 40 days. Supervised field trials from the USA matching this GAP were submitted.

In cherries following treatment with chlorothalonil according to Canadian GAP, residues were (n=10): 0.04, 0.073, 0.12, 0.13, 0.28, 0.5, 0.74, 0.8, 1.2, 1.3 mg/kg.

The corresponding residues of SDS-3701 were (n=10): < 0.01(8), 0.011, 0.03 mg/kg

The Meeting estimated a maximum residue level, an STMR and an HR value of 3 mg/kg, 0.39 mg/kg and 1.8 mg/kg (based on a single highest field sample) for chlorothalonil in cherries, respectively.

For dietary intake purposes the Meeting also estimated an STMR of 0.01 mg/kg and an HR of 0.035 mg/kg (based on a single highest field sample) for SDS-3701 in cherries.

Peaches and nectarines (subgroup)

Chlorothalonil is registered in Canada on peaches and nectarins with a rate of 3×4.5 kg ai/ha with a PHI of 60 days. Supervised field trials from the USA matching the GAP were submitted.

In peaches following treatment with chlorothalonil according to Canadian GAP residues were (n=12): < 0.01, < 0.01, 0.01, 0.014, 0.063, 0.12, 0.12, 0.13, 0.18, 0.24, 0.3, 0.9 mg/kg.

The corresponding residues of SDS-3701 were (n=12): < 0.01(11), 0.01 mg/kg

The Meeting estimated a maximum residue level, an STMR and an HR value of 1.5 mg/kg, 0.12 mg/kg and 1.1 mg/kg (based on a single highest field sample) for chlorothalonil in peaches, respectively.

For dietary intake purposes the Meeting also estimated an STMR of 0.01 mg/kg and an HR of 0.011 mg/kg (based on a single highest field sample) for SDS-3701 in peaches (including nectarines and apricots).

Cranberry

Chlorothalonil is registered in Canada on cranberries with a rate of 3×5.5 kg ai/ha with a PHI of 50 days.

Supervised field trials from the USA matching the GAP were submitted; however supportive storage stability data indicated a substantial loss of residues after the seven month storage interval of the field samples. The Meeting concluded that the data could not be used for assessment.

Bulb onions

Chlorothalonil is registered in the USA on dry onions and shallots with a rate of 3×2.5 kg ai/ha with a PHI of 7 days. Supervised field trials from the USA matching this GAP were submitted.

In bulb onions following treatment with chlorothalonil according to USA GAP residues were (n=8): 0.068, 0.083, 0.22, 0.4, 0.4, 0.48, 0.56, 0.68 mg/kg.

The corresponding residues of SDS-3701 were (n=8): < 0.01(7), 0.026 mg/kg.

The Meeting estimated a maximum residue level, and STMR and an HR value of 1.5 mg/kg, 0.4 mg/kg and 0.69 mg/kg (based on a single highest field sample) for chlorothalonil in bulb onions, respectively.

For dietary intake purposes the Meeting also estimated a STMR of 0.01 mg/kg and an HR of 0.028 mg/kg (based on a single highest field sample) for SDS-3701 in bulb onions.

The Meeting agreed to extrapolate the results to shallots.

Green onions

Chlorothalonil is registered in the USA on green onions with a rate of 3×2.5 kg ai/ha with a PHI of 14 days.

Three supervised field trials from the USA matching the GAP application rate and PHI were submitted. However, one of these trials was conducted at a late growth stage of BBCH 49 which showed substantially higher residues (39 mg/kg) than the two other trials treated at BBCH 17–18 (0.29 mg/kg and 0.42 mg/kg).

The Meeting concluded that the total dataset available is inadequate and no recommendation on green onions can be made.

Peppers

Chlorothalonil is registered in Brazil on pepper with a rate of 2×0.2 kg ai/hL with a PHI of 7 days. Supervised field trials from Brazil matching this GAP were submitted to the 2010 Meeting and supported by additional trials this year.

Residues of chlorothalonil in peppers following treatment according to Brazilian GAP based on trials submitted to the 2010 JMPR were (n=4): 1.1, 1.5, 1.7 and 4.4 mg/kg.

Additional trials submitted this year on peppers gave chlorothalonil residues of (n=8): 0.15, 0.16, 0.22, 0.28, 0.44, 0.74, 1.9, 2.9 mg/kg

Total residues (2010+2015 data) in peppers following treatment according to Brazilian GAP were (n=12): 0.15, 0.16, 0.22, 0.28, 0.44, 0.74, 1.1, 1.5, 1.7, 1.9, 2.9 and 4.4 mg/kg.

The corresponding residues of SDS-3701 (when analysed) were (n=5): < 0.01(5) mg/kg.

In the USA chlorothalonil is registered on peppers with a rate of 8×1.3 kg ai/ha with a PHI of 3 days. Supervised field trials from the USA matching this GAP were submitted.

In bell peppers following treatment with chlorothalonil according to USA GAP residues were (n=8): 0.5, 0.76, 1.0, 1.4, 1.6, 1.7, 2.8, 2.9 mg/kg. The corresponding residues of SDS-3701 were (n=8): < 0.03(8) mg/kg.

In non-bell peppers following treatment with chlorothalonil according to USA GAP residues were (n=7): 0.26, 0.62, 0.62, 0.7, 1.0, 1.6, 1.6 mg/kg. The corresponding residues of SDS-3701 were (n=7): 0.029, < 0.03(6) mg/kg.

The Meeting recognized that chlorothalonil residues in peppers treated according to Brazilian GAP resulted in the highest residue and estimated a maximum residue level of 7 mg/kg based on this dataset for peppers.

For dietary intake purposes of chlorothalonil the Meeting concluded that the STMR value for bell peppers treated according to US GAP was higher than the STMR according to the Brazilian GAP. Since both GAPs were supported by a sufficient number of trial data, the higher STMR of 1.5 mg/kg was selected for dietary intake purposes. An HR of 4.4 mg/kg was estimated based on the Brazilian GAP.

Residues of SDS-3701 were generally below the LOQs of 0.01 mg/kg to 0.03 mg/kg except for one finite residue at 0.029 mg/kg. The Meeting estimated both an STMR and HR of 0.03 mg/kg for SDS-3701 in peppers based on the more critical US dataset.

For the extrapolation from sweet pepper to dried chili pepper a default processing factor of 10 was taken into account. The Meeting estimated a maximum residue level of 70 mg/kg for chlorothalonil in dried chili pepper as wells as a STMR of 15 mg/kg and a HR of 44 mg/kg. For SDS-3701 both a STMR and HR of 0.3 mg/kg were estimated.

Tomato

Chlorothalonil is registered in Poland on tomatoes under protected conditions with a rate of 2 × 0.1 kg ai/hL (up to 1 kg ai/ha per application) with a PHI of 3 days. Protected supervised field trials on cherry tomatoes from various European countries approximating the GAP but with higher spray concentrations of 0.13 kg ai/hL to 0.2 kg ai/hL were submitted.

Compared to the Polish GAP all supervised field trials involved treatment at exaggerated spray concentrations, however the rates applied approximate the GAP maximum of 1 kg ai/ha and application. Since in the field trials submitted tomatoes were cultivated as high crops, the Meeting concluded that the spray concentration is the most sensitive parameter in terms of residues and decided to use the proportionality approach based on the spray concentration.

In protected tomatoes following treatment with 0.13 kg ai/hL (scaling factor 0.77) chlorothalonil residues were 0.45 mg/kg (0.77×0.59 mg/kg) and SDS-3701 residues were < 0.01 mg/kg (unscaled).

In protected tomatoes following treatment with 0.17 kg ai/hL (scaling factor 0.59) chlorothalonil residues were 0.94, 1.1, 1.8 mg/kg (0.59×1.6, 1.8 and 3.1 mg/kg) and SDS-3701 residues were 0.006, 0.012, 0.024 mg/kg (0.59×0.01, 0.02 and 0.04 mg/kg).

In protected tomatoes following treatment with 0.2 kg ai/hL (scaling factor 0.5) chlorothalonil residues were 0.5, 1.1, 1.7, 2.8 mg/kg (0.5×0.99, 2.2, 3.4 and 5.5 mg/kg) and SDS-3701 residues were 0.005, 0.015, 0.015, 0.035 mg/kg (0.5×0.01, 0.03, 0.03 and 0.07 mg/kg).

Total scaled residues of chlorothalonil were (n=8): 0.45, 0.5, 0.94, 1.1, 1.1, 1.7, 1.8 and 2.8 mg/kg

Total scaled residues of SDS-3701 were (n=8): 0.005, 0.006, < 0.01, 0.012, 0.015, 0.015, 0.024 and 0.035 mg/kg

The Meeting estimated a maximum residue level, an STMR and an HR value of 5 mg/kg, 1.1 mg/kg and 2.8 mg/kg for chlorothalonil in tomatoes, respectively.

For dietary intake purposes the Meeting also estimated a STMR of 0.0135 mg/kg and an HR of 0.035 mg/kg for SDS-3701 in tomatoes.

Mushroom

Chlorothalonil is registered in the USA on mushrooms for soil drench application with a rate of 12.7 kg ai/ha as a first treatment followed by 6.4 kg ai/ha as second treatment with a PHI of 7 days. Supervised field trials from the USA matching the GAP were submitted.

In mushrooms following treatment with chlorothalonil according to USA GAP residues were (n=2): 0.09, 0.43 mg/kg.

The corresponding residues of SDS-3701 were (n=2): < 0.01, 0.16 mg/kg.

The Meeting concluded that the data submitted for mushroom was insufficient upon which to make recommendations.

Ginseng

Chlorothalonil is registered in the USA on ginseng with a rate of 8×1.7 kg ai/ha with a PHI of 14 days. Supervised field trials from the USA matching the GAP were submitted.

In ginseng roots (washed and dried) following treatment with chlorothalonil according to USA GAP residues were (n=3): 0.19, 0.35, 0.78 mg/kg.

The corresponding residues of SDS-3701 were (n=3): 0.19, 0.3, 0.61 mg/kg.

The Meeting estimated a maximum residue level, and STMR and an HR value of 2 mg/kg, 0.35 mg/kg and 1.0 mg/kg (based on a single highest field sample) for chlorothalonil in dried ginseng (including red ginseng), respectively.

For dietary intake purposes the Meeting also estimated an STMR of 0.3 mg/kg and an HR of 0.61 mg/kg (based on a single highest field sample) for SDS-3701 in dried ginseng (including red ginseng).

Horseradish

Chlorothalonil is registered in the USA on horseradish with a rate of 8×2.5 kg ai/ha with a PHI of 14 days. Supervised field trials from the USA matching this GAP were submitted.

In horseradish roots following treatment with chlorothalonil according to USA GAP residues were (n=3): 0.031, 0.25, 0.38 mg/kg.

The corresponding residues of SDS-3701 were (n=3): 0.027, 0.14, 0.25 mg/kg.

The Meeting estimated a maximum residue level, an STMR and an HR value of 1 mg/kg, 0.25 mg/kg and 0.48 mg/kg (based on a single highest field sample) for chlorothalonil in horseradish, respectively.

For dietary intake purposes the Meeting also estimated an STMR of 0.14 mg/kg and an HR of 0.28 mg/kg (based on a single highest field sample) for SDS-3701 in horseradish.

Root and tuber vegetables, except horseradish

In 2010 the Meeting recommended a maximum residue level for root and tuber vegetables of 0.3 mg/kg. Due to the higher maximum residue level of 1 mg/kg for chlorothalonil in horseradish, the Meeting decided to exclude horseradish from the group maximum residue level.

The Meeting estimated a maximum residue level of 0.3 mg/kg for root and tuber vegetables, except horseradish. In 2010 the Meeting decided to accommodate for the uncertainty involved with the residue data by basing the dietary risk assessment (chronic and acute) on the maximum residue level also.

The Meeting withdraws its previous recommendation of 0.3 mg/kg for chlorothalonil in root and tuber vegetables.

Asparagus

Chlorothalonil is registered in the USA on asparagus with a rate of 3×3.4 kg ai/ha applied after harvest to the fern with a PHI of 190 days. Supervised field trials from the USA matching the GAP were submitted.

In asparagus spears following treatment with chlorothalonil according to USA GAP residues were (n=8): < 0.01(8) mg/kg.

The corresponding residues of SDS-3701 were (n=8): < 0.01(8) mg/kg.

The Meeting estimated a maximum residue level of 0.01* mg/kg for chlorothalonil in asparagus.

For dietary intake purposes the Meeting concluded that the application of chlorothalonil after harvest to the fern does not lead to significant residues in asparagus spears in the next growing season. Therefore the STMR and HR for both chlorothalonil and SDS-3701 were estimated at 0 mg/kg, although no trials conducted at exaggerated rates were submitted.

Rhubarb

Chlorothalonil is registered in the USA on rhubarb with a rate of 6×2.5 kg ai/ha with a PHI of 30 days. Supervised field trials from the USA matching this GAP were submitted.

In rhubarb stalks following treatment with chlorothalonil according to USA GAP residues were (n=3): 0.39, 0.55, 2.8 mg/kg.

The corresponding residues of SDS-3701 were (n=3): < 0.02(3) mg/kg.

The Meeting estimated a maximum residue level, an STMR and an HR value of 7 mg/kg, 0.55 mg/kg and 3.9 mg/kg (based on a single highest field sample) for chlorothalonil in rhubarb, respectively.

For dietary intake purposes the Meeting also estimated an STMR and an HR of 0.02 mg/kg for SDS-3701 in rhubarb.

Pistachio nut

Chlorothalonil is registered in the USA on pistachio nuts with a rate of 5×5.0 kg ai/ha and a PHI of 14 days. Supervised field trials from the USA matching the GAP were submitted.

In pistachio nutmeat following treatment with chlorothalonil according to USA GAP residues were (n=3): < 0.01, 0.082, 0.11 mg/kg.

The corresponding residues of SDS-3701 were (n=3): < 0.01(3) mg/kg.

The Meeting estimated a maximum residue level, an STMR and an HR value of 0.3 mg/kg, 0.082 mg/kg and 0.14 mg/kg (based on a single highest field sample) for chlorothalonil in pistachios, respectively.

For dietary intake purposes the Meeting also estimated an STMR and an HR of 0.01 mg/kg for SDS-3701 in pistachios.

Residues in rotational crops

Following application of chlorothalonil the major metabolite SDS-3701 has a potential to be taken up by succeeding crops. However, the additional uses evaluated by this JMPR either involve treatment of permanent crops not being subject to crop rotation or their total seasonal rate is lower than the maximum seasonal rate of 20 kg ai/ha used in 2010 to estimate residues in rotational crops. The

Meeting concluded that the assessment of SDS-3701 residues in rotational crops, as evaluated in 2010, also covers uses evaluated this year.

For primary uses evaluated this year on crops being subject to crop rotation, the Meeting decided to take into account the soil uptake of SDS-370 on crop residues. STMR and HR values following direct treatment were added to the corresponding values estimated for rotational crops to address the potential use of chlorothalonil in previous years.

For bulb onions and shallots STMR and HR values of 0.01 mg/kg and 0.028 mg/kg were identified after treatment according to current GAP. In 2010 STMR and HR values of 0.01 mg/kg and 0.04 mg/kg were estimated for SDS-3701 in rotated bulb vegetables. For the dietary intake assessment the Meeting estimated overall STMR and HR values of 0.02 mg/kg and 0.068 mg/kg, respectively.

In peppers grown as rotational crop (see fruiting vegetables) the 2010 Meeting estimated an STMR and an HR value of 0.015 mg/kg and 0.06 mg/kg for SDS-3701, respectively. The current Meeting evaluated uses on peppers (STMR and HR: 0.03 mg/kg each) and estimated overall STMR and HR-values of 0.045 mg/kg and 0.09 mg/kg. For dried chili pepper a default processing factor of 10 was applied, resulting in STMR and HR values of 0.45 mg/kg and 0.9 mg/kg for SDS-3701.

Uses on tomatoes evaluated by the current Meeting are only related to protected conditions and therefore not subject to crop rotation.

In horseradish grown as rotational crop (see root and tuber vegetables) the 2010 Meeting estimated an STMR and an HR value of 0.02 mg/kg and 0.03 mg/kg for SDS-3701, respectively. The current Meeting evaluated uses on horseradish (STMR: 0.14 mg/kg and HR: 0.28 mg/kg) and estimated overall STMR and HR-values of 0.16 mg/kg and 0.31 mg/kg for SDS-3701.

Asparagus, cherries, ginseng, peaches, pistachio nuts and protected tomatoes were not considered relevant in terms of residues derived from crop rotation.

Fate of residues during processing

In 2010 the JMPR Meeting concluded that under simulated processing conditions in sterile buffer solutions at pH 4 chlorothalonil residues were relatively stable with > 90% remaining at 90 °C and 73% remaining at 120 °C. At pH 5 and 100 °C a moderate degradation was observed in all samples, leaving approx. 80% of the initial chlorothalonil. The major degradation product was identified as SDS-3701 at 19% of the initial residue. For pH6 at 120 °C chlorothalonil is quickly degraded. Under addition of a sodium acetate buffer, less than 4% of the chlorothalonil remained. Main degradation products were SDS-3701 (48%) and an artefact (28%, identified as 4-amino-2,5,6-trichloroisophthalonitrile). In sterile water without buffer approx. 26% of the chlorothalonil remained. SDS-3701 constituted 59% of the residue while there was no formation of the artefact.

In contrast to the results obtained from sterile buffer solutions processing studies involving background matrices gave much lower levels of SDS-3701 after processing. The 2010 Meeting decided that besides the normal processing factors for chlorothalonil, yield factors for the conversion of parent substance into SDS-3701 should be taken into account for the estimation of the dietary intake. Depending on the outcome, the higher processing factor of SDS-3701 → SDS-3701 or chlorothalonil → SDS-3701 is used for the overall estimation of STMR-P and HR-P for SDS-3701 in the processed product.

Raw commodity (chlorothalonil)	Processed commodity	Chlorothalonil → Chlorothalonil (see 2010 JMPR Evaluation)		
		Individual processing factors	Mean or best estimate processing factor	STMR-P in mg/kg
Tomato (STMR: 1.1 mg/kg)	Juice, raw	0.3	See juice, bottled	See juice, bottled
	Juice, bottled	0.09, 0.1, 0.11, 0.13	0.1	0.11

	pomace, dry	13, 14, 16, 18	15	0.2

Raw commodity (chlorothalonil)	Processed commodity	Chlorothalonil → SDS-3701 (see 2010 JMPR Evaluation)		
		Individual processing factors	Mean or best estimate processing factor	STMR-P in mg/kg
Tomato (STMR: 1.1 mg/kg)	Juice, raw	0.001	See juice, bottled	See juice, bottled
	Juice, bottled	0.002(4)	0.002	0.0022
	Puree	0.01(3), 0.02	0.01	0.011
	Canned/preserve	0.002, 0.004, 0.004, 0.005	0.004	0.0044
	pomace, wet	0.003, 0.04	See pomace, dry	See pomace, dry
	pomace, dry	0.03(3), 0.04	0.03	0.033

For chlorothalonil in processed tomato products, based on an STMR value of 1.1 mg/kg, the Meeting estimated STMR-P values of 0.11 mg/kg for tomato juice, 0.011 mg/kg for tomato puree and canned tomatoes and 1.4 mg/kg for tomato dry pomace.

For SDS-3701, based on processing factor from SDS-3701 → SDS-3701 and an STMR value of 0.0135 mg/kg, the Meeting estimated STMR-P values of 0.0135 mg/kg for tomato juice, 0.085 mg/kg for tomato puree, 0.027 mg/kg for canned tomatoes and 0.2 mg/kg for tomato dry pomace.

Residues in animal commodities

For all uses under evaluation in this JMPR for chlorothalonil only tomato pomace was identified as a relevant feed item to livestock animals. Since residues in tomato pomace in the dietary feed burden are superseded by residues of grape pomace being in the same Codex feed item group, no increase in the dietary burden for SDS-3701 by the uses evaluated this year compared to 2010 can be expected.

RECOMMENDATIONS

The Meeting estimated the STMR, HR and MRL values shown in Annex 1.

Definition of the residue for compliance with MRL for plant commodities: *chlorothalonil*

Definition of the residue for estimation of dietary intake for plant commodities: chlorothalonil SDS-3701 (2,5,6-trichloro-4-hydroxyisophthalonitrile), all considered separately.

Definition of the residue for compliance with MRL and for estimation of dietary intake for animal commodities: *SDS-3701 (2,5,6-trichloro-4-hydroxyisophthalonitrile)*.

The residue is considered not fat-soluble.

[a] The contribution of SDS-3701 by uptake from soil cannot be estimated for dried ginseng.

[b] STMR and HR values represent the sum of SDS-3701 found after direct application and in crops grown as rotational crop (see Residues in rotational crops

[c] Based on 2010 Evaluation

DIETARY RISK ASSESSMENT

Long-term intake

The evaluation of chlorothalonil has resulted in recommendations for MRLs and STMRs for raw and processed commodities. The International Estimated Daily Intakes for the 17 GEMS/Food cluster diets, based on this years estimated STMRs and previous STMRs from 2010 and 2012 were in the range 10–50% of the maximum ADI of 0.02 mg/kg bw.

The evaluation of SDS-3701 has resulted in recommendations for STMRs for raw and processed commodities following primary treatment and after uptake from soil as rotational crop.

The International Estimated Daily Intakes for the 17 GEMS/Food cluster diets, based on this years estimated STMRs and previous STMRs from 2010 and 2012 were in the range 4–10% of the maximum ADI of 0.008 mg/kg bw.

The results are shown in Annex 3 to the 2015 Report.

The Meeting concluded that the long-term intake of residues of chlorothalonil and its metabolite SDS-3701, from uses that have been considered by the JMPR, is unlikely to present a public health concern.

Short-term intake

The International Estimated Short Term Intake (IESTI) for chlorothalonil and its metabolite SDS-3701 were separately calculated for the plant and livestock commodities (and their processing fractions) for which new STMRs and HRs were estimated and for which consumption data were available. The results are shown in Annex 4 to the 2015 Report.

The IESTI for chlorothalonil varied from 0–30% of the ARfD (0.6 mg/kg bw) and the IESTI for its metabolite SDS-3701 from 0–10% of the ARfD (0.03 mg/kg bw). The Meeting concluded that the short-term intake of residues of chlorothalonil and SDS-3701, from uses that have been considered by the JMPR, is unlikely to present a public health concern.

CYANTRANILIPROLE (263)

The first draft was prepared by Dr Guibiao Ye, Institute for the Control of Agrochemicals, Ministry of Agriculture, Beijing, China

EXPLANATION

Cyantraniliprole is a diamide insecticide with a mode of action (ryanodine receptor activation) similar to chlorantraniliprole and flubendiamide. It has root systemic activity with some translaminar movement and is effective against the larval stages of lepidopteran insects; and on thrips, aphids, and some other chewing and sucking insects.

Cyantraniliprole was first evaluated for toxicology and residues by JMPR in 2013 and an ADI of 0–0.03 mg/kg bw/day was established. An ARfD was deemed to be unnecessary. Residue definitions were also established:

- Definition of residue for compliance with MRL for both animal and plant commodities: *cyantraniliprole*.
- Definiton of residue for estimation of dietary intake for unprocessed plant commodities: *cyantraniliprole*.
- Definition of residue for estimation of dietary intake for processed plant commodities: *sum of cyantraniliprole and IN-J9Z38, expressed as cyantraniliprole.*
- Definition of residue for estimation of dietary intake for animal commodities—*sum of cyantraniliprole, 2-[3-Bromo-1-(3-chloro-2-pyridinyl)-1H-pyrazol-5-yl]-3,4-dihydro-3,8-dimethyl-4-oxo-6-quinazolinecarbonitrile [IN-J9Z38], 2-[3-Bromo-1-(3-chloro-2-pyridinyl)-1H-pyrazol-5-yl]-1,4-dihydro-8-methyl-4-oxo-6-quinazolinecarbonitrile [IN-MLA84], 3-Bromo-1-(3-chloro-2-pyridinyl)-N-[4-cyano-2-(hydroxymethyl)-6-[(methylamino)carbonyl]phenyl]-1H-pyrazole-5-carboxamide [IN- N7B69] and3-Bromo-1-(3-chloro-2-pyridinyl)-N-[4-cyano-2[[(hydroxymethyl)amino]carbonyl]-6-methylphenyl]-1H-pyrazole-5-carboxamide [IN-MYX98], expressed a cyantraniliprole.*
- The residue is not fat soluble.

At the 46th Session of the CCPR(2014) cyantraniliprole was scheduled for evaluation of additional use patterns by 2015 JMPR.

The Meeting received the residue data for citrus fruits, strawberries, grapes, pomegranates, olives, cucumber, squash, melons, beans, peas, soya beans, carrots, radishes, artichokes, corn, rice, tree nuts, cotton, tea, coffee and tobacco, and information on proposed/registered uses of cyantraniliprole on corresponding crops, and the processing studies of oranges, grapes, olives, and cotton. Some of these studies had been submitted to and evaluated by 2013 JMPR.

USE PATTERNS

Cyantraniliprole is registered in many countries for the control of insect pests on fruits, vegetables and cereals. Cyantraniliprole is intended for use as foliar applications in a wide range of fruit and vegetable crops, tree crops and oil seed crops. Other applications include seed treatments and pre-plant soil application. The information available to the Meeting on registered uses is summarized in the following table.

Table 1 Registered uses of cyantraniliprole

Crop	Country	Formulation		Application				PHI (days)	Remarks
		g ai./L or g ai/kg	type	Method	Rate (g ai/ha)	Water L/ha	No

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received information on supervised field trials following foliar, drip irrigation or seed treatment applications of cyantraniliprole to the following crops: strawberries, cucumbers (greenhouse), beans, peas, soya beans, artichokes, corn, almonds, pecans and tea.

The supervised trials were documented with laboratory and field reports. Laboratory reports included method validation including procedural recoveries with spiking at residue levels similar to those occurring in samples from the supervised trials. Dates of analyses or duration of residue samples storage were also provided. Although trials included control plots, no control data are recorded in the tables unless residues in control samples exceeded the LOQ. In such cases, the residues found are noted as “c = nn mg/kg” in the Reference and Comments columns. Residue data are recorded unadjusted for recovery.

Results from replicated field plots are presented as individual values. When residues were not detected they are shown as ND. Residues and application rates have been reported as provided in the study reports, although the results from trials used for the estimation of maximum residue levels (underlined) have been rounded to two significant digits (or if close to the LOQ, rounded to one significant digit) in the Appraisal.

In some trials, samples were taken just before the final application and then, again on the same day after the spray had dried. The notation for these two sampling times in the data tables is '–0' and '0' respectively.

When multiple applications were made to a crop, the application rates, spray concentrations and spray volumes were not always identical from one application to the next. In

most trials, the actual treatment rates were within 10% of the listed 'target' application rates; but, if not, the actual treatment rates are listed.

The analytical methods used in the field trials were capable of analysing both cyantraniliprole and from one to seven metabolites (among them, four metabolites are considered in the residue definition). In most cases, residues of these metabolites were not detected (LOD of 0.003 mg/kg in most trials) or in some cases were reported at levels below the LOQ of 0.01 mg/kg. Where metabolite residues were present at levels above the LOQ, these values are recorded in the following tables using the abbreviations listed below:

- M1 = IN-J9Z38 2-[3-Bromo-1-(3-chloro-2-pyridinyl)-1*H*-pyrazol-5-yl]-3,4-dihydro-3,8-dimethyl-4-oxo-6-quinazolinecarbonitrile
- M2 = IN-MYX98 3-Bromo-1-(3-chloro-2-pyridinyl)-N-[4-cyano-2[[(hydroxymethyl)amino]carbonyl]-6-methylphenyl]-1*H*-pyrazole-5-carboxamide
- M3 = IN-N7B69 3-Bromo-1-(3-chloro-2-pyridinyl)-N-[4-cyano-2-(hydroxymethyl)-6-[(methylamino)carbonyl]phenyl]-1*H*-pyrazole-5-carboxamide
- M4 = IN-MLA84 2-[3-Bromo-1-(3-chloro-2-pyridinyl)-1*H*-pyrazol-5-yl]-1,4-dihydro-8-methyl-4-oxo-6-quinazolinecarbonitrile
- M5 = IN-JCZ384-[[[3-Bromo-1-(3-chloro-2-pyridinyl)-1*H*-pyrazol-5-yl]carbonyl]amino]-N′3′,5-dimethyl-1,3-benzenedicarboxamide
- M6 = IN-N5M09 6-Chloro-4-methyl-11-oxo-11*H*-pyrido[2,1-*b*]quinazoline-2-carbonitrile
- M7 = IN-F6L99 3-Bromo-N-methyl-1*H*-pyrazole-5-carboxamide

Citrus fruits

All trials from Europe and the USA on oranges, grapefruit, lemons and mandarins submitted to the Meeting were evaluated by the 2013 Meeting.

Berries and other small fruits

Strawberry

In trials on strawberries conducted in Europe, two to four foliar applications of 0.075 kg ai/ha cyantraniliprole (OD formulation) were applied at 6–7 day intervals, using 500–800 L/ha, with adjuvant added, or 2–4 drip irrigation of 0.075 kg ai/ha cyantraniliprole (SC formulation) were applied at 7 day intervals, using 3× vol tubing, with no adjuvant added.

Samples were stored at –18 °C for up to 9 months before analysis (within 5 days of extraction) for cyantraniliprole and six metabolites using analytical method DP15736, with reported LOQs of 0.01 mg/kg. Average concurrent recoveries were 98–101% (cyantraniliprole) and 96–106% (metabolites) in samples spiked with 0.01 and 0.1 mg/kg.

Cucurbit vegetables

Cucumber

In trials conducted in North America on greenhouse cucumbers, three foliar applications of 0.15 kg ai/ha cyantraniliprole (SE formulation) were applied at 5 day intervals, using 300–1200 L/ha with adjuvant added.

Duplicate samples were stored at –20 °C for up to 11 months before analysis of whole fruit or pulp and peel for cyantraniliprole and six metabolites using an adaptation of method DP-15736, with reported LOQs of 0.01 mg/kg. Average concurrent recoveries were 92–98% (cyantraniliprole) and 86–114% (metabolites) in samples spiked with 0.01, 0.1, 0.2 and 0.6 mg/kg.

Legume vegetables (Group 014)

Pea—Europe

In trials conducted in Europe on peas (without pods, fresh) in the field, two applications of 0.075 kg ai/ha cyantraniliprole (WG formulation) were applied 7 days interval, using 200–1000 L spray mix/ha with added surfactants.

Samples of pods (with seeds) and foliage (leaves and stems) were stored at –18 °C for up to 10 months before extraction and analysis for cyantraniliprole and six metabolites (same day of extraction) using method DP15736, with reported LOQs of 0.01 mg/kg. Average concurrent recoveries were 81–104% (cyantraniliprole) and 80–101% (metabolites) in samples spiked with 0.01, 0.1, 0.2, 1.0, 3.4 mg/kg and also 5 mg/kg cyantraniliprole.

Bean/Pea—North America

In trials conducted in Northern America on bean/peas (edible-podded, succulent shelled, dry shelled) in the field, three foliar applications of 0.15 kg ai/ha cyantraniliprole (SE/OD formulation) were applied at 5 day intervals, using 200–500 L spray mix/ha with added surfactants.

Samples of pods (with seeds) and foliage (leaves and stems) were stored at –20 °C for up to 14 months before extraction and analysis for cyantraniliprole and six metabolites using method DP15736, with reported LOQs of 0.01 mg/kg. Average concurrent recoveries were 81–104% (cyantraniliprole) and 75–102% (metabolites) in samples spiked with 0.01, 0.1, 1.0, 2.0, and 4.0 mg/kg cyantraniliprole.

Stalk and stem vegetables

Artichoke

In trials conducted on artichokes in Europe, two foliar applications of 0.05 kg ai/ha cyantraniliprole (OD formulation) were applied at 10–13 day intervals, using 800–1000 L/ha with no adjuvant.

Samples of artichoke were stored at –20 °C for up to 12 months before extraction and analysis for cyantraniliprole and six metabolites using method DP-15736, with reported LOQs of 0.01 mg/kg. Average concurrent recoveries were 97–108% (cyantraniliprole) and 83–106% (metabolites) in samples spiked with 0.01, 0.1 and 0.2 mg/kg.

Cereals

Maize

In twenty-three trials conducted on field or pop maize in the USA, seed treatment of 0.5 mg ai/seed of cyantraniliprole (FS formulation) or seed treatment of 0.5 mg ai/seed plus two foliar applications of 0.15 kg ai/ha of cyantraniliprole(WG formulation) were applied, with adjuvants added in foliar applications.

Samples were stored at –20 °C up to 16 month until analysed for cyantraniliprole and the metabolite using analysis method DP-15736. The reported LOQs for cyantraniliprole were 0.01 mg/kg. Average concurrent recoveries were 79–94% (cyantraniliprole) and 73–97% (metabolites) in samples spiked with 0.01, 0.1, 1.0, 5, 14–80 mg/kg.

Tea, green

In field trials conducted in Japan and reported by Higuchil, 2013 [Ref: DP-37521], one foliar application of 0.20 kg ai/ha cyantraniliprole (OD formulation) was applied with no adjuvant added.

Samples of raw tea leaves were processed within one day, the processed tea samples were stored at –20 °C up to 2 months until analysis for cyantraniliprole and the metabolite using method DP-15736, with reported LOQs of 0.04 mg/kg. Average concurrent recoveries were 73–88% cyantraniliprole and 82–88% IN-J9Z38 in samples spiked with 0.04, 2.0 and 25 mg/kg.

Table 36 Residues in tea from supervised trials in Japan following a single foliar application of cyantraniliprole, OD formulation

Fate of residues in storage and processing

Maize (corn)

In two field trials on maize conducted in the USA and reported by Thomas J. Mäyer, 2013 [Ref: TK0029740], plots were treated with one seed treatment of 0.5 mg ai/seed (FS formulation) plus two late season foliar applications at an exaggerated rate of 0.75 kg ai/ha (5×) cyantraniliprole (WG formulation) with added surfactant; samples of were taken 14 day before harvest for processing.

Bulk samples were composited and shipped at ambient temperature directly to the processing facility where samples were processed into aspirated grain fraction, meal, flour, grits, refined oil (dry and wet milling) and starch.

M2: Residues of metabolite IN-MYX98 M3: Residues of metabolite IN-N7B69

M4: Residues of metabolite IN-MLA84 M5: Residues of metabolite IN-JCZ38

M6: Residues of metabolite IN-N5M09 M7: Residues of metabolite IN-F6L99

For calculation purposes, where the residue in the processed commodity was reported as ND (< LOD), a value of 0.003 mg/kg was used and where residues were above the LOD but below the LOQ, a value of 0.01 mg/kg was used. In both cases, the PF was expressed as "less than" (e.g. < 0.01). Where residues of IN-J9Z38 are below the LOQ in the RAC, a value of 0.01 has been used to calculate 'total' residues.

Table 49 Summary of processing factors for cyantraniliprole and cyantraniliprole + IN-J9Z38

RAC	Matrix	Cyantraniliprole [a]		Cyantraniliprole + IN-J9Z38 [b]

AGF: Aspirated Grain Faction

[a] Each value represents a separate study where residues were above the LOQ in the RAC. The factor is the ratio of the cyantraniliprole residues in the processed item divided by the residue of cyantraniliprole in the RAC.

[b] Each value represents a separate study where residues were above the LOQ in the RAC. The factor is the ratio of the combined cyantraniliprole plus IN-J9Z38 metabolite residues in the processed item divided by the residue of cyantraniliprole in the RAC.

APPRAISAL

Cyantraniliprole is a diamide insecticide with a mode of action (ryanodine receptor activation) similar to chlorantraniliprole and flubendiamide, with foliar and systemic activity. It is effective against the larval stages of lepidopteran insects and also on thrips, aphids and other chewing and sucking insects.

Cyantraniliprole was initially evaluated for toxicology and residues by JMPR in 2013 and a ADI of 0–0.03mg/kg bw/day was estastablished. An ARfD was deemed to be unnecessary. The residue definitions were also established:

Definition of residue for compliance with MRL for both animal and plant commodities: cyantraniliprole.

Definiton of residue for estimation of dietary intake for unprocessed plant commodities: cyantraniliprole.

Definition of residue for estimation of dietary intake for processed plant commodities: sum of cyantraniliprole and IN –J9Z38, expressed as cyantraniliprole.

Definition of residue for estimation of dietary intake for animal commodities:

sum of cyantraniliprole, *2-[3-Bromo-1-(3-chloro-2-pyridinyl)-1H-pyrazol-5-yl]-3,4-dihydro-3,8-dimethyl-4-oxo-6-quinazolinecarbonitrile [IN-J9Z38], 2-[3-Bromo-1-(3-chloro-2-pyridinyl)-1H-pyrazol-5-yl]-1,4-dihydro-8-methyl-4-oxo-6-quinazolinecarbonitrile [IN-MLA84], 3-Bromo-1-(3-chloro-2-pyridinyl)-N-[4-cyano-2-(hydroxymethyl)-6-[(methylamino)carbonyl]phenyl]-1H-pyrazole-5-carboxamide [IN- N7B69] and 3-Bromo-1-(3-chloro-2-pyridinyl)-N-[4-cyano-2[[(hydroxymethyl)amino]carbonyl]-6-methylphenyl]-1H-pyrazole-5-carboxamide [IN-MYX98],* expressed a cyantraniliprole.

The residue is not fat soluble.

At the Forty-sixth Session of the CCPR(2014), cyantraniliprole was scheduled for evaluation of additional use patterns by 2015 JMPR.

The Meeting received supervised residue trial data for foliar and soil applications of cyantraniliprole on a range of fruit and vegetable crops, cereals, tree nuts and tea, and information on registered uses of cyantraniliprole on corresponding crops. The processing studies on corn were also submitted to the Meeting.

Methods of analysis

The analytical methods were previously evaluated (2013 Meeting). The same methods were used in the trials submitted to the current Meeting, and are considered valid for the commodities evaluated.

Stability of residues in stored analytical samples

The stability of residues of cyantraniliprole and metabolites in stored samples was covered by the freezer stability studies evaluated by the 2013 JMPR, and is considered adequate for the trials submitted to the current Meeting.

Results of Supervised residue trials on crops

The Meeting received the residue trials for strawberry, greenhouse cucumber, bean, pea, soya bean, artichoke, maize, and tea.

Where residues have been reported as not detected (ND), i.e., <LOD, the values have been considered as <LOQ (< 0.01 mg/kg) for the purposes of MRL setting. If a higher residue level was observed at a longer PHI than the GAP, the higher value has been used in MRL setting.

The Meeting noted that GAP has been authorised for the use of cyantraniliprole and the product labels were available from Canada, Columbia, India, Japan, Vietnam and USA.

Citrus fruits

The critical GAP for cyantraniliprole on citrus fruits is in USA: 3 foliar applications of 0.15 kg ai/ha with a total of 0.45 kg ai/ha/season, applied at least 7 days intervals with a PHI of 1 day. The 2013 Meeting received the supervised residue trials for cyantaniliprole on citrus fruit (orange, lemon, grapefruit and mandarin). The current Meeting evaluated the data against the GAP for citrus fruits from the USA. Cyantraniliprole was also registered for soil application in citrus, however, the residue trials with soil application showed that the soil application did not contribute significant residues in citrus fruits.

Orange

In trials conducted in USA and Europe matching the USA GAP (with 3 applications of 0.15 kg ai/ha, PHI of 1 day), cyantraniliprole residues in whole fruit were: 0.1(2), 0.12, 0.17, 0.2, 0.21, 0.22, 0.23, 0.26, 0.28, 0.3, 0.35 and 0.39 mg/kg (n=13). The cyantraniliprole residues in pulp were: 0.01, 0.013, 0.018, 0.021, 0.036, 0.04, 0.041, 0.043, 0.046, 0.064, 0.069, and 0.086(2) mg/kg (n=13).

Lemon

In trials conducted in USA matching the USA GAP (with 3 applications of 0.15 kg ai/ha, PHI of 1 day), cyantraniliprole residues in whole fruit were: 0.16(2), 0.19, **0.21 and 0.3 mg/kg (**n=5). Cyantraniliprole residues in pulp were: 0.023, 0.057, 0.063, 0.07 and 0.11 mg/kg (n=5).

Grapefruit

In trials conducted in USA matching the USA GAP (with 3 applications of 0.15 kg ai/ha, PHI of 1 day), cyantraniliprole residues in whole fruit were: 0.091, 0.12(2), 0.14, 0.16, 0.19, and 0.31**mg/kg (**n=7). Cyantraniliprole residues in pulp were: 0.014, 0.021, 0.026, 0.029, 0.032, 0.033 and 0.049 mg/kg (n=7).

Mandarins

In trials conducted in Europe matching the USA GAP (with 3 applications of 0.15 kg ai/ha, PHI of 1 day), cyantraniliprole residues in whole fruit were: 0.47 **mg/kg (**n=1). Cyantraniliprole residues in pulp were: 0.2 mg/kg (n=1).

The Meeting noted that the GAP in USA was for citrus and the medians of the data sets for oranges, lemons, grapefruits and mandarins differed by less than 5-fold, and agreed to consider a group maximum residue level. In deciding on the data set to use for estimating a group maximum residue level (the Kruskal-Wallis H-test indicated that the residue populations for oranges, lemons, grapefruits and mandarins were not different) it was agreed to combine the results to give a data set of: 0.091, 0.1(2), 0.12(3), 0.14, 0.16(3), 0.17, 0.19(2), 0.2, 0.21(2)**,** 0.22, 0.23, 0.26, 0.28, 0.3(2), 0.31, 0.35, 0.39 and 0.47 mg/kg (n=26) to recommend a maximum residue level for the citrus fruit group. It was agreed to combine the results in pulp to give a data set of: 0.01, 0.013, 0.014, 0.018, 0.021(2), 0.023, 0.026, 0.029, 0.032, 0.033, 0.036, 0.04, 0.041, 0.043, 0.046, 0.049, 0.057, 0.063, 0.064, 0.069, 0.07, 0.086(2), 0.11 and 0.2 mg/kg (n=26).

The Meeting estimated an STMR of 0.041 mg/kg and an HR of 0.2 mg/kg based on residues in pulp, and recommended a group maximum residue level of 0.7 mg/kg for cyantraniliprole on citrus fruit. The Meeting estimated an STMR of 0.20 mg/kg in orange fruit for calculation of STMR-P.

Pomegranate

The approved GAP for cyantraniliprole on pomegranate is available from India, up to 3 foliar applications of 0.09 kg ai/ha, applied at least 7-10 day intervals with a PHI of 5 days. The assessment was undertaken using the supervised residue trials for cyantaniliprole on pomeganate received by the 2013 Meeting. The current Meeting evaluated the data against the new GAP for pomegranate from India.

In one trial conducted on pomegranate in India matching the Indian GAP cyantraniliprole residues in rind, seed and juice were < 0.01 mg/kg (n=1). In other trials conducted in four locations in India with 2, 3, 5 applications at rate of 0.075-0.18 kg ai/ha and PHI of 5 days, the cyantraniliprole residues in rind, seed and juice were all < 0.01 mg/kg (n=11).

The Meeting noted that since different times and rates of application resulted in the same residues in pomegranate, the Meeting agreed to combine the data together to estimate a maximum residue level of 0.01* mg/kg, and an STMR of 0.01 mg/kg.

Fruiting vegetables, Cucurbits

The critical GAP for cyantraniliprole on cucurbit vegetables is in Canada, up to 4 foliar applications of 0.15 kg ai/ha, applied at least 5–7 day intervals with a PHI of 1 day.

The new trials conducted on protected cucumber in North America (with 3 applications of 0.15 kg ai/ha, a PHI of 0 day) did not match the critical GAP. The meeting confirmed the previous recommendation.

Legume vegetables

The critical GAP for cyantraniliprole on legume vegetables in Canada is up to 4 foliar applications of 0.15 kg ai/ha, applied at least 5 day intervals with a PHI of 1 day for succulent seed. The 2013 Meeting received the supervised residue trials for cyantaniliprole on bean and pea from Europe. The current Meeting received new trials on bean, pea and soya bean, and evaluated all trials available to the Meeting against the new GAP for legume vegetables from Canada.

Pea with pod

In trials conducted on pea with pod (edible-podded peas) in USA matching the Canadian GAP (4 foliar applications of 0.15kg ai/ha, 1 day PHI), cyantraniliprole residues in pea with pod were: 0.29, 0.61, 0.78 and 0.79 mg/kg (n=4).

The Meeting estimated an STMR of 0.7mg/kg, and the maximum residue level of 2.0 mg/kg for cyantraniliprole in pea with pod.

Pea without pod

In trials conducted on pea without pod (succulent shelled pea) in USA matching the Canadian GAP (4 foliar applications of 0.15 kg ai/ha, 1 day PHI), cyantraniliprole residues in seed of pea without pod were: 0.019, 0.046, 0.065, 0.076, 0.082 and 0.10 mg/kg (n=6).

The Meeting estimated an STMR of 0.07 mg/kg, and maximum residue level of 0.3 mg/kg in pea without pod.

Bean with pod

In trials conducted on bean with pod (edible-podded beans) in USA matching the Canadian GAP (4 foliar applications of 0.15kg ai/ha, PHI of 1 day), cyantraniliprole residues in bean were: 0.11, 0.11, 0.23, 0.29, 0.36, 0.43, and 0.73 mg/kg (n=7).

The Meeting estimated an STMR of 0.29 mg/kg and recommended the maximum residue level of 1.5 mg/kg for cyantraniliprole in bean with pod.

Bean without pod

In trials conducted on bean without pod (succulent shelled beans) in the USA matching the Canadian GAP (4 foliar applications at 0.15kg ai/ha, PHI of 1 day), cyantraniliprole residues in seed of succulent shelled bean were: 0.01, 0.023 and 0.057 mg/kg (n=3).

Since three trials were insufficient to estimate the STMR and maximum residue level, the Meeting agreed to extrapolate the STMR and maximum residue level from pea without pods. The Meeting estimated an STMR of 0.07 mg/kg, and a maximum residue level of 0.3 mg/kg in bean without pod.

Soya bean, immature seed

In trials conducted on soya bean in the USA matching Canadian GAP (4 applications at 0.15 kg ai/ha, PHI of 1 day). The cyantraniliprole residues in immature seed were: 0.019, 0.035, 0.036, 0.042 and 0.14 mg/kg (n=5)

The Meeting estimated an STMR of 0.036 mg/kg and recommended the maximum residue level of 0.3 mg/kg for cyantraniliprole in soya bean, immature seed.

Pulses

The critical GAP for cyantraniliprole on pulses in Canada is up to 4 foliar applications of 0.15 kg ai/ha, applied at 5 day intervals with a PHI of 7 days.

Beans (dry)

In new trials conducted on bean, dry (dry shelled beans) in USA matching the Canadian GAP (4 foliar applications of 0.15kg ai/ha, PHI of 7 day), cyantraniliprole residues in bean, dry were: < 0.01, < 0.01, < 0.01, < 0.01, < 0.01, 0.01, 0.015, 0.021, 0.048, 0.049, 0.088 and 0.22 mg/kg (n=12).

The Meeting estimated a STMR of 0.01 mg/kg and recommended the maximum residue level of 0.3 mg/kg for cyantraniliprole in bean (dry).

Peas (dry)

In new trials conducted on pea, dry (dry shelled peas) in the USA matching Canadian GAP (4 foliar applications of 0.15kg ai/ha, PHI of 7 day), cyantraniliprole residues in peas (dry) were: 0.019, 0.077, 0.086 and 0.51 mg/kg (n=4).

The Meeting agreed that four trials were insufficient for the estimation of a STMR and maximum residue level recommendation.

Soya bean (dry)

In new trials, conducted on soya bean in the USA, matching the Canadian GAP (4 applications of 0.15 kg ai/ha, PHI of 7 days), cyantraniliprole residues in soya bean (dry) were: < 0.01, 0.011, 0.012, 0.017, 0.022, 0.023, 0.027, 0.027, 0.031, 0.031, 0.033, 0.044, 0.056, 0.061, 0.083, 0.1, 0.12, 0.13, 0.15, 0.16 and 0.25 mg/kg (n=21).

The meeting estimated an STMR of 0.033 mg/kg and recommended the maximum residue level of 0.4 mg/kg for cyantraniliprole in soya bean (dry).

Artichoke

The GAP for cyantraniliprole on artichoke in Canada is up to 4 foliar applications of 0.025–0.15 kg ai/ha with a total of 0.45 kg ai/ha/season, applied at least 5–7 day intervals with a PHI of 7 days.

The new trials conducted on artichoke in Europe (2 foliar applications of 0.05kg/ha) did not match the Canadian GAP.

Maize

The GAP for cyantraniliprole on maize is available from Canada, for seed treatment at 0.012–0.024 kg ai/ha (up to 0.25 mg ai/ seed, or 100 g ai/100 kg seeds).

There were no trials matching the Canadian GAP, however, the Meeting noted that in 23 trials conducted on maize in North America, seed treatment of 0.5 mg ai/ seed, i.e., 2× GAP rate, the residues of cyantraniliprole in maize grain were all < 0.01 mg/kg. The Meeting agreed to estimate a STMR of 0 mg/kg and recommend a maximum residue level of 0.01 mg/kg for cyantraniliprole in maize grain.

Tree nuts

The critical GAP for cyantraniliprole on tree nuts is from the USA, 3 foliar applications of 0.15 kg ai/ha, with a seasonal total of 0.45 kg ai/ha, applied at 7 day intervals with a PHI of 5 days. The Meeting received four new trials on almond and six new trials on pecan. In addition, the 2013 Meeting received supervised residue trials for cyantaniliprole on almond (6) and pecan (6). The current Meeting evaluated all available trials together against the GAP of the USA.

Almond

In trials conducted on almonds in the USA, matching US GAP (3 foliar application of 0.15 kg ai/ha, 0.45 kg ai/ha/season, PHI of 5 days), cyantraniliprole residues in nutmeat were < 0.01 (5), 0.01, 0.012, 0.014, 0.018 and 0.023 mg/kg (n=10).

Pecan

In trials conducted on pecans in the USA, matching US GAP (3 foliar application of 0.15 kg ai/ha, 0.45 kg ai/ha/season, PHI of 5 days), cyantraniliprole residues in nutmeat were all < 0.01 mg/kg (n=12).

The Meeting noted that the GAP in the USA was for tree nuts and the medians of the data sets for almond and pecan differed by less than 5-fold and agreed to consider a group maximum residue level. In deciding on the data set to use for estimating a group maximum residue level (the Kruskal-Wallis H-test indicated that the residue populations for almond and pecan were not different) it was agreed to combine the results to give a data set of: < 0.01(16), 0.01(2), 0.012, 0.014, 0.018 and 0.023 mg/kg (n=22) to recommend a maximum residue level for the tree nut group.

The Meeting estimated an STMR of 0.01 mg/kg, and recommended a group maximum residue level of 0.04 mg/kg for cyantraniliprole on tree nuts.

Oilseeds

The 2013 Meeting received supervised residue trials for cyantraniliprole on cotton, rapeseed and sunflower. The current Meeting evaluated the data against the GAP of the USA.

Cotton

The critical GAP for cyantraniliprole on cotton in the USA is for up to 3 foliar applications of 0.15 kg ai/ha with a total of 0.45 kg ai/ha/season, applied at 7 day intervals with a PHI of 7 days.

In trials conducted on cotton in the USA matching GAP, cyantraniliprole residues in cotton seed were: 0.012, 0.025, 0.035, 0.12, 0.12, 0.14, 0.16, 0.18, 0.2, 0.22, 0.26, 0.29 and 0.99 mg/kg (n=13).

The Meeting estimated an STMR of 0.16 mg/kg, and recommended the maximum residue level of 1.5 mg/kg for cyantraniliprole in cotton seed.

Rape seed (canola)

The critical GAP for cyantraniliprole on rape seed (canola) in the USA is up to 3 foliar applications of 0.15 kg ai/ha with a total of 0.45 kg ai/ha/season, applied at 7 day intervals with a PHI of 7 days.

In trials conducted on canola in the USA matching GAP, cyantraniliprole residues in rapeseed were: 0.019, 0.021, 0.022, 0.05, 0.059, 0.061, 0.07, 0.07, 0.084, 0.12, 0.17, 0.18, 0.27, 0.29, 0.32 and 0.61 mg/kg (n=16).

The Meeting estimated the maximum residue level of 0.8 mg/kg and an STMR of 0.077 mg/kg for cyantraniliprole in rapeseed.

Sunflower

The critical GAP for cyantraniliprole on sunflower in the USA is for up to 3 foliar applications of 0.15 kg ai/ha with a total of 0.45 kg ai/ha/season, applied at 7 day intervals with a PHI of 7 days.

In trials conducted on sunflower in the USA matching the USA GAP, cyantraniliprole residues in sunflower seed were: 0.028, 0.039, 0.059, 0.064, 0.067, 0.085, 0.092, 0.14 and 0.32 mg/kg (n=9).

The Meeting estimated the maximum residue level of 0.5 mg/kg and a STMR of 0.067 mg/kg for cyantraniliprole in sunflower.

Seed for beverages and sweets

Coffee

The 2013 Meeting received supervised residue trials for cyantraniliprole on coffee. The current Meeting evaluated the data against the new GAP from Columbia.

The new approved GAP for cyantraniliprole on coffee from Columbia is for up to 2 foliar application of 2.5–3.5 g ai/5 litres/100 trees, equivalent to 0.06–0.175 kg ai/ha with a total of 0.3 kg ai/ha/season, with a PHI of 7 days.

In two Brazilian trials matching the Columbian GAP, cyantraniliprole residues in green coffee beans were: < 0.01 and 0.02 mg/kg.

The Meeting noted that in a further eight trials from Brazil involved 2 foliar applications that matched the Columbian GAP but in which two soil drenches (0.01–0.06 g ai/100 mL/plant to achieve the equivalent of 0.2 kg ai/ha/treatment) were also applied 90 and 120 days before harvest, cyantraniliprole residues in green bean were: < 0.01 (3), 0.01(2), 0.02, 0.02, and 0.03 mg/kg (n=8).

The Meeting agreed that since the early season soil drench treatments did not appear to contribute to the final residue in coffee beans, the data from these two sets of results could be combined, giving a data set of: < 0.01(4), 0.01(2), 0.02(3) and 0.03 mg/kg (n=10).

The Meeting estimated a STMR of 0.01 mg/kg, and recommended a maximum residue level of 0.05 mg/kg for cyantraniliprole on coffee bean, with the withdrawal of the previous maximum residue level recommendation of 0.03 mg/kg.

Tea, green, dry

The approved GAP for cyantraniliprole on tea is from Japan, with 1 foliar application of 0.1–0.2 kg ai/ha and a PHI of 7 days.

In trials conducted in Japan matching the Japanese GAP, cyantraniliprole residues in tea, green(dry) were 4.19 and 20.6 mg/kg (n=2). The Meeting agreed that two trials were insufficient for the estimation of a STMR and a maximum residue level recommendation.

Animal feed

Bean forage and bean hay

The 2013 Meeting received supervised residue trials for cyantaniliprole on beans from Europe. The current Meeting received new trials on beans from the USA, and evaluated all available trials against the new GAP for pulses from Canada.

In new trials conducted on bean forage and hay (dry shelled beans) in the USA, matching the Canadian GAP (3 foliar applications of 0.15kg ai/ha, PHI of 7 day), cyantraniliprole residues in bean forage (dry matter) were: 6.3, 7.6, 11.6, and 16.9 mg/kg (n=4); cyantraniliprole residues in bean hay (dry matter) were: 5.2, 7.7, 9.2 and 19.1 mg/kg (n=4).

The Meeting estimated a median residue of 9.6 mg/kg and a highest residue of 16.9 mg/kg for cyantraniliprole in bean forage (dry matter) for the calculation of livestock dietary burdens.

The Meeting estimated a median residue of 8.5 mg/kg and a high residue of 19.1 mg/kg for cyantraniliprole in bean hay (dry matter), and recommended a maximum residue level of 40 mg/kg (DM).

Pea vine and pea hay

The 2013 Meeting received supervised residue trials for cyantaniliprole on peas from Europe. The current Meeting received new trials on peas from the USA, and evaluated all available trials against the new GAP for pulses from Canada.

In new trials conducted on pea vine and hay in USA matching the Canadian GAP (3 foliar applications of 0.15kg ai/ha, 7 day PHI), cyantraniliprole residues in pea vine (dry matter basis) were: 4.1, 6.6, 11.4 and 47.1 mg/kg (n=4); cyantraniliprole residues in pea hay (dry matter) were: 3.5, 6.6, 12.8 and 28.5 mg/kg (n=4).

The Meeting estimated a median residue of 9.0 mg/kg and a highest residue of 47.1 mg/kg (DM) for cyantraniliprole in pea vine (dry matter) for calculation of livestock dietary burdens.

The Meeting estimated a median residue of 9.7 mg/kg and a highest residue of 28.5 mg/kg for cyantraniliprole in pea hay, and recommended a maximum residue level of 60 mg/kg (DM) for cyantraniliprole in pea hay,

Soya bean forage and hay

The Meeting received new trials conducted on soya bean forage and hay from the USA, matching Canadian GAP (3 applications of 0.15 kg ai/ha, PHI of 7 days).

The cyantraniliprole residues in soya bean forage, on dry matter basis, were: 1.2, 2.7, 4.5, 4.9, 6.1, 12.0, 12.5 14.2, 16.9, 17.8, 21.6, 27.1, 27.2, 30.6, 39.5 and 45.3 mg/kg (n=16).

The cyantraniliprole residues in soya bean hay in dry matter were: 1.6, 2.5, 6.0, 10.0, 10.8, 10.9, 13.1, 13.2, 14.3, 22.5, 27.3, 28.4, 28.9, 32.8, 42.7 and 46.4 mg/kg (n=16)

The Meeting estimated a median residue of 15.5 mg/kg and a highest residue of 45.3 mg/kg for cyantraniliprole in soya bean forage (dry matter) for calculation of animal dietary burdens.

The Meeting estimated a median residue of 13.7 mg/kg and a highest residue of 46.4 mg/kg for cyantraniliprole in soya bean hay (dry matter), and recommended a maximum residue level of 80 mg/kg (DM) for cyantraniliprole in soya bean hay.

Almond hull

The 2013 Meeting received supervised residue trials for cyantaniliprole on almond hulls. The current Meeting evaluated the data against the new GAP from the USA.

In trials conducted on almonds hulls in the USA, matching US GAP (3 foliar application of 0.15 kg ai/ha, 0.45 kg ai/ha/season, PHI of 5 days), cyantraniliprole residues in almond hulls were: 0.72, 0.88, 0.93, 1.4, 1.9, 1.9, 2.5, 2.9, 3.6 and 4.6 mg/kg (n=10).

The Meeting estimated a mean residue of 1.9 mg/kg, a highest residue of 4.6 mg/kg on almond hulls for the purpose of estimating livestock dietary burdens.

Cotton gin trash

The 2013 Meeting received supervised residue trials for cyantraniliprole on cotton gin trash. The current Meeting evaluated the data against the GAP of the USA (3 applications of 0.15 kg ai/ha, with interval of 7 days and a PHI of 7 days).

In trials conducted on cotton in the USA, matching US GAP, residues in cotton gin trash were: 2.6, 2.7, 3.5 and 5 mg/kg (n=4)

The Meeting estimated the median residue of 3.1 mg/kg and the highest residue of 5 mg/kg in cotton gin trash for estimating livestock dietary burden.

Fate of residues during processing

The Meeting received processing studies on cyantranilipole residues in maize, cottonseed and oranges. The Meeting agreed that for commodities not being considered for maximum residue levels at this Meeting, the relevant processing studies would not be reviewed and processing factors would not be estimated. Estimated processing factors and STMR-Ps for the commodities considered at this Meeting are summarized below.

Summary of processing factors and STMR-P for cyantraniliprole+IN-J9Z38

RAC	Commodity	Cyantraniliprole+IN-J9Z38 [a]		RAC STMR (mg/kg) [b]	STMP-P (mg/kg)[d]
		Calculated processing factors	PF best estimate		
Maize	Grain			0.01	
	Asp gr fn [f]	175, 177.4	176		1.76
	Meal	0.22, 0.44	0.33		0.0033

	oil		8.5		1.7
	canned		<0.03		<0.006
Orange	Oil	2.3, 8.2, 6.2[e]	6.2[e]		

[a] Each PF value represents a separate study where residues were above the LOQ in the RAC. The factor is the ratio of the combined cyantraniliprole plus IN-J9Z38 metabolite residues in the processed item divided by the residue of cyantraniliprole in the RAC.

[b] Residues in the RAC is cyantraniliprole.

[c] The processing factor was estimated in 2013 JMPR, the STMR-P was calculated in this Meeting.

[d] Residues in processed commodities is cyantraniliprole plus IN-J9Z38

[e] The processing factor based on residues of cyantraniliprole only for estimation of maximum residue level.

[f] Aspirated grain faction

The Meeting noted that in the studies available, cyantraniliprole residues did not concentrate in food commodities during processing except for orange oil. The Meeting estimated a maximum level of 4.5 (0.7×6.2) mg/kg for citrus oil, the processing factor was based on residues of parent only.

Residues in animal commodities

Farm animal dietary burden

The dietary burdens were estimated using the OECD diets listed in Appendix IX of the 2009 edition of FAO Manual. Potential cattle feed items include: pea, soya bean, cotton gin trash, maize and potatoes (including by-products). Dietary burden calculations for beef cattle, dairy cattle, broilers and laying poultry are presented Annex 6 to the Report and are summarized below.

Estimated maximum and mean dietary burden of farm animal (ppm of dry matter diet)

	Animal dietary burden, cyantraniliprole							
	US-Canada		EU		Australia		Japan	
	max	mean	max	mean	max	mean	max	mean
Beef cattle	0.69	0.37	12.6	3.38	46.8 [a]	15.59 [c,]	0.14	0.009
Dairy cattle	9.86	3.42	14	3.82	35.95 [b]	12.05 [d]	0.29	0.024
Poultry-broiler	0.00	0.00	0.05	0.02	0.00	0.00	0.00	0.00
Poultry-layer	0.00	0.00	4.71 [e, g]	1.56 [f, h]	0.00	0.00	0.00	0.00

[a] Highest maximum beef or dairy cattle dietary burden suitable for MRL estimates for mammalian meat

[b] Highest maximum dairy cattle dietary burden suitable for MRL estimates for mammalian milk

[c] Highest mean beef or dairy cattle dietary burden suitable for STMR estimates for mammalian meat

[d] Highest mean dairy cattle dietary burden suitable for STMR estimates for mammalian milk

[e] Highest maximum poultry dietary burden suitable for MRL estimates for poultry tissues

[f] Highest mean poultry dietary burden suitable for STMR estimates for poultry tissues

[g] Highest maximum poultry dietary burden suitable for MRL estimates for poultry eggs

[h] Highest mean poultry dietary burden suitable for STMR estimates for poultry eggs

Animal commodity maximum residue level

For beef and dairy cattle, the calculated maximum dietary burden suitable for estimating maximum residue levels in mammalian tissues and milk are 47 ppm and 36 ppm dry weight of feed, and the calculated mean dietary burdens suitable for estimating STMRs in mammalian tissues and in milk are 16 ppm and 12 ppm dry weight of feed respectively. The residue levels of cyantraniliprole and metabolites included in the residue definition in milk and tissue were calculated by estimation based on 10ppm, 30ppm and 100ppm feeding level in the feeding studies.

Cyantraniliprole feeding study	Feed level, ppm, for		Residue [a], mg/kg				
	Tissue residue	Milk residue	Milk	Muscle	Liver	Kidney	Fat
MRL, beef or dairy cattle							
Feeding study [b]	30	30	0.445	0.11	0.936	0.427	0.27
	100	100	1.109	0.373	2.3	1.351	1.03
Dietary burden and high residue	47	36	0.50	0.17	1.26	0.65	0.45
STMR, beef or dairy cattle							
Feeding study [c]	10	10	0.11	0.026	0.246	0.128	0.065
	30	30	0.445	0.081	0.722	0.356	0.202
Dietary burden mean residue estimate	16	12	0.21	0.041	0.38	0.19	0.10

[a] Residue values used in estimating STMR are the sum of cyantraniliprole and metabolites IN-N7B69, IN-J9Z38, IN-MLA84 and IN-MYX98

[b] high residues for tissues and mean residues for milk

[c] mean residues for tissues and mean residues for milk

Residues of cyantraniliprole expected in cattle milk and tissues for use in estimating maximum residue levels are: 0.45 mg/kg (fat), 0.17 mg/kg (muscle), 1.26 mg/kg (liver) and 0.65 mg/kg (kidney) and the mean residue for milk is 0.50 mg/kg.

The Meeting estimated maximum residue levels of 0.2 mg/kg for cyantraniliprole in meat (from mammals other than marine mammals), 1.5 mg/kg for edible offal (mammalian), 0.5 mg/kg for mammalian fat and 0.6 mg/kg for milks. The Meeting estimated STMRs (parent plus metabolites) for dietary intake estimation are 0.041 mg/kg for meat, 0.38 mg/kg for edible offal, 0.1 mg/kg for fat and 0.21 mg/kg for milk. The previous recommendations should be replaced.

For poultry, noting that in some countries, laying hens may also be consumed; the calculated maximum dietary burden suitable for estimating maximum residue levels in poultry tissues and eggs is 4.7 ppm and the calculated mean dietary burden suitable for estimating STMRs in poultry tissues and in eggs is 1.6 ppm. The residue levels of cyantraniliprole and metabolites included in the residue definition in eggs and tissue were calculated by estimation based on 3.0 ppm and 10 ppm feeding level, or extrapolation below the 3.0 ppm feeding level in the feeding studies.

Residues in kidney and liver at the expected dietary burden

	Feed level, ppm, for		Residue [a], mg/kg			
	Tissues residues	Eggs residues	Eggs	Muscle	Liver	Fat
Highest residue level, hens						
Feeding study [b]	3	3	0.151	0.009	0.098	0.014
	10	10	0.32	0.028	0.225	0.084
Calculated burden	4.7	4.7	0.13	0.014	0.13	0.031
STMR, hens						
Feeding study [c]	3	3	0.082	0.0075	0.0617	0.0159
Calculated burden	1.6	1.6	0.0426	0.0039	0.0321	0.0083

[a] Residue values used in estimating STMR are the sum of cyantraniliprole and metabolites IN-N7B69, IN-J9Z38, IN-MLA84 and IN-MYX98

[b] high residues for tissues and mean residues for egg

[c] mean residues for tissues and mean residues for egg

Residues of cyantraniliprole expected in poultry egg and tissues for use in estimating maximum residue levels are: 0.031 mg/kg (fat), 0.014mg/kg (muscle), and 0.13mg/kg (liver) and the mean residue for egg is 0.13 mg/kg.

The Meeting estimated maximum residue levels of 0.02 mg/kg for cyantraniliprole in poultry meat, 0.15 mg/kg for poultry offal, 0.04 mg/kg for poultry fat and 0.15 mg/kg for eggs. The Meeting estimated STMRs (parent plus metabolites) for dietary intake estimation are 0.004 mg/kg for meat, 0.032 mg/kg for edible offal, 0.008 mg/kg for fat and 0.043 mg/kg for egg. The Meeting withdrew its previous recommendations.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed are suitable for establishing maximum residue limits and for and for IEDI assessment.

CCN	**Commodity**	**Recommended Maximum residue level (mg/kg)**		**STMR or STMR-P mg/kg**	**HR or HR-P mg/kg**
		New	**Previous**		
VP 0526	Common bean (pods and/or immature seeds)	1.5		0.29	
VP 0062	Beans, shelled	0.3		0.07

[a] DM – Dry matter

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Daily Intake (IEDI) for cyantraniliprole was calculated for the food commodities for which STMRs or HRs were estimated and for which consumption data were available. The results are shown in Annex 3 to the 2015 Report.

The International Estimated Daily Intakes of cyantraniliprole for the 17 GEMS/Food regional diets, based on estimated STMRs were 2–20% of the maximum ADI of 0.03 mg/kg bw. The Meeting concluded that the long-term intake of residues of cyantraniliprole from uses that have been considered by the JMPR is unlikely to present a public health concern.

Short-term intake

The 2013 JMPR decided that an ARfD was unnecessary and concluded that the short-term intake of cyantraniliprole residues is unlikely to present a public health concern.

CYAZOFAMID (281)

The first draft was prepared by Dr Michael Doherty, United States Environmental Protection Agency, Washington, DC, USA

EXPLANATION

Cyazofamid (ISO common name, published) is a fungicide belonging to both the cyano-imidazole and sulphonamide classes of compounds. The biochemical mode of action is inhibition of all stages of fungal development. It is registered for control of and protection against Oomycete fungi. Cyazofamid was considered for the first time for toxicology and residues by the 2015 JMPR.

Note that throughout this document, values are listed to the precision provided in the submitted reports, except for method recoveries (whole number) and values calculated by the JMPR (two significant figures for processing factors and for combined residues of cyazofamid and CCIM). All rounding was in accordance with ISO standards.

IDENTITY

ISO common name	Cyazofamid (published)
Chemical Name	
IUPAC	4-chloro-2-cyano-N,N-dimethyl-5-*p*-tolylimidazole-1-sulfonamide
CAS	4-chloro-2-cyano-N,N-dimethyl-5-(4-methylphenyl)-1H-imidazole-1-sulfonamide
CIPAC No.	653
CAS No.	120116-88-3
Structural Formula	Molecular formula	$C_{13}H_{13}ClN_4O_2S$
Molecular mass	324.8

Physical and chemical properties

Cyazofamid is registered as a suspension concentrate (SC) formulation containing 400 g ai/L.

METABOLISM AND ENVIRONMENTAL FATE

Metabolism and environmental fate studies were conducted with cyazofamid labelled in either the imidazole (Im) or benzene (Bz) rings (Figure 1 and Figure 2, respective).

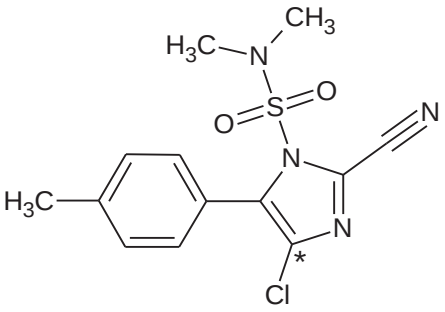

Figure 1. [imidazole-14C]cyazofamid

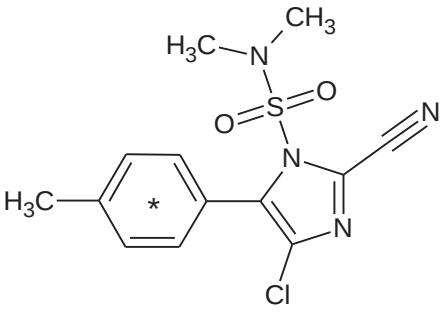

Figure 2. [benzene-14C]cyazofamid

Chemical names, structures, and code names of metabolites and degradation products of cyazofamid are shown below (Table 2). All of the compounds in Table 2 were identified in at least one matrix in studies with radiolabelled cyazofamid.

Table 2 Known metabolites and degradation products of cyazofamid

Code Names	Chemical name, molecular formula, molar mass	Structure	Where found ≥ 10% TRR
Cyazofamid	4-chloro-2-cyano-N,N-dimethyl-5-*p*-tolylimidazole-1-sulfonamide		Tomato Lettuce Potato (rinsate only) Confined rotational lettuce tops

Code Names	Chemical name, molecular formula, molar mass	Structure	Where found ≥ 10% TRR

Plant metabolism

The Meeting received studies depicting the metabolism of cyazofamid in grape, tomato, lettuce, and potato. All of the studies were conducted with cyazofamid which was radiolabelled, separately in the imidazole (Im) and the benzene (Bz) ring (see Figs. 1 and 2).

Grape

The nature of the residues of cyazaofamid in Pinot Noir grapes were investigated by Mamouni (1997, Report RA-3002). For each radiolabel position, five applications of cyazofamid, formulated as a suspension concentrate, were made to grapevines growing in the field. All five applications were at a rate of ca. 100 g ai/ha and were made at intervals of 21–25 days. Grapes were harvested 44 days after the last treatment (DAT). Harvested grapes were crushed and assayed for total radioactivity. The harvested grapes were also processed into wine, yielding vin de goutte, vin de presse, and marc, and into juice, yielding juice and pulp. Both types of wine were clarified using bentonite and/or centrifugation. Radioactivity was determined by combustion/LSC (grapes and solid material after preparation of wine and juice) or direct LSC [wine (raw and clarified) and juice]. Neither characterization nor identification of residues was reported in the study.

Mean (n=5) TRR in grapes was 0.31 mg eq./kg (0.62 % of applied) for the Im label and 0.53 mg eq./kg (0.89% of applied) for the Bz label. When the grapes were processed into wine, TRR (both labels) distributed as approximately 15% into vin de goutte (0.21 mg eq./L), 10% into

vin de presse (0.32 mg eq./L), and 70% into marc (3.7 mg eq./kg). A small amount (<6% TRR) of radioactivity was associated with the nylon bag used to press the grapes. Following clarification, 74 to 90% of the initial radioactivity remained in the vin de goutte and 50 to 60% remained in the vin de presse. When the grapes were processed into juice, TRR (both labels) distributed as 33% (0.30 mg eq./L) into juice and 54% (1.4 mg eq./kg) into marc. More radioactivity was retained by the nylon bag (12% TRR) used for juicing than the bag used for wine making.

Tomato

The metabolism of cyazofamid in tomato was investigated by Neal and Gupta (1999, Report RA-3009). For each radiolabel position, four applications of cyazofamid, formulated as a suspension concentrate (10% ai) and at rates of approximately 60, 95, 95, and 95 g ai/ha, were made at 7-day intervals to foliage of tomato plants grown in the field. At additional test plots, applications were made at exaggerated rates (nominally 4×). Samples from the exaggerate-rate trials were not analysed.

Mature tomato fruits and foliage were harvested 1 DAT. The harvested fruits were rinsed with ACN, homogenized, and centrifuged to separate juice from pulp. Radioactivity was determined by LSC for the rinsate and juice, and by combustion/LSC for the pulp. Residues in pulp were extracted with hexane, ethyl acetate, and H_2O, separately. Tomato rinsate, juice, and pulp extracts were subjected to various levels of clean-up and HPLC analysis. For juice, the TM-1 fractions from the HPLC analysis underwent ion exchange chromatography, hydrolysis of oligosaccharides, oxidation and reduction of sugars, dimedone adduction, esterification, and acetylation treatments to characterize the residues. Pulp samples were subjected to chemical treatments in order to fractionate the material into its cell wall components for determination of radioactivity in natural plant constituents.

The TRR in fruits, measured as a sum of residues in surface rinses, juice, and pulp were 0.080 mg eq./kg for the Im label and 0.290 mg eq./kg for the Bz label. Of the total residue, the majority was contained in the surface rinse (54% and 83% for the Im and Bz labels, respectively). Of the radioactivity remaining in the fruits, approximately 71-87% was in the pulp fraction. HPLC analysis indicated the presence of 18 metabolites. Across all sample components, cyazofamid was the only major residue, accounting for ca. 78% TRR (0.064 and 0.22 mg/kg). Other residues were < 6% TRR and < 0.02 mg eq./kg (Table 3).

[a] TRR and % TRR values are reported for fraction TM-6, which was found to contain, in part, CCBG.

Analysis of the TM-1 fraction showed incorporation of radioactivity into sugars (sucrose, glucose, and fructose) and citric acid (specific amounts not reported. Analysis of the post-extraction solids (PES) from the tomato pulp demonstrated incorporation of radioactivity in structural components (Table 4).

Results from foliage were similar to those from fruits and are not further evaluated herein.

Lettuce

The metabolism of cyazofamid in glasshouse-grown lettuce was investigated by Gupta and Song (2002, Report RA-3092). Three applications of cyazofamid, formulated as a suspension concentrate (10% ai) containing both the Bz and Im radiolabel in a 1:1 ratio, were made to lettuce at a nominal rate of 100 g ai/ha. Applications were made on a 14-day interval and the final application was two weeks prior to harvest of mature leaves.

Harvested lettuce samples were homogenized and the TRRs in each sample were determined by combustion analysis and LSC. Samples were extracted three times with ACN:H_2O (60:40, 0.1% acetic acid; v/v). Radioactivity in the extracts was determined by LSC and the extracted residues were analysed by HPLC. Metabolites were isolated from the extract by HPLC fraction collection. Fractions were subjected to acid and base hydrolysis, and ion-exchange chromatography. Radioactivity of PES was determined by combustion/LSC, followed by chemical treatments to isolate radioactivity in cell wall components.

Total radioactive residues were 0.85 mg eq./kg, of which 97% was extracted (Table 5). Analysis of the extracts showed parent to be the predominant residue. Four metabolites were identified, of which CCIM was the most abundant (0.31 mg/kg, 3.7% TRR). Other identified metabolites were < 0.01 mg/kg (<1% TRR). Analysis of the extract and the PES showed incorporation of radioactivity into natural products (0.028 mg eq./kg, 3.3% TRR and 0.022 mg eq./kg, 2.6% TRR, respectively).

Potato

The metabolism of cyazofamid in both field-grown and greenhouse-grown potato was investigated by Gupta (1999, Report RA-3008). For each radiolabel position, cyazofamid was formulated as a soluble concentrate (10% ai) and applications were made to the foliage of growing plants on a one-week interval, with the final application being 7 days before harvest. For the field study, three applications were made at rates of either 100 (1 plant) or 400 (3 plants) g ai/ha. For the greenhouse study, five applications were made at a rate of 400 (3 plants) g ai/ha.

Samples of potato tuber were harvested, washed gently with water to remove soil, and then air dried. Tubers were rinsed with ACN:H_2O (80:20, v/v) prior to homogenization and the radioactivity in the rinsate was determined by LSC. One subsample from the field study and two samples from the greenhouse study were peeled prior to homogenization to determine residue levels in peel. Tuber samples and one separated peel/pulp sample were extracted sequentially with ACN, ACN:H_2O (80:20, v/v), and ACN:H_2O (50:50, v/v). Radioactivity in each extract was assayed. Extractable residues were analysed by HPLC. PES were analysed for incorporation of radioactivity into natural products. Potato foliage samples were also harvested and analysed. Residue in foliage was ca. 97% parent compound; therefore, detailed evaluation is not presented herein.

The majority of the radioactivity remained with the tuber after the ACN:H_2O rinse (Table 6). Based on the samples from the greenhouse study, approximately 20% of the residue in the rinsed potato was associated with the peel. The result from the field study indicates 50%, but that figure may be less robust due to the low residue levels and the results reflecting only one plant.

Table 6 Average (n=3) total radioactive residues (mg eq./kg) in and on potato tubers following treatment with cyazofamid

	[Im-^{14}C]		[Bz-^{14}C]

Pulp (% of TRR in tuber)	--	79	--	78

[a] Results from one plant

The majority of the residue in the rinsate from the greenhouse 5×400 g ai/ha treatment consisted of cyazofamid (0.0009-0.0018 mg/kg, 67–80% TRR), with lesser amounts of CCIM (0.0003 mg/kg, 14–20% TRR; Table 7). For the tubers, three metabolite fractions were found in the extracts of peel and pulp. The majority of the radioactivity (0.005 mg/kg, ca. 30% TRR) was associated with a fraction that was shown to consist primarily of starch. The remaining two fraction were determined to be cyazofamid (0.001 mg/kg, 4.8% TRR) and CCIM (0.0002 mg/kg, 1% TRR). The balance of the radioactivity was not extracted.

Overall, the metabolism of cyazofamid in grape, tomato, lettuce, and potato is similar. The metabolic pathway proposed for grapes in the industry submission is provided as an illustrative example in Figure 3.

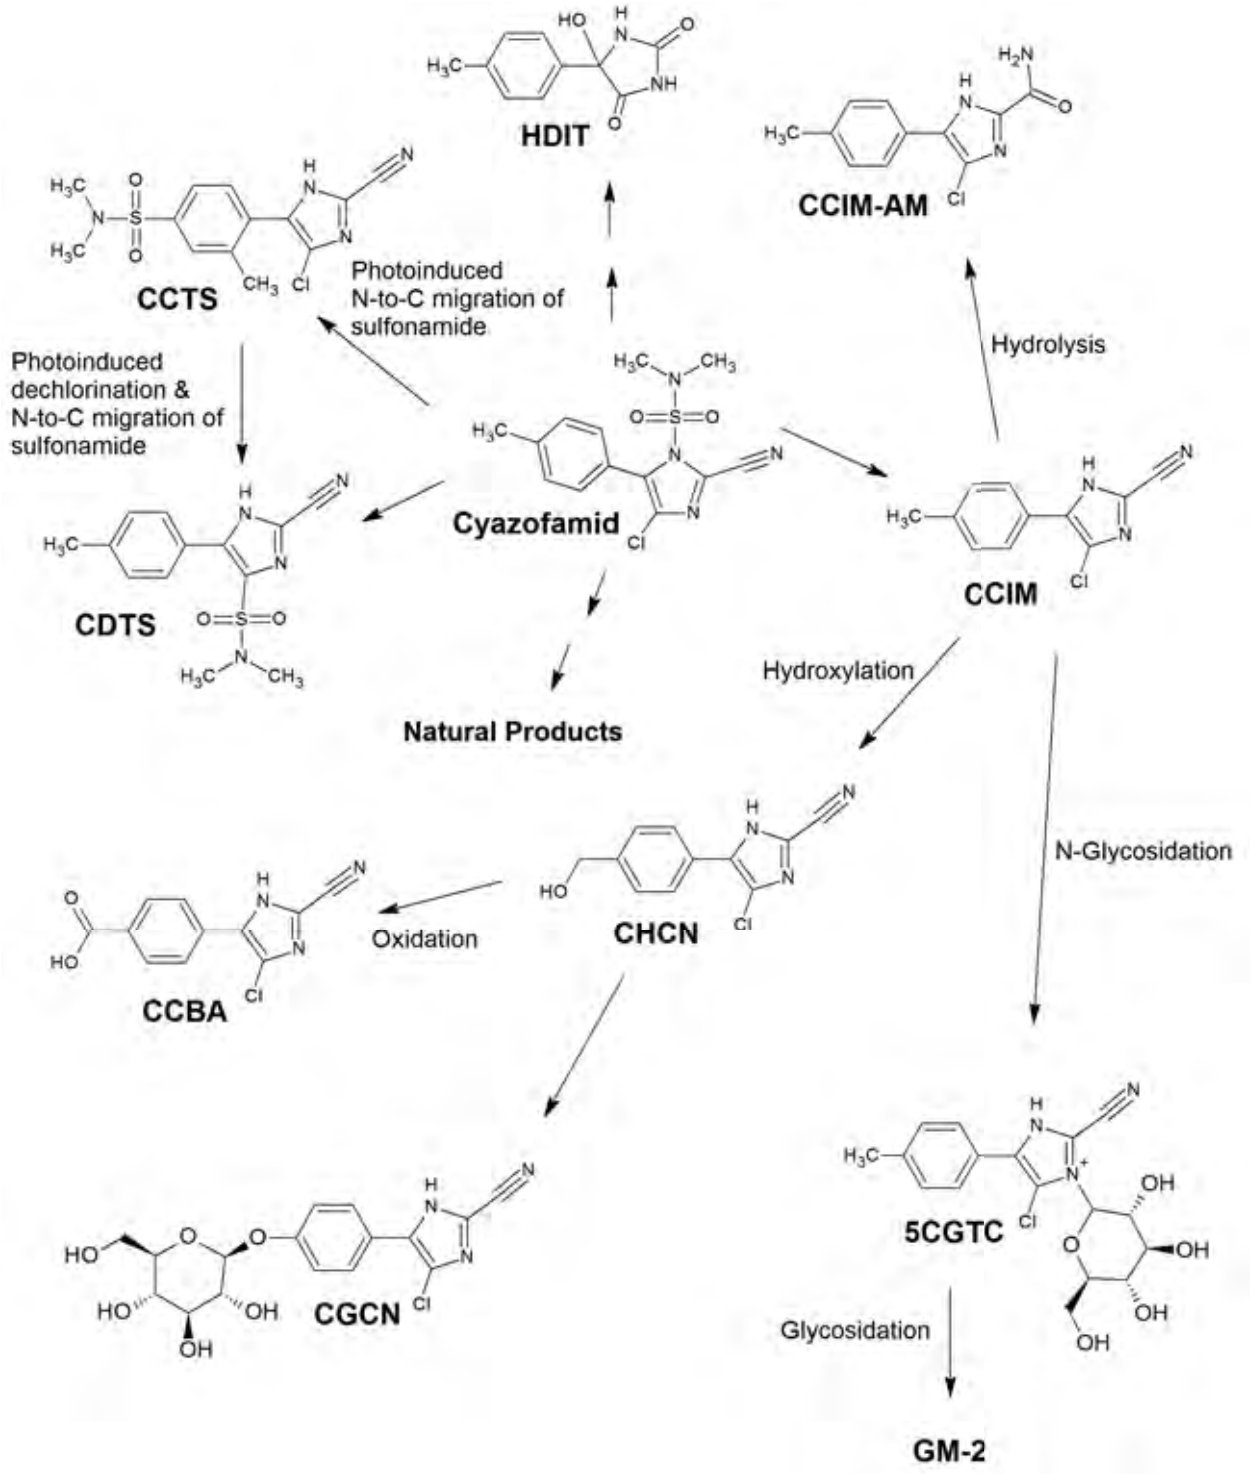

Figure 3 Proposed metabolic pathway of cyazofamid in target and rotational crops.

Animal Metabolism

The Meeting received metabolism studies on laboratory animals, lactating goats, and laying hens. All of the studies with laboratory animals, lactating goats, and laying hens were conducted with cyazofamid which was radiolabelled, separately, in the benzene ring [(u)Benzene-^{14}C; Bz] or the number 4 carbon of the imidazole ring [Imidazole-4-^{14}C; Im].

Laboratory animals

Examination of radioactivity following gavage dosing of Bz- and Im-radiolabelled cyazofamid to rats indicated that cyazofamid is well absorbed, with the majority of excretion occurring via urine. In a biotransformation study where blood, liver, and stomach (with contents) were analysed 0.5 hours after a dosing of [^{14}C-Bz] cyazofamid, most (97.2%) of the radiolabel in the stomach contents was the parent compound and a small fraction was CCIM. Analysis of the liver from this group showed only 6.1% of the radiolabel was cyazofamid, while 24.2% was CCIM and 41.9% was CCBA. In the plasma, there was no cyazofamid and the majority of radiolabel was CCIM. These data demonstrate that a dose of cyazofamid is rapidly metabolized, and that CCIM is a major metabolite in the initial metabolism of cyazofamid. At 0.5 hours after a dose of [^{14}C-Bz]-CCIM, all of the radiolabel in the stomach contents was CCIM, and most of the radiolabel in liver (76.5%) and plasma (67.9%) was CCIM. CCBA, the main metabolite seen in these tissues 0.5 hours after dosing with CCIM, was also found in the blood and liver from the animals dosed with cyazofamid. Concentrations in blood and liver were greater in the CCIM-dosed animals than that in cyazofamid treated animals, suggesting that CCIM was much more rapidly absorbed than cyazofamid.

Lactating goats

The metabolism of cyazofamid in lactating goats was investigated by Hatzenbeler and Savides (1998, Study RA-3001). For each radiolabel position, two goats were dosed for five days at 32.5 mg/day (Im) or 25.4 mg/day (Bz; both equivalent to ca. 10 ppm in the diet). Milk was collected twice daily, and excreta and stanchion washes were collected once daily throughout the study. Goats were terminated ca. 8 hours after the final dosing, at which point tissues and blood were collected for analysis.

Total radioactive residues (TRR) in urine stanchion wash, and milk were determined by direct liquid scintillation counting (LSC). The TRR in faeces, blood, and tissues was determined by combustion followed by LSC. Samples were processed differently, depending on the matrix. Milk from the Day 5 sampling was extracted twice with acetonitrile (ACN). The extract was then concentrated and the residues partitioned against hexane; the aqueous partition was concentrated prior to analysis by HPLC. Kidney, liver, and faeces were extracted once with ACN followed by two extractions with ACN:H_2O (50:50, v/v). The ACN and ACN:H_2O were concentrated, separately, and analysed by HPLC. The post-extraction solids (PES) were dried, combusted, and analysed by LSC to determine unextracted radioactivity. Liver PES were further processed by acid (1.0 M HCl) and base (1.0 M NaOH) hydrolysis and enzyme (protease) digestion, followed by LSC analysis and, in the case of the enzyme digest samples, HPLC. Muscle and fat samples were extracted two times with ACN:H_2O (75:25, v/v). The extracts were combined, concentrated, and analysed by HPLC. The PES were dried, combusted or solubilized, and analysed by LSC to determine unextracted radioactivity. The limit of detection for the LSC analysis was defined to be twice the disintegrations per minute of control samples, which translated to 0.001 to 0.005 mg eq./kg.

Four HPLC systems were used to analyse samples. All were reverse-phase systems using UV and radioactive flow detectors. The systems differed in the mobile phase gradients that were used, the specific column (though all were C-18), and the mobile phase modifiers (acetic acid or tetrabutylammonium bromide).

The total recovery of radioactivity was 58 and 60% of the administered dose (AD) for the Im and Bz labels, respectively (Table 8). The totals do not include the GI tract or its contents. Nearly 100% of the radioactivity was recovered in the excreta (99+%), with the principal residues being unchanged parent compound in faeces (ca. 85% TRR, ca. 7 mg eq./kg) and CCBA in urine (86-92% TRR, 1.6–2.2 mg eq./kg). Radioactivity in milk was low, ranging from 0.002 mg eq./kg to 0.010 mg eq./kg. The levels of TRR appeared to plateau for the Bz label by Day 2; however, the Im label showed a consistent increase over the five-day treatment period. Major metabolites (>10% TRR) identified in milk were CCBA (42% TRR, 0.004 mg eq./kg maximum on Day 5) and CCBA-AM (29% TRR, 0.002 mg eq./kg maximum on Day 5); all other identified residues in milk were <5% TRR (< 0.001 mg eq./kg). Radioactivity in liver was ca.

0.12 mg eq./kg, with CCIM-AM being the only major residue (12% TRR, 0.014 mg eq./kg). In kidney, the major residue was the cysteine conjugate of CCBA (70% TRR, 0.073 mg eq./kg). In muscle and fat, the major residues were CCBA and CCIM. In muscle, the two residues occurred at similar TTR levels (ca. 25%) and were low (≤ 0.002 mg eq./kg). In fat, CCBA occurred at higher levels than CCIM in terms of both relative (38–58% TRR vs. 26–33% TRR) and absolute (0.003–0.006 mg eq./kg vs. 0.002-0.003 mg eq./kg) amounts.

In summary, cyazofamid was not a significant residue in goat tissues or milk. The principal residues in were CCBA (free or cysteine-conjugated), CCIM, and their amide analogues. Although these metabolites are considered major residues based on percent of TRR, the absolute levels in mg eq./kg were generally low. The HPLC system used for most matrices

did not separate CCBA from its cysteine conjugate; however, the results from the analysis of kidney samples indicates that the cysteine conjugate likely makes up the majority of the CCBA-related residues. Extraction with ACN and/or ACN:H_2O extracted 73-101% of the radioactive residues from all matrices except liver (ca. 41%). Treatment of liver PES with acid, base, or enzymatic extraction released an additional 24-36% of the residue, of which a greater proportion partitioned into the aqueous or aqueous+emulsion fractions. Further identification was not possible due to low levels of radioactivity and matrix interferences. Analysis of the enzymatic extraction showed a number of radiolabelled components, none greater than 0.005 mg eq./kg. The proposed metabolic pathway in goats is summarized in Figure 4.

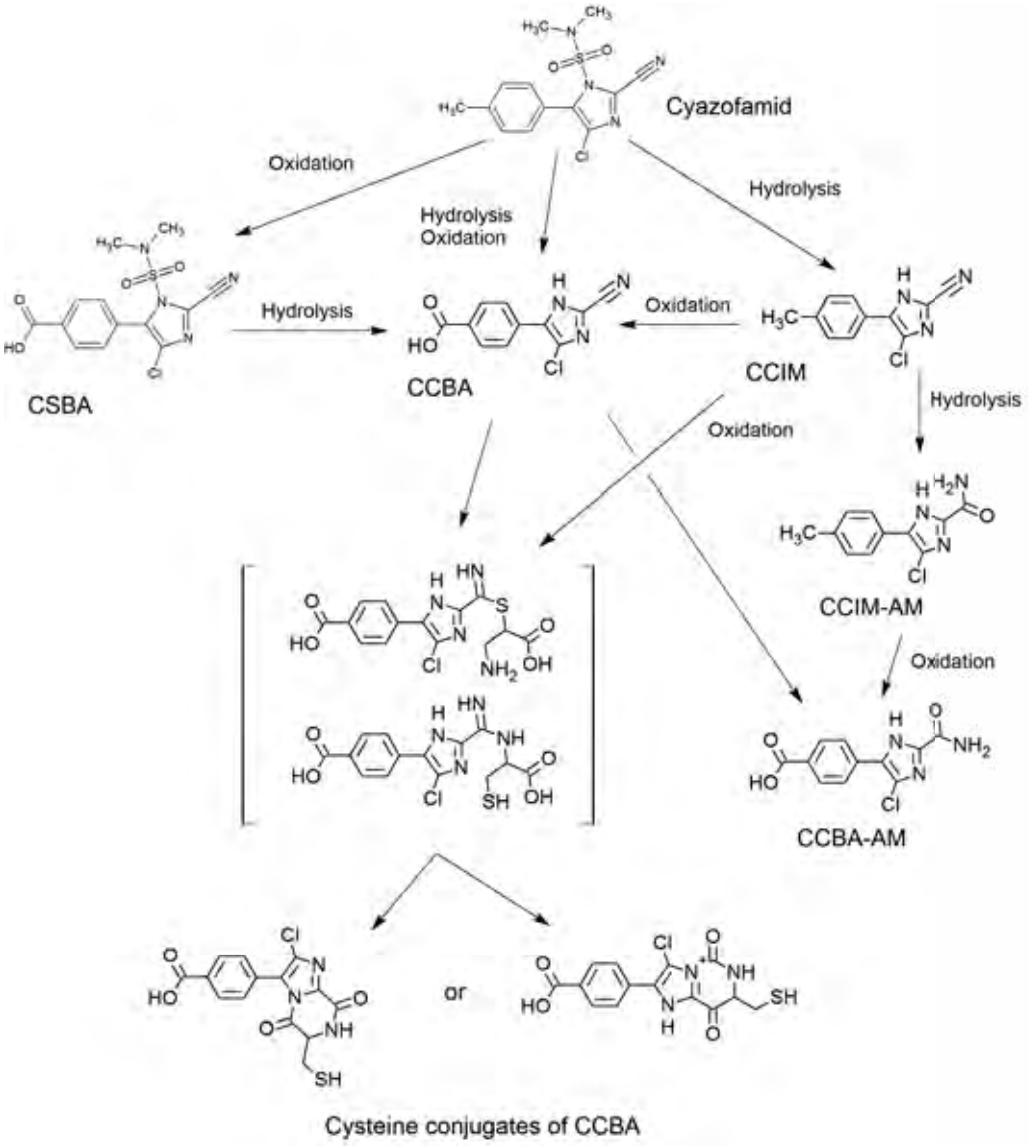

Figure 4 Proposed metabolic pathway of cyazofamid in lactating goat

Laying hens

The metabolism of cyazofamid in laying hens was investigated by Gupta and Bassett (1999, Study RA-3011). Cyazofamid was radiolabelled in the imidazole (Im) or benzene (bz) rings. For each radiolabel position, a group of ten hens was dosed for five consecutive days at ca. 1.1 mg/bird/day (equivalent to ca. 10 ppm in the diet). Eggs were collected twice daily, pooled based on test group from the evening and morning collections, and separated into yolks and whites. Excreta were

collected once daily throughout the study. Hens were sacrificed 9 hours after the final dosing, at which point tissues and blood were collected for analysis.

All samples were mixed or homogenized prior to subsampling for analysis. Tissues were homogenized in the presence of dry ice. Total radioactive residues were determined by combustion and LSC for all tissues and for egg white. The TRR of egg yolk was determined by direct LSC of solubilized sample. Excreta were extracted with ACN, and the TRR was determined by LSC of the extract and combustion/LSC of the PES. Samples of kidney and liver were each extracted with ACN (2×) followed by ACN:H_2O (50:50, v/v + 0.2-1% acetic acid; 2×). The PES from kidney, liver, and excreta were treated with 1.0 M HCl, protease, amylase, collagenase, 6.0 M HCl, and 1.0 M NaOH, in that order. The metabolic profiles of solvent-extracted liver, kidney, and excreta residues and 1.0 M HCl-extracted excreta residues were determined by HPLC. Samples of egg, breast muscle, thigh muscle, blood, fat, skin, and cage wash were not assayed for metabolite profiles due to the low level of radioactivity in those matrices. The limit of detection for the LSC analysis was defined to be twice the disintegrations per minute of control samples, which translated to 0.006 mg eq./kg. Approximately 30% of the TRR in liver and approximately 50% of the TRR in kidney was extracted. Further treatments of the PES quantitatively released the unextracted residues remaining from the solvent extraction.

Five HPLC systems were used to analyse samples. All were reverse-phase systems using UV and radioactive flow detectors. The systems differed in the mobile phase gradients that were used and the specific column (four C-18, one phenyl).

Approximately 90% of the administered dose was excreted and < 0.1% was accounted for in tissues (liver and kidney; Table 17). Residues identified in excreta were cyazofamid, CCBA, CCIM, CCTS, CHCN, and unidentified conjugates of CHCN. Total radioactive residues were < 0.006 mg eq./kg in all samples of eggs, muscle, blood, fat, and skin; as such, residue plateau in eggs could not be assessed. In kidney (

Table 18), the only major residues for both label positions were CHCN conjugates (15% TRR, 0.0044-0.0086 mg eq./kg), CCBA (12% TRR, 0.0035-0.0064 mg eq./kg), and unextracted residues (56% TRR, 0.017–0.031 mg eq./kg). In liver (Table 19), the only major residues were unextracted residues (75% TRR, 0.033–0.066 mg eq./kg). Further workup of the post-extraction solids in kidney and liver released the entire unextracted residue (104 and 109%, respectively) from the Bz label and nearly all from the Im label (95 and 87%, respectively). The majority of the residue was extracted with the 1 M HCl, protease, and amylase treatments (Table 20). In the 1 M HCl hydrolysate of kidney and liver PES, the major identified residues (Table 21) were CHCN conjugate (30-67%TRR) and CCBA (14% TRR; liver from Im label only). Residues of all fractions in the hydrolysate were ≤ 0.01 mg eq./kg and most were < 0.001 mg eq./kg.

In summary, the poultry metabolism study shows essentially no transfer of cyazofamid residues into poultry eggs, meat, fat, and skin, and only very little transfer of residues into poultry offal. CCBA and conjugates of CHCN were the only identified residues occurring at greater than 10% TRR in any matrix; even so, the absolute levels of these metabolites were low. The proposed metabolic pathway of cyazofamid in laying hens is portrayed in Figure 5.

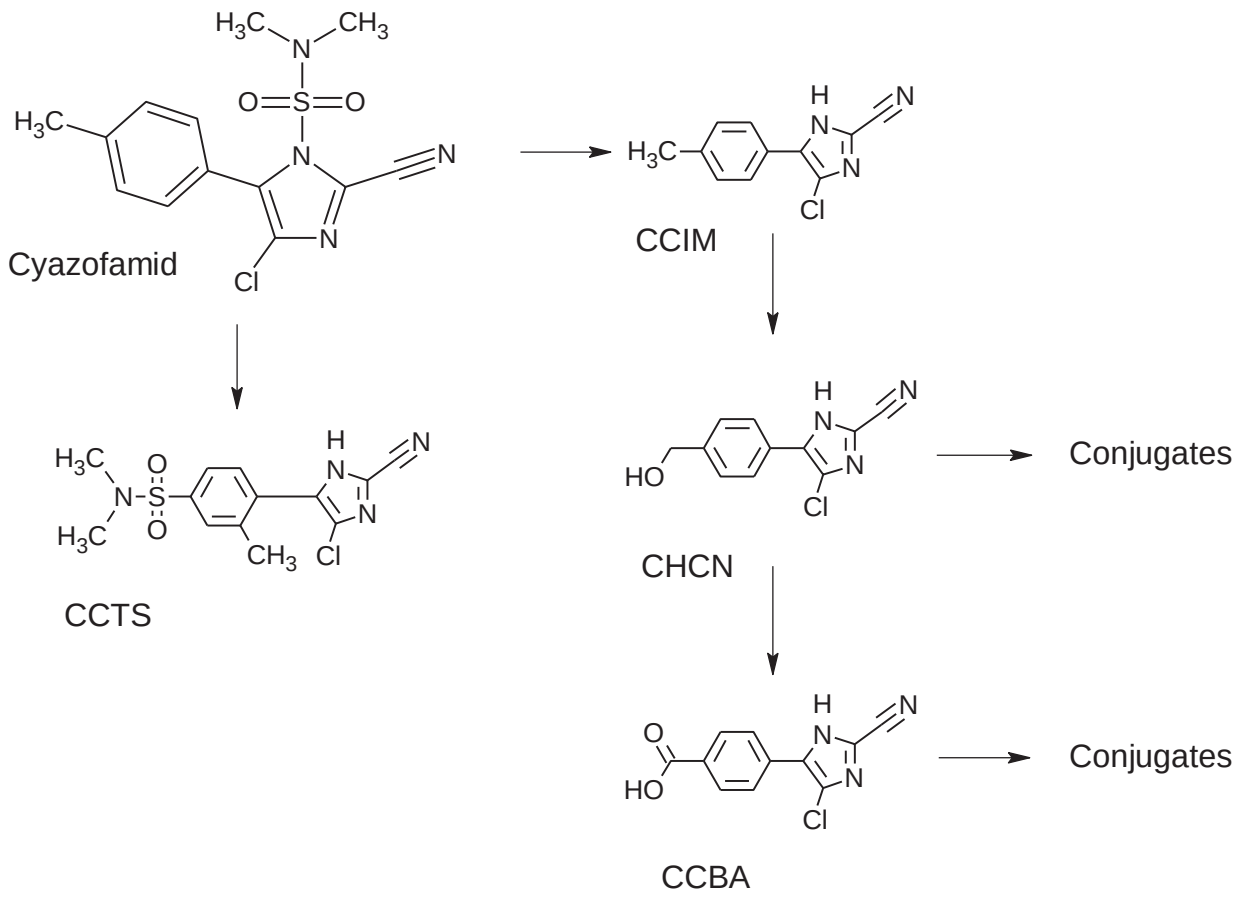

Figure 5 Proposed metabolic pathway of cyazofamid in laying hens

Environmental fate

The Meeting received studies for cyazofamid depicting the aqueous hydrolysis, aqueous and soil photolysis, aerobic soil metabolism, and a confined rotational crop study with carrot, lettuce, and wheat.

Hydrolysis

Hydrolysis of cyazofamid was investigated by I. S. Hendrix and T.R. Neal (1997, RA-4003; see Table 1).

The test material was hydrolysed, with half-lives ranging from 10.6 days to 13.3 days at 25 °C and from 0.39 to 0.55 days at 50 °C.

Hydrolysis of the cyazofamid metabolites CCIM, CCIM-AM, and CTCA was investigated in a separate study by T. Repko (1999, RA-4205). Each of the three compounds, radiolabelled in the benzene ring, was dissolved in sterile buffered solutions (pH 4, 7, and 9) with acetonitrile (< 1%) as a co-solvent. The solutions were maintained in darkness at 50±0.1 °C and sampled after 0 and 5 days. Hydrolysis of each test substance was minimal, as summarized in Table 22.

Table 22 Hydrolysis of cyazofamid metabolites at 50 °C

Photolysis

Photolysis of cyazofamid in **aqueous buffer** was investigated by Hendrix (1999, Report RA-4013; see Table 1). Cyazofamid degraded very rapidly, with a half-life of approximately 30 minutes. Cyazofamid also dissipated in the dark-control samples, with recovery falling to 21% by Day 26.

Photolysis of cyazofamid on the surface of a loamy sand **soil** was investigated by Shelby (1999, Report RA-4018). Cyazofamid, radiolabelled in either the benzene (Bz) ring or the imidazole (Im) ring, was applied to soil and exposed to simulated sunlight for 30 days (12-hr light/dark cycle). At intervals throughout the study, samples were extracted with ACN and water and analysed by radio-HPLC. Reference standards included in the study design were cyazofamid, CCIM, CCIM-AM, CHCN, CHCA, CCBA, CTCA, CTI, and CCIS

Mass balance recovery in the study was acceptable, ranging from 75 to 102% (Table 23). The proportion of unextracted residues increased during the 30-day exposure period. In the study, CCIM was formed from parent cyazofamid. The CCIM was then reduced to CCIM-AM and then oxidized to CCBA. CCBA underwent further degradation to unidentified products. As with the aqueous photolysis study, residues of cyazofamid in dark-control samples declined during the exposure period. Calculated first-order $DT_{50}$and DT_{90} times for cyazofamid were similar between the light-irradiated samples and their dark-control counterparts. Although the initial degradation of cyazofamid is not significantly impacted by photolytic processes, time-course data indicate that photolysis does impact the amount of CCBA metabolite present in the samples (

Table 24). Formation of CO_2 was minimal (12% Im, 3% Bz).

Aerobic soil metabolism

Two studies depicting the metabolism and degradation kinetics of cyazofamid in aerobic soils were submitted. In the first, Hartman (1997, Report RA-4004) treated a loamy sand soil with benzene- (Bz) or imidazole- (Im) radiolabelled cyazofamid to a level of 0.1 mg/kg. After thorough mixing, the soils samples were placed into a metabolism apparatus (dark conditions, 20 °C) and analysed 0, 1, 3, 5, 10, 15, 20, 26, 30, 44, and 59 days after treatment. In the second study (Hartman, Korsch, and Lentz, 1999, Report RA-4012), a sandy loam soil (20 °C), a sandy soil (20 °C and 10 °C), and a loamy sand soil (20 °C) were treated in the same manner as the first study and incubated under aerobic conditions for 30 or 45 days (20 °C) or 110 days (10 °C), with samples taken intermittently for analysis.

In both studies, soil samples were extracted twice with ACN/H_2O (80/20, v/v), and the extracts were analysed for total radioactivity by LSC. At later sampling times (first study ≥ Day 20, second study ≥ Day 7), additional extractions were done with ACN/H_2O (50/50, v/v) followed by 0.1N NaCl. All extracts were analysed by HPLC. Radioactivity in the PES was determined by combustion/LSC. In addition, PES from the 10- and 59-Day samples in the first study were fractionated into their various organic matter constituentsand the radioactivity in those fractions was assayed combustion/LSC or direct LSC.

Mass balance from both studies was acceptable. Average recovery of radioactivity across extracted, unextracted, and CO2 fractions and across all soils, temperatures, and sampling times ranged from 96% to 100% of applied. Over the time course of the studies, unextracted residues increased from < 5% of applied material at Hour 0 to 35–64% at termination. Similarly, 14CO2 increased from 0% of applied radioactivity at the onset of the incubation period to 14% at study termination. Results from the first and second studies from incubations at 20 °C gave similar DT50 estimates of approximately 5 days. Estimated DT90 values were more diverse, ranging in the first study from 16 to 25 days and in the second study from 35 to 39 days. Dissipation times were longer at the 10 °C incubation temperature, averaging 16 days for DT50 and > 110 days for DT90. Degradates identified in the two studies were CCIM, CCIM-AM, and CTCA. All occurred at ≥ 10% of the applied radioactivity at some point in the study; as such, they would be ≥ 10% TRR and are considered to be major degradates. In terms of relative kinetics, parent compound appears to first degrade to CCIM, which peaks early in the temporal profile, followed by CCIM-AM. Degradate CTCA forms last; data are inconclusive of whether CTCA has peaked by study termination. Characterization of the PES from the first study showed association of radioactivity predominantly with fulvic acid and to a lesser extent humin and humic acid.

Confined rotational crop studies

The fate of cyazofamid as it relates to rotational crops was investigated by McFadden (1999, Report OR-4019). In that study, carrot, lettuce, and wheat were planted into a loamy sand soil that had been treated with cyazofamid, radiolabelled in either the benzene (Bz) or imidazole (Im) ring, at a rate of ca. 500 g/ha (100 g/ha×5 applications at 7-day interval). The crops were planted into the soil at 31, 120, and 360 days after treatment. At each plant-back interval (PBI), samples of immature and mature crop were collected.

Harvested samples were homogenized in the presence of dry ice and stored frozen (≤ 7 days) prior to analysis. Total radioactive residues in each sample were determined by combustion. Further analysis of the samples was determined by their TRR levels: <

0.01 mg eq./kg, no further analyses were attempted; between 0.01 and 0.05 mg eq./kg, samples underwent limited solvent extraction; and > 0.05 mg eq./kg, samples underwent a more exhaustive extraction. Limited extraction consisted of three extractions with ACN/0.1% formic acid (9/1, v/v) followed by partitioning against methylene chloride. Extracts and PES were analysed for radioactivity by LSC (combustion/LSC for PES). The aqueous fraction was neutralized with 0.2 M potassium carbonate, concentrated, and filtered prior to carbohydrate analysis by HPLC. The more exhaustive extraction was performed on the organic fraction by diluting it with 0.1 N formic acid to make a 1:4 solvent:formic acid solution, and then partitioning it twice with ethyl acetate and cleaned up by solid-phase extraction. All eluents from solid-phase extraction were assayed by LSC and ACN/H_2O eluates were analysed by HPLC. Residues in PES from wheat tissues were characterized by acid hydrolysis in addition to combustion analysis.

Total radioactive residues in the rotational crops are shown in Table 25. In all samples, residues resulting from the Im treatment were greater than those from the Bz treatment. Decreases in TRR were generally modest between the 31- and 120-day PBIs and then more pronounced between the 120- and 360-day intervals. Characterization of residues is based on residues in the 31- and 120-day PBI samples due to the low levels of radioactivity in the 36-day PBI samples.

Mass balance of radioactivity was generally adequate, with recovery of radioactivity from the aqueous fraction, the organic fraction, and PES, combined, ranging from 61 to 123% of the TRR. Low recoveries were associated with highly pigmented extracts and may be due to quenching during LSC rather than actual low recovery.

Table 25 Summary of TRRs in rotational crops at each plant-back interval following application of cyazofamid

Crop	Harvest (DAT)			TRR (mg eq./kg) [Im-^{14}C]			[Bz-^{14}C]		
PBI (DAT)	31	120	360	31	120	360	31	120	360
Carrot (immature)	94	202	460	0.059	0.025	0.011	0.017	0.020	0.005
Carrot (foliage)	150	228	511	0.074	0.045	0.018	0.019	0.019	0.005
Carrot (root)	150	228	511	0.018	0.010	0.003	0.009	0.006	0.002
Lettuce (immature)	86	145	448	0.037	0.022	0.004	0.016	0.009	0.002
Lettuce (mature)	108	179	479	0.015	0.008	0.006	0.005	0.004	0.007

Wheat (chaff)	251	291	571	0.269	0.289	0.017	0.046	0.027	0.012
Wheat (straw)	251	291	571	0.498	0.209	0.031	0.126	0.085	0.015
Wheat (grain)	251	291	571	0.090	0.062	0.002	0.024	0.014	0.001

DAT = Days after last treatment.

Total radioactivity in extracts from lettuce (all PBIs), carrot (120- and 360-day PBIs), and wheat grain (all PBIs) was low, and samples were not further analysed to determine the nature of the residues. HPLC analysis of carrot tops (Im label only) from the 31-day PBI showed residues of CCBA (2.2% TRR), CCIM (10.4% TRR), CCIM-AM (39.5% TRR, 0.001 mg/kg), and cyazofamid (20.1% TRR, 0.003 mg/kg). Radioactivity in wheat forage and chaff was associated primarily with carbohydrates (0.01-0.195 mg eq./kg); levels of cyazofamid and metabolites were ≤ 0.003 mg eq./kg. Similar results occurred for wheat straw. The proposed metabolic pathway for cyazofamid in rotational crops was included previously in Figure 3.

RESIDUE ANALYSIS

Summary of analytical methods

Methods for the analysis of cyazofamid and CCIM used in the residue trials are generally the same, consisting of solvent extraction (usually acetonitrile) followed by partitioning and solid-phase extraction clean-up steps. Analysis of the residue was most frequently accomplished using LC-

MS/MS, although some studies used HPLC-UV or GC-NPD. The methods are summarized in Table 26. The LC-MS/MS and HPLC-UV methods underwent independent laboratory validation and appear to be suitable for enforcement purposes.

Table 26 Overview of the analytical methods submitted for cyazofamid and CCIM

[a] Defined as the lowest limit of method validation.

Plant materials

Methods used for the analysis of residues of cyazofamid and CCIM in plant materials in residue trials are all very similar (see Table 26). Extraction of homogenized sample is by a relatively polar solvent followed, in most cases, by partitioning of the residue into a non-polar solvent. Further clean-up is by solid-phase extraction using various sorbents. Most of the methods use either LC-MS/MS or HPLC-UV for separation and detection of the analytes. Method validation recoveries across all matrices and fortification levels (0.01–100 mg/kg) ranged from 63 to 128%, with a weighted average and relative standard deviation of 90±8% (Table 27).

Three methods underwent independent laboratory validation and were determined to be suitable for compliance purposes. In the first method, validated using bulb onion, lettuce, and green hops (Study RA-1177), cyazofamid and CCA are extracted by homogenizing the sample in 120 mL of acetonitrile/acetone (8/2, v/v), isolating the extract by vacuum filtration, and reducing the volume of the extract to 5 mL by rotary evaporation. Clean-up of the extract is by C-18 solid-phase extraction, and analysis of the residues is by LC-MS/MS on a C-18 column with an isocratic mobile phase consisting of acetonitrile (80%) and 0.2% acetic acid in water (20%). Mass transitions [$M+H^+$] of 325.1 m/z→108.0 m/z for cyazofamid and 218.3 m/z→183.2 m/z for CCIM are used for quantification. Confirmation of cyazofamid is made using the same ion transitions but with a cyano column on a gradient mobile phase. Confirmation of CCIM is based on a mass transition of 218.3 m/z→139.2 m/z. A confirmatory transition for cyazofamid is available (325.1 m/z→261.2 m/z).

In the second method, validated using barley grain and olive (Study RA-1177), cyazofamid and CCIM are extracted by shaking samples in 10 mL water followed by 10 mL acetonitrile (barley), or 10 mL acetonitrile only (olive). The extracts are then cleaned up using dispersive solid-phase extraction (onto magnesium sulfate, sodium chloride, sodium citrate dibasic sesquihydrate, and sodium citrate tribasic dihydrate). Analysis of the residues is the same as described in the first method.

In the third method, validated using tomato (Study RA-3062), cyazofamid and CCIM are extracted with acetonitrile. Co-extracted materials are then partitioned into hexane, which is discarded. Residues in the acetonitrile portion are then concentrated by rotary evaporation. A second partitioning is then done using sodium sulfate (2%) and methylene chloride. The methylene chloride phase is retained and evaporated to dryness. Residues of cyazofamid and CCIM are dissolved in ethyl ether and cleaned up by passing over a Florisil® column. After elution from the column, the ethyl ether is evaporated and the residues dissolved in acetonitrile/0.5% ascorbic acid in water (1/1, v/v) for analysis by HPLC-UV. Separation is achieved on a C18 column using a mobile phase of acetonitrile/0.5% ascorbic acid in water (1/1, v/v); detection is a 280 nm.

Table 27 Summary of analyte recoveries from method validations of methods for cyazofamid and CCIM

Stability of residues in stored samples

The stability of cyazofamid and CCIM in frozen storage has been investigated in bean, grape (homogenized and unhomogenized; cyazofamid only), oilseed rape, potato, and tomato. For all matrices except grape, samples were spiked, separately, with cyazofamid and CCIM. Samples were placed into frozen storage and analysed after varying durations in frozen storage to determine the amounts of analyte remaining in the sample. For grape, a large sample of was collected from a field trial location and split into two subsamples. One subsample was homogenized and the other was maintained as whole, unhomogenized grapes. Both subsamples were placed into stored frozen.

Incurred residues of cyazofamid were analysed at various storage durations to determine the amount of compound remaining.

Residues of both analytes were stable (≥ 70% remaining) for at least 400 days in beans and oilseed rape, and for up to 181 days in potato. In tomato, cyazofamid was stable for up to 365 days and CCIM was stable for at least 1093 days. In grape, residues of cyazofamid appeared to be more stable in unhomogenized matrix, generally showing > 70% remaining for the 365-day duration of the study versus homogenized matrix, in which the percent remaining was generally <70% at sampling times greater than 8 days. Interpretation of the cyazofamid stability data in grape is complicated by the experimental design and the variability in residue levels, especially for the unhomogenized grape subsample.

In addition to the specific storage stability studies summarized above, a storage stability component was included in the experimental designs of studies conducted by IR-4. The storage stability data from these studies do not include analysis of residues at 0 days. If fortifications were made correctly, the data indicate that under frozen storage conditions, cyazofamid and CCIM are stable for at least 860 days in cabbage; for at least 634 days in lettuce; for at least 977 days in mustard greens; for at least 949 days in spinach; at least 887 days in bean pods with seeds, at least 889 days in bean plants with pods, and at least 140 days in ben seeds without pods; and at least 509 days in hops cones. Cyazofamid was stable for at least 284 days in fresh basil and 297 days in dried basil; however, CCIM was not stable in either commodity (47% remaining in fresh basil and 59% remaining in dried basil). Neither cyazofamid nor CCIM were shown to be stable in carrot, with 58% cyazofamid and 38% CCIM remaining after 374 days in storage.

[a] Do not apply more than 480 g ai/ha/season

[b] Do not apply more than 790 g ai/ha/season. Can be applied to basil grown in a glasshouse

[c] Make a single soil application followed by 5 foliar applications. Do not apply more than 1.15 kg ai/ha/season

[d] Do not apply more than 480 g ai/ha/season. Do not apply to cowpeas used for livestock feed

[e] Do not apply more than 877 g ai/ha/season

[f] Last 2 applications to be made at maximum rate, plant-back interval 30 days

[g] Do not apply more than 800 g ai/ha/season; Last 2-3 applications to be made at maximum rate

[h] Crop Group 5 = Broccoli; broccoli, Chinese (gai lon); broccoli raab (rapini); Brussels sprouts; cabbage; cabbage, Chinese (bok choy); cabbage, Chinese (napa); cabbage, Chinese mustard (gai choy); cauliflower; cavalo broccolo; collards; kale; kohlrabi; mizuna; mustard greens; mustard spinach; and rape greens

[I] Crop Group 9 = Chayote (fruit) ; Chinese waxgourd (Chinese preserving melon) ; citron melon ; cucumber ; gherkin ; gourd, edible (includes hyotan, cucuzza, hechima, Chinese okra); Momordica spp. (includes balsam apple, balsam pear, bitter melon, Chinese cucumber); muskmelon (hybrids and/or cultivars of Cucumis melo; includes true cantaloupe, cantaloupe, casaba, crenshaw melon, golden pershaw melon, honeydew melon, honey balls, mango melon, Persian melon, pineapple melon, Santa Claus melon, and snake melon); pumpkin ; squash, summer (includes crookneck squash, scallop squash, straightneck squash, vegetable marrow, zucchini); squash, winter (includes butternut squash, calabaza, hubbard squash, acorn squash, spaghetti squash); and watermelon

[j] Crop Group 8-10 = African eggplant; bush tomato; cocona; currant tomato; eggplant; garden huckleberry; goji berry; groundcherry; martynia; naranjilla; okra; pea eggplant; pepino; pepper, bell; pepper, nonbell; roselle; scarlet eggplant; sunberry; tomatillo; tomato; tree tomato

[k] Crop Subgroup 4A = Amaranth; arugula; chervil; chrysanthemum, edible-leaved; chrysanthemum, garland; corn salad; cress, garden; cress, upland; dandelion; dock; endive; lettuce; orach; parsley; purslane, garden; purslane, winter; radicchio (red chicory); spinach; spinach, New Zealand; spinach, vine

[l] Crop Subgroup 1C = Arracacha; arrowroot; artichoke, Chinese; artichoke, Jerusalem; canna, edible; cassava, bitter and sweet; chayote (root); chufa; dasheen; ginger; leren; potato; sweet potato; tanier; turmeric; yam bean; yam, true

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received data from supervised residue trials conducted on grape, basil, hops, broccoli, cabbage, cucumber, summer squash, muskmelon, peppers, tomato, head and leaf lettuce, mustard greens, spinach, snap bean, lima bean, carrot, and potato. In all trials, a soluble concentrate (SC) formulation was applied as a tank mixture prepared uniquely for that trial site. Trials were conducted in the USA for all crops. In addition, trials on grapes were conducted in Argentina, Mexico, Northern Europe, and Southern Europe; trials on lettuces were conducted in Canada; trials on potato were conducted in Canada and Brazil; and trials on hops were conducted in Germany and the USA. Trials on basil included field-grown and glasshouse-grown crops.

The field trial reports included method validation data, as recoveries from spiked samples at levels reflecting those observed in the field trial samples; dates from critical events during the study, including application, harvest, storage, and analysis; as well as detailed information on the field site and treatment parameters. Analytical reports were sufficiently detailed and included example chromatograms and example calculations. Samples were analysed by the methods described above. The results are supported by concurrent recoveries ranging, across all commodities, 77–95% ± 4–21% (mean ± RSD) for cyazofamid and 86–101% ± 5–19% for CCIM. The maximum durations for samples in frozen storage were:

- Grape = 295 days,
- Broccoli = 773 days,
- Cabbage = 860 days,
- Cucumber = 552 days,
- Summer squash = 535 days,
- Muskmelon = 278 days,
- Peppers = 272 days (bell) and 268 days (non-bell),
- Tomato = 455 days,
- Lettuce = 634 days (head) and 624 days (leaf),
- Mustard greens = 965 days,
- Spinach = 927 days,
- Snap bean = 945 days,
- Lima bean = 147 days,
- Carrot = 443 days,
- Potato = 535 days,
- Basil = 284 days (fresh) and 297 days (dried), and
- Hops = 552 days.

Except for carrot (cyazofamid and CCIM) and basil (CCIM only), the storage durations are less than or equal to those for which residues have been demonstrated to be stable. Unless otherwise noted in the tables below, harvested commodities were maintained whole in the field and not cut or homogenized until they reached the analytical laboratory.

The field trial study designs included control plots. All measured residues from control plots were < 0.01 mg/kg (i.e., < LOQ) and are not included in the summary tables in this evaluation. In the summary tables, values used for making maximum residue level recommendations are underlined, values used for dietary intake estimates are italicized, and highest individual values for estimating dietary intake are bolded. Trial locations that appear to be dependent are grouped by a heavy cell border in the tables (e.g., Table 36).

Supervised trials for cyazofamid:

Category	Crop	Table
Berries and other small fruits	Grape (FB 0269)	35
Brassica (cole or cabbage) vegetables, head cabbage, flowerhead Brassicas	Broccoli (VB 0400)	36
	Cabbage (VB 4175)	37
Fruiting vegetables, cucurbits	Cucumber (VC 0424)	38
	Summer squash (VC 0431)	39
	Muskmelon (VC 4239)	40
Fruiting vegetables, other than cucurbits	Peppers (VO 0051)	41
	Tomato (VO 0448)	42
Leafy vegetables (including Brassica leafy vegetables)	Lettuce, head/leaf (VL 0482/VL0483)	43
	Mustard greens (VL 0485)	44
	Spinach (VL 0502)	45
Legume vegetables	Lima bean, young pods and/or immature beans(VP 0534)	46
	Snap bean, young pods (VP 4453)	47
Root and tuber vegetables	Carrot (VR 0577)	48
	Potato (VR 0589)	49
Herbs	Basil (HH 0722)	50
Dried herbs	Hops, dry (DH 1100)	51

[a] Molecular weight ratio cyazofamid:CCIM = 1.49. Combined = Cyazofamid residue + (CCIM residue × 1.49)

FATE OF RESIDUES IN STORAGE AND PROCESSING

Nature of the residue during processing

High-temperature hydrolysis

High-temperature hydrolysis of cyazofamid was investigated by J. Bernal (2014, RA-3186). In the study, [^{14}C]cyazofamid (radiolabel position not specified) was spiked into buffered solutions, in triplicate, at a target concentration of 1 mg/L. The spiked solutions were put into conditions, in the dark, simulating pasteurisation (90 °C, pH 4, 20 min.); baking, brewing, boiling (100°C, pH 5, 60 min); and sterilisation (120 °C, pH 6, 20 min.). Prior to and after processing, an aliquot from each sample was collected and analysed by LSC for total radioactivity and by radio-HPLC for determination of hydrolysis products. Mass balance of radioactivity after processing was 102, 107, and 116% for 90 °C/pH4, 100 °C/pH5, and 120 °C/pH6, respectively. The correlation between temperature and mass balance was surmised in the study report to be due to better solubilisation after heating.

Radio-HPLC analysis showed a single peak prior to processing and two peaks after processing. The second peak was shown to be the cyazofamid metabolite CCIM. Under pasteurisation conditions, most of the cyazofamid was converted to CCIM; under the other two conditions tested, 100% of the test material converted to CCIM (Table 52).

Residues after processing

The Meeting received data depicting residues of cyazofamid and CCIM in raw and processed commodities of basil, hops, grape, tomato, and potato.

For basil, fresh leaves and stem from field trial samples (see Table 50[a] Molecular weight ratio cyazofamid:CCIM = 1.49. Combined = Cyazofamid residue + (CCIM residue × 1.49)

) were dried according to "local commercial practices," with a recommended procedure of placing the sample in a drier, at 43–49 °C, for 24 hours. Stability of CCIM has not been demonstrated for the storage durations used in the study.

[a] Molecular weight ratio cyazofamid:CCIM = 1.49. Combined = Cyazofamid residue + (CCIM residue × 1.49)

Hop cones from plots treated six times at 96–201 g ai/ha were harvested, dried, and processed into beer. Dried cones were stored, frozen, for ca. 90 days prior to processing into beer. Residues of both cyazofamid and CCIM were reduced upon processing (Table 54).

In one of the grape studies conducted in the USA (RA-3058), grapes harvested from trials approximating the USA GAP were processed into raisins by sun drying for 37 days. Residues of cyazofamid and CCIM decreased during processing of grapes into raisins. Grapes/raisins from this study were stored frozen for a total of 249 days from sampling to analysis. For both cyazofamid and CCIM, the processing factor is <1, indicating that residues are reduced upon processing.

In grape trials conducted in France (RA-3082), Germany (RA-3083), and Italy (RA-3086), samples of treated grapes were processed into must and wine using simulated commercial practices suitable for each grape type and region. In the case of France, wine was divided into young wine and mature wine, and both must and wine were assayed before and after pasteurisation. In the trial from Germany, wine was divided into young and mature wine; processed products were not pasteurised. Frozen storage time for must and wine samples ranged from 237 to 412 days. For must, the processing factors for cyazofamid were rather variable, ranging from 0.21 to 2.3. There is a trend for cyazofamid to concentrate in must from red varieties but not in must from white varieties. NOTE: Method issue for raisins

Tomatoes for processing were obtained from a field trial which received five applications at the target rate and a final application at a 3X exaggerated rate (RA-3065). Samples were processed into paste and puree (RA-3065) using simulated commercial practices. Residues of cyazofamid did not show concentration in either paste or puree; however, residues of CCIM may concentrate in those commodities.

For potato, samples of tubers taken from a field-trial plot receiving nine applications at the target GAP rate and a tenth application at a 10× exaggerated rate were processed into wet peels, potato flakes, and potato chips (RA-3066). The processing followed simulated commercial practices. Samples were stored frozen from 95 to 422 days. Residues were <LOQ in all samples; therefore, meaningful processing factors could not be calculated.

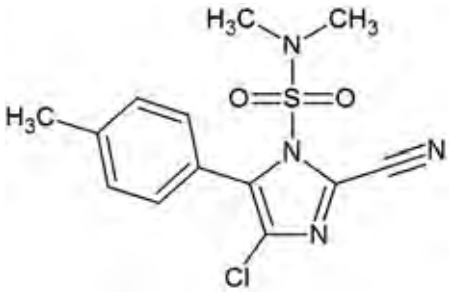
APPRAISAL

Cyazofamid (ISO common name, published) is a fungicide belonging to both the cyano-imidazole and sulphonamide classes of compounds. The biochemical mode of action is inhibition of all stages of fungal development. It was considered for the first time by the 2015 JMPR for toxicology and for residues.

The IUPAC name for cyazofamid is 4-chloro-2-cyano-*N*,*N*-dimethyl-5-*p*-tolylimidazole-1-sulfonamide and the CA name is 4-chloro-2-cyano-N,N-dimethyl-5-(4-methylphenyl)-1H-imidazole-1-sulfonamide, with registry number 120116-88-3.



Cyazofamid with ^{14}C radiolabelling in the benzene ring or in the imidazole ring was used in the metabolism and environmental fate studies. In this appraisal, these positions are referred to as the Bz and Im labels, respectively.

The following abbreviations, along with IUPAC names and structures, are used for the metabolites discussed in this appraisal:

CCBA	4-(4-chloro-2-cyanoimidazol-5-yl)benzoic acid	
CCBA (cysteine conjugates)		CCBA-AM	4-(4-chloro-2-amidoimidazol-5-yl)benzoic acid	CCIM	4-chloro-5-p-tolylimidazole-2-carbonitrile	CCIM-AM	4-chloro-5-p-tolylimidazole-2-carboxamide	CHCN	4-chloro-5-(4-hydroxymethylphenyl) imidazole-2-carbonitrile	CTCA	4-chloro-5-p-tolylimidazole-2-carboxylic acid	
Plant metabolism

The Meeting received studies depicting the metabolism of cyazofamid in grapes, tomatoes, lettuce, and potatoes. All of the studies were conducted with cyazofamid which was radiolabelled, separately, in the benzene and imidazole rings.

Cyazofamid was applied five times, at ca. 100 g ai/ha at 21–25-day intervals, to grapevines growing in the field. Grapes were harvested 44 days after the last application (DALA). TRR in grapes was greater following treatment with Bz-labelled material (0.53 mg eq/kg, 0.89% of applied) than with Im-labelled material (0.31 mg eq/kg, 0.62% of applied). When processed into wine, radioactivity distributed primarily into the marc (wet pomace; 70% TRR, 3.7 mg eq/kg), with significantly lesser amounts in the vin de goutte (juice prior to pressing; 15% TRR, 0.21 mg eq/L) and vin de presse (juice after pressing; 10% TRR,

0.32 mg eq/L), indicating radioactivity may have been associated with surface residues. For grapes processed into juice, a similar trend was observed: 54% TRR (1.4mg eq/kg) in the marc and 33% TRR (0.3 mg eq/L) in the juice. Neither characterization nor identification of residues was reported in the study.

Metabolism of cyazofamid on tomatoes was investigated following treatment of field-grown plants with four foliar applications of cyazofamid at approximately 60, 95, 95, and 95 g ai/ha at 7-day intervals. In fruits harvested 1 DALA, TRR (surface rinses + juice + pulp) was 0.08 mg eq/kg from the Im treatment and 0.29 mg eq/kg from the Bz treatment. Of the total residue, the majority was contained in the surface rinse (54% and 83% for the Im and Bz labels, respectively). Of the radioactivity remaining in the fruits after rinsing, 71–81% TRR (ca. 0.033 mg eq/kg) was associated with the pulp and 13–29% TRR (ca. 5.5 mg eq/kg) was associated with the juice. Extraction of the pulp with, sequentially, hexane, ethyl acetate, and water released 75% of the radioactivity from the Bz-labelled sample and 90% from the Im-labelled sample. The principal residue from both labels was parent cyazofamid (ca. 78% TRR; 0.064 mg eq/kg Im, 0.22 mg/kg Bz), which is not unexpected given the short interval between application and harvest. The next-highest identified residue was CCIM (ca. 4–5% TRR, 0.004–0.13 mg/kg). A chromatographic fraction which was shown to consist primarily of radiolabelled sugars and citric acid accounted for 2.5–5.4% TRR (0.002–0.16 mg eq/kg), indicating breakdown of cyazofamid and incorporation into natural plant constituents.

Metabolism in lettuce was investigated following foliar treatment of glasshouse-grown plants. Three applications were made at a nominal rate of 100 g ai/ha on 14-day intervals. The test material was a mixture of cyazofamid labelled, separately, in the Im and Bz positions (in a 1:1 ratio). Lettuce leaves were harvested 14 DALA. Total radioactive residues were 0.85 mg eq/kg in the harvested leaves and 97% of the residues were extracted with ACN:H_2O (60:40, v/v with 0.1% acetic acid). Cyazofamid made up 89% of the TRR (0.76 mg/kg). No other compounds occurred at > 10% TRR. CCIM occurred at 3.7% TRR (0.031 mg/kg). Radioactivity in natural plant constituents occurred at 3.3% TRR (0.028 mg eq/kg). Based on analysis of the post-extraction solids (PES), those plant constituents consisted of starch and other water-soluble polysaccharides, protein, cellulose, and lignin.

Metabolism of cyazofamid was investigated in both field-grown and glasshouse-grown potatoes. In the field study, three foliar applications were made at rates of 100 or 400 g ai/ha. In the glasshouse study, five foliar applications were made at a rate of 400 g ai/ha. In both cases, applications were made on a 7-day interval and harvesting was done 7 DALA. In foliage, nearly all of the residue was cyazofamid. In tubers, the majority of the radioactivity was associated with the pulp. Sequential extractions of the pulp with ACN, ACN:H_2O (80:20, v/v), and ACN:H_2O (50:50, v/v) released 43 to 70% of the radioactivity, with the Bz-labelled samples generally being at the higher end of that range. In rinses of the tubers, the majority of the residue was cyazofamid (67–80% TRR, 0.0009–0.0018 mg/kg) and CCIM (14–20% TRR, 0.003 mg/kg); whereas in the tuber itself, the majority of the radioactivity was associated with starch (23–30% TRR, 0.005 mg/kg). Cyazofamid and CCIM were both < 5% TRR in tubers.

In plant metabolism studies with identification of residues, cyazofamid was the major residue in aerial portions of the plants and there was consistent demonstration of incorporation of radioactivity into natural plant components. The available data indicate that cyazofamid is translocated. The metabolite CCIM was consistently identified in these studies but never occurred at greater than 10% TRR.

Animal metabolism

The Meeting received studies elucidating the metabolism of cyazofamid in laboratory animals, lactating goats, and laying hens.

In rats, cyazofamid is well absorbed at doses relevant to dietary exposure, and rapidly metabolised, with the majority of excretion occurring via urine. In the plasma, there was no cyazofamid and the majority of radiolabel was CCIM. At 0.5 hours after a dose of [^{14}C-Bz]-

CCIM, all of the radiolabel in the stomach contents was CCIM, and most of the radiolabel in liver (76.5%) and plasma (67.9%) was CCIM. CCBA, the main metabolite seen in these tissues 0.5 hours after dosing with CCIM, was also found in the blood and liver from the animals dosed with cyazofamid. Concentrations in blood and liver were greater in the CCIM-dosed animals than that in cyazofamid treated animals, suggesting that CCIM was much more rapidly absorbed than cyazofamid.

In goats dosed for five consecutive days at approximately 32 mg/animal/day (Im) or 25 mg/animal/day (Bz; both equivalent to 10 ppm in the diet), overall recovery of radioactivity was ca. 60% of the administered dose (AD). Most of the recovered radioactivity was in urine and faeces, with only 0.22% (Im) or 0.18% (Bz) of the AD accounted for in tissues. Despite the low retention of radioactivity, sufficient residues were present to characterize and identify specific compounds in all tissues. Total radioactive residues (TRR) in urine and faeces appeared to plateau by Day 3 of dosing. In milk from Bz-treated goats, TRR remained near the limit of quantification (LOQ, 0.005 mg eq/kg) for the duration of the dosing period. TRR did not plateau during the dosing period for the Im label, rising steadily from 0.005 mg eq/kg to 0.10 mg eq/kg. Aside from this difference in milk, there was little difference in the behaviour of cyazofamid based on the position of the radiolabel. Solvent (ACN or ACN:H_2O) extracted 74% TRR, 90% TRR, and 100% TRR in muscle, milk, and fat, respectively, and sequential extraction with ACN and ACN:H_2O extracted 92% TRR from kidney. For liver, the same sequential solvents used for kidney extracted only ca. 50% TRR. An additional 45% TRR was released from liver, in total, using HCl, NaOH, and protease treatments of the post-extraction solids (PES). Liver and kidney contained the highest levels of radioactivity (ca. 0.1 mg eq/kg). In other tissues and in milk, radioactivity was approximately an order of magnitude lower than in liver/kidney. Cyazofamid residues were < 0.001 mg/kg (0.1–0.3% TRR) in all tissues. The principal residues in tissues and milk were CCBA (free or cysteine-conjugated), CCIM, and their amide analogs. Total CCBA-related residues ranged from 12% TRR (< 0.002 mg/kg; muscle) to 85% TRR (0.090 mg/kg; kidney), and total CCIM-related residues ranged from 5.3% TRR (0.006 mg/kg; kidney) to 39% TRR (< 0.003 mg/kg; fat); the highest concentrations of CCIM-related residues was in liver, at 0.016 mg/kg (14% TRR). The chromatographic system used in the goat metabolism studies was generally not able to separate CCBA and its cysteine conjugate, and those residues were typically the main residues in all tissues.

In hens dosed for five consecutive days at 1.1 mg/bird/day (10 ppm in the diet), total radioactive residues (TRR) in excreta accounted for approximately 85–90% of the dosed material, and < 0.1% of the AD was retained in tissues/eggs. Total radioactive residues were < 0.006 mg eq/kg in all samples of eggs, muscle, blood, fat, and skin. Residue plateau in eggs could not be assessed. Acetonitrile + ACN:H_2O extraction was not efficient at solubilizing residues in kidney (ca. 50% TRR) and liver (ca. 30% TRR); however, chemical and enzymatic treatment of the resulting PES was able to release the unextracted residues, resulting in 100% recovery of TRR. In kidney, the only identified compounds occurring at > 10% TRR were CCBA (solvent-extracted; 12% TRR, 0.0035–0.0064 mg/kg), and CHCN conjugates (not further identified; solvent-extracted; 17% TRR, 0.005–0.010 mg/kg and PES acid hydrolysate; 30–67% TRR, 0.003–0.010 mg/kg). Two unidentified fractions from the acid-hydrolysate treatment, CM-2 and CM-3, accounted for ca. 15% TRR (0.001 mg eq/kg) each. Residue profiles in liver were similar to those in kidney, consisting of CCBA (acid hydrolysate only, 14% TRR, 0.002 mg/kg), CHCN conjugates (solvent extract, 12% TRR, 0.011 mg eq/kg; acid hydrolysate, 47% TRR, 0.0073 mg eq/kg), and CM-2/CM-3 (acid hydrolysate, 13% TRR, 0.002 mg eq/kg).

Overall, the animal metabolism studies show that the majority (99+%) of the dosed radioactivity is excreted. In goat, the principal terminal residues are CCBA, CCIM, and their related conjugates and amides. In hens, the principal terminal residues are CCBA, CHCN, and their conjugates. Although CCBA is common to both species, the formation of that compound appears to occur through different pathways.

Environmental fate

Cyazofamid is prone to hydrolysis (25 °C, pH 4, 7, 9). The main product of hydrolysis at 25 °C at all pH levels was CCIM, which represented ca. 82% of the radioactivity at pHs of 4, 5, and 7, and 77% at pH 9. At pH 9, CCIM-AM was found at level of ca. 10% of the radioactivity. CCIM itself is stable to hydrolysis. Cyazofamid is also prone to photolysis in aqueous systems [DT_{50} of 30 minutes], forming CCIM and CCTS; both of which undergo further photolysis. In soil, photolysis does not appear to be a significant pathway for degradation since dissipation was similar in both irradiated and dark samples.

In an aerobic soil metabolism study, cyazofamid had DT_{50} estimates of ca. five days and DT_{90} estimates ranging from 16 to 25 days. The major residues following treatment with cyazofamid were CCIM (peak on Day 3, ca. 20% AD, ca 0.025 mg eq/kg), CCIM-AM (peak on Day 7, 13% AD, 0.016 mg eq/kg), and CTCA (peak ca. Day 20 at ca. 20% of the applied dose, 0.025 mg eq/kg). The aerobic soil metabolism study also showed an increase in unextracted residues over time (up to 64% at study termination) as well as production of $^{14}CO_2$ (14% of applied material by study termination). In unextracted residues, radioactivity was associated predominantly with fulvic acid as well as humin and humic acid.

In a study with confined rotational crops, bare soil was treated with 5× 100 g/ha (for both radiolabel positions on a 7-day interval). Crops of lettuce, carrot, and wheat were put into the treated soil at plant-back intervals (PBIs) of 31, 120, and 360 days. For all PBIs, residues in lettuce, carrot root, carrot tops (Days 120 and 360), and wheat grain were too low to allow residue identification/characterization. In carrot tops (Day 31 only), residues of CCBA (2.2% TRR), CCIM (10.4% TRR), CCIM-AM (39.5% TRR, 0.001 mg/kg), and cyazofamid (20.1% TRR, 0.003 mg/kg) were identified. In wheat chaff, forage and straw, residues were associated primarily with carbohydrates (0.01–0.20 mg eq/kg). Residues of cyazofamid and metabolites were $\leq$ 0.003 mg eq/kg in those matrices. No field rotational crop or field dissipation studies were provided. The Meeting concluded that the confined rotational crop study adequately reflects critical gap conditions and that residues are not expected in rotational crops following treatments according to the GAPs under consideration.

Overall, there are no indications that cyazofamid or any of its degradation products are expected to accumulate in soils. Significant dissipation pathways in an agricultural system appear to be hydrolysis and potentially photolysis. The DT_{90} estimates for cyazofamid in the aerobic soil metabolism study indicate that applications made more than ca. 1 month prior to harvest will not contribute significantly to the residue levels in harvested crops.

Methods of residue analysis

The Meeting received analytical methods for the analysis of cyazofamid and CCIM in plant matrices. Method validation recoveries were reported for grapes, cucurbit vegetables, root crops, Brassica vegetables, leafy vegetables, beans, peppers, and hops. Three methods for plant matrices underwent independent laboratory validation. No methods were submitted for analysis of animal materials or soil (aside from the techniques used in the studies with radiolabelled material).

In summary, extraction of residues in field trial samples was accomplished with ACN, ACN:H_2O (80:20, v/v), ACN:H_2O w/ 2% acetic acid (50:50, v/v), ACN:acetone (80:20, v/v) or acetone. Extracted residues were then generally cleaned up by partitioning into a non-polar organic solvent, with additional clean-up by solid-phase extraction (or in one case gel-permeation chromatography). Analysis of residues was by LC-MS/MS, HPLC-UV, or GC-NPD. Three methods underwent independent laboratory validation. For those methods, extraction of cyazofamid and CCIM is by ACN:acetone, H_2O followed by acetonitrile, or acetonitrile only. Clean-up varies across the three methods, consisting of traditional solid-phase extraction (C_{-18}), dispersive solid-phase extraction (magnesium sulphate, sodium chloride, sodium citrate dibasic sesquihydrate, and sodium citrate tribasic dehydrate), or liquid/liquid partitioning (hexane and methylene chloride, sequentially) with Florisil® solid-phase extraction. For the validated methods, residue separation and quantitation is by LC-MS/MS in positive ionisation mode or by HPLC-UV (280 nm). For LC-MS/MS, evaluated ion transitions [M+H+] for quantification were

325.1 m/z→108.0 m/z for cyazofamid and 218.3 m/z→183.2 m/z for CCIM. Confirmation of cyazofamid is made using the same ion transitions, but with a cyano column on a gradient mobile phase. Confirmation of CCIM is based on a mass transition of 218.3 m/z→139.2 m/z. Based on results from other submitted studies, a confirmatory transition for cyazofamid is available (325.1 m/z→261.2 m/z). Method validation testing resulted in percent recoveries for cyazofamid ranging from 70 to 111% (except for raisins at 67%) and for CCIM ranging from 74 to 120% (except for potato chips at 68%). For both analytes in all matrices, relative standard deviations of recovery were less than 21%. An LOQ of 0.01 mg/kg was achieved for all matrices and analytes.

The solvent used for extraction is similar to that used in the metabolism studies with lettuce and potato (the first two extraction solvents in the tomato metabolism study were much less polar). On that basis, the methods are expected to have adequate extraction efficiency of incurred residues.

Testing of cyazofamid and CCIM through the FDA PAM multi-residue method protocols demonstrated that for most protocols, the test compounds showed poor sensitivity, poor recovery, and/or poor chromatography. An open-literature study[1] demonstrated good recovery of both cyazofamid (80% to 105%) and CCIM (75% to 99%) from fortified crop samples using the QuEChERS method, with relative standard deviations of ≤ 16%.

Analytical methods are available for analysis of cyazofamid and CCIM in plant commodities. Analytical methods for the analysis of cyazofamid residues in animal commodities were not provided.

Stability of residues in stored analytical samples

The Meeting received data indicating that residues of cyazofamid and CCIM are stable under frozen conditions as follows:

Matrix	Cyazofamid	CCIM
Grape (homogenized)	Up to 8 days	No Data
Grape (unhomogenized)	At least 365 days	No Data
Basil (fresh)	At least 284 days	Not stable [a] (less than 284 days)
Basil (dried)	At least 297 days	Not stable [a] (less than 297 days)
Hops cones	At least 509 days	At least 509 days
Cabbage	At least 860 days	At least 860 days
Tomato	Up to 365 days	At least 1093 days
Lettuce	At least 634 days	At least 634 days
Mustard greens	At least 977 days	At least 977 days
Spinach	At least 949 days	At least 949 days
Bean plants with pods	At least 889 days	At least 889 days
Bean pods with seeds	At least 887 days	At least 887 days
Been seeds without pods	At least 140 days	At least 140 days
Dry beans	At least 400 days	At least 400 days
Carrot	Not stable [a] (less than 374 days)	Not stable [a] (less than 374 days)
Potato	Up to 181 days	Up to 181 days

[a] Residues were measured only at the indicated storage period, and the amount remaining was < 70%. Basil and carrot samples were analysed on the same day as extraction.

Cyazofamid and CCIM were demonstrated to be stable in extracts of oilseed rape and dry beans for at least four days. Stability of these analytes in extracts from other matrices was not reported.

Definition of the residue

In plants, parent cyazofamid was the only compound to occur as a major residue in metabolism studies, and suitable methods are available for analysis. CCIM was consistently identified in

[1] Lee, H. Kim, E, Lee, JH. Sung, JH, Choi, H, and Kim, JH. 2014. Bull Environ Contam Toxicol 93(5):586-90. Analysis of cyazofamid and its metabolite in the environmental and crop samples using LC-MS/MS.

metabolism studies as a minor residue and occurred at levels that were typically at least five-fold lower than cyazofamid, and typically < 0.01 mg/kg, in supervised residue trials. The Meeting considered residues of cyazofamid in rotational crops and concluded that uptake of residues from soil into rotational crops will be insignificant. Cyazofamid is expected to degrade during the production of processed products; especially those in which heating and/or hydrolysis occurs, resulting in the formation of CCIM. Nevertheless, levels of CCIM in processed commodities are generally low.

Cyazofamid exhibited low acute oral toxicity, and there was an absence of developmental toxicity and any other toxicological effects that would be likely to be elicited by a single dose. The primary plant metabolite, CCIM, however, was more acutely toxic than the parent compound and resulted in clinical signs at all doses tested in acute toxicity studies. For long-term exposures, the toxicity of CCIM is adequately addressed by parent cyazofamid.

The Meeting concluded that the residue definition for enforcement of MRLs in plant commodities is the parent compound, cyazofamid, only. Furthermore, the Meeting concluded that the residue definition for assessing long-term dietary intake from plant commodities is the combined residues of cyazofamid and CCIM, expressed as cyazofamid. An ARfD is not necessary for cyazofamid; however, the current Meeting established an ARfD for CCIM, and the residue definition for assessing short-term dietary intake from plant commodities is CCIM.

Studies depicting the nature of the residues in animals show generally low transfer of residues to tissues, milk, and eggs. Metabolism studies indicate that of the amount retained, residues are expected to be highest in offal and lower by approximately an order of magnitude in other matrices. Cyazofamid was not detected in any livestock matrix. The metabolite CCBA (free and as cysteine conjugates) was consistently found as a major residue (> 10% TRR, ranging from 0.002 mg/kg to 0.09 mg/kg) in goat and hen commodities. Data from goat kidney indicate that the cysteine conjugates form the majority of the CCBA residues (separate free/conjugated residue data were not reported for other matrices). The Meeting was uncertain about the relative amounts of free and cysteine-conjugated CCBA in tissues other than liver and about the availability of reference standards for cysteine-conjugated CCBA. The Meeting agreed not to establish residue definitions for livestock commodities.

Definition of the residue for compliance with the MRLs for plant commodities: *Cyazofamid.*

Definition of the residue for long-term dietary intake from plant commodities: *Cyazofamid and CCIM, expressed as cyazofamid.*

Noting that the current meeting established an ARfD for CCIM (in the absence of an ARfD for cyazofamid), the definition of the residue for short-term dietary intake from plant commodities is *CCIM*.

Definition of the residue for compliance with the MRLs and for dietary intake for animal commodities: *Not defined.*

Results of supervised residue trials on crops

The Meeting received supervised residue trial data for grapes, basil, hops, broccoli, cabbage, cucumber, summer squash, muskmelon, peppers, tomatoes, head and leaf lettuce, mustard greens, spinach, snap beans, lima beans, carrots, and potatoes. The trials were conducted in the USA for all crops, as well as Argentina, Europe (north and south), and Mexico for grapes; Germany for hops; Canada for lettuces; and Brazil and Canada for potatoes. For basil, residue data reflect both field and glasshouse growing conditions. All residue results are supported by adequate method and storage stability data unless otherwise noted.

For field trials with cabbage, all cabbage heads were cut in the field in order to reduce the size/weight of the sample; for lettuce and muskmelon, some samples were cut in the field. A comparison of the residue levels in field-cut and uncut samples indicates that field-cutting did not compromise the quality of the residue data obtained from field-cut samples.

For estimating dietary intake, combined residues (cyazofamid + CCIM) were calculated by multiplying the individual sample results from field trials of CCIM by the molecular weight factor of 1.49 (cyazofamid molecular weight = 324.8, CCIM molecular weight = 217.7) and adding the result to the corresponding residue of cyazofamid. For residues below the LOQ, the residue was assumed to be at the LOQ for calculation purposes; the "less than" designation was retained only if both residues were below the LOQ. Examples are shown below:

Cyazofamid	CCIM	Combined (expressed to two significant figures)
0.5 mg/kg	0.06 mg/kg	0.5 mg/kg + (0.06 mg/kg × 1.49) = 0.59 mg/kg
0.5 mg/kg	< 0.01 mg/kg	0.5 mg/kg + (0.01 mg/kg × 1.49) = 0.51 mg/kg
< 0.01 mg/kg	0.06 mg/kg	0.01 mg/kg + (0.06 mg/kg × 1.49) = 0.099 mg/kg
< 0.01 mg/kg	< 0.01 mg/kg	< 0.01 mg/kg + (< 0.01 mg/kg × 1.49) = < 0.025 mg/kg

Grapes

In grapes, the critical GAP based on highest application rate and shortest PHI is from the registration in Germany (eight foliar applications at 0.1 kg ai/ha on a 12- to 14-day interval with a 21-day PHI). Only a single field trial is available from Germany; however, additional residue trials matching the critical GAP are available from France, Italy, Spain, and Portugal. The Meeting noted that in all of these trials, grapes were stored as whole berries and, therefore, the residue levels are supported by the available storage stability data.

Mean field trial residues of cyazofamid from independent field trials matching the critical GAP (n=7) were: 0.01, 0.03, 0.04, 0.04, 0.06, 0.09, and 0.66 mg/kg.

Based on those data, the Meeting estimated a maximum residue level for grapes of 1.5 mg/kg.

From the trials cited above, residues of CCIM were (n=7): < 0.01 (7) mg/kg. For assessing short-term dietary intake from grapes, the HR, from a single sample, is 0.01 mg/kg.

From the trials cited above, the combined residues of cyazofamid and CCIM, expressed as cyazofamid, were (n=7): 0.02, 0.04, 0.05, 0.06, 0.08, 0.1, and 0.67 mg/kg. For assessing long-term dietary intake from grapes, the STMR from that data set is 0.06 mg/kg.

Brassica (Cole or Cabbage) Vegetables, Head Cabbage, Flowerhead Brassicas

The critical GAP is from the registration of cyazofamid on the Brassica (Cole) leafy vegetables crop group in the USA (one soil application at 0.753 kg ai/ha followed by five foliar applications at 0.08 kg ai/ha on a 7-10-day interval with a zero-day PHI). Supervised residue trials matching this GAP are available from the USA.

Mean field trial residues of cyazofamid in broccoli from independent field trials matching the critical GAP (n=5) were: 0.23, 0.34, 0.37, 0.46, and 0.84 mg/kg.

Mean field trial residues of cyazofamid in cabbage (with wrapper leaves) from independent field trials matching the critical GAP (n=9) were: 0.13, 0.15, 0.20, 0.25, 0.28, 0.30, 0.32, 0.56, and 0.75 mg/kg.

Noting that the residue trials address crops in the Codex commodity designation Brassica (Cole or cabbage) vegetables, head cabbage, flowerhead Brassicas and that the median residues from each crop are within a 5-fold range, the Meeting determined that a group MRL is appropriate. The cyazofamid residue data across the test crops are not significantly different by the Kruskal-Wallis test; therefore, the Meeting grouped the data together and is estimating a group maximum residue level for Brassica (Cole or cabbage) vegetables, head cabbage, flowerhead Brassicas based on the following cyazofamid residue data set (n=14): 0.13, 0.15, 0.20, 0.23, 0.25, 0.28, 0.30, 0.32, 0.34, 0.37, 0.46, 0.56, 0.75, and 0.84 mg/kg.

Based on those data, the Meeting estimated a maximum residue level for Brassica (Cole or cabbage) vegetables, head cabbage, and flowerhead Brassicas of 1.5 mg/kg.

From the trials cited above, residues of CCIM were (n=14): < 0.01 (11), 0.012, 0.014, and 0.023 mg/kg. For assessing short-term dietary intake from Brassica (Cole or cabbage) vegetables, head cabbage, flowerhead Brassicas, the HR, from a single sample, is 0.025 mg/kg.

From the trials cited above, the combined residues of cyazofamid and CCIM, expressed as cyazofamid, were (n=14): 0.14, 0.16, 0.21, 0.24, 0.26, 0.3, 0.31, 0.33, 0.35, 0.38, 0.47, 0.58, 0.78, and 0.85 mg/kg. For assessing long-term dietary intake from Brassica (Cole or cabbage) vegetables, head cabbage, flowerhead Brassicas, the STMR from that data set is 0.31 mg/kg.

Fruiting vegetables, Cucurbits

The critical GAP is from the registration of cyazofamid on the cucurbit vegetables crop group in the USA (six foliar applications at 0.08 kg ai/ha on a 7–10-day interval with a zero-day PHI). Supervised residue trials matching this GAP are available from the USA.

Mean field trial residues of cyazofamid in cucumber from independent field trials matching the critical GAP (n=4) were: 0.01 and 0.02 (3) mg/kg.

Mean field trial residues of cyazofamid in summer squash from independent field trials matching the critical GAP (n=4) were: 0.02 (2) and 0.04 (2) mg/kg.

Mean field trial residues of cyazofamid in muskmelon from independent field trials matching the critical GAP (n=6) were: < 0.01, 0.02 (3), 0.03 (2), and 0.06 mg/kg.

Noting that the residue trials address crops in the Codex commodity designation Fruiting Vegetables, Cucurbits and that the median residues from each crop are within a 5-fold range, the Meeting determined that a group MRL is appropriate. The cyazofamid residue data across the test crops are not significantly different by the Kruskal-Wallis test; therefore, the Meeting grouped the data together and is estimating a group maximum residue level for Fruiting Vegetables, Cucurbits based on the following cyazofamid residue data set (n=14): < 0.01, 0.01, 0.02 (5), 0.03 (2), 0.04 (2), and 0.06 mg/kg..

Based on those data, the Meeting estimated a maximum residue level for Fruiting Vegetables, Cucurbits of 0.09 mg/kg.

From the trials cited above, residues of CCIM were (n=14): < 0.01 (12) and 0.01 (2) mg/kg. For assessing short-term dietary intake from Fruiting Vegetables, Cucurbits, the HR, from a single sample, is 0.01 mg/kg.

From the trials cited above, the combined residues of cyazofamid and CCIM, expressed as cyazofamid, were (n=14): 0.02 (2), 0.03, 0.04 (7), 0.04, 0.06 (2), and 0.08 mg/kg. For assessing long-term dietary intake from Fruiting Vegetables, Cucurbits, the STMR from that data set is 0.04 mg/kg.

Fruiting vegetables, other than Cucurbits (except Sweet Corn and Mushroom)

The critical GAP is from the registration of cyazofamid on the fruiting vegetables crop group in the USA (six foliar applications at 0.08 kg ai/ha on a 7–10-day interval with a zero-day PHI). Supervised residue trials matching this GAP are available from the USA.

Mean field trial residues of cyazofamid in peppers, sweet (including pimento or pimiento) from independent field trials matching the critical GAP (n=6) were: 0.038, 0.055, 0.058, 0.072, 0.098, and 0.22 mg/kg.

Mean field trial residues of cyazofamid in peppers, chili from independent field trials matching the critical GAP (n=3) were: 0.24, 0.25, and 0.31 mg/kg.

Mean field trial residues of cyazofamid in tomatoes from independent field trials matching the critical GAP (n=14) were: < 0.010, 0.025, 0.030 (2), 0.035, 0.040, 0.050 (4), 0.065, 0.075, 0.11, and 0.15 mg/kg.

Noting that the residue trials in the USA address crops in the Codex commodity designation Fruiting Vegetables, Other Than Cucurbits (except Sweet Corn and Mushrooms), the Meeting considered whether a group MRL is appropriate. Based on the five-fold difference in the median residue values, The Meeting concluded that a group recommendation is appropriate. Analysis of the data set by the Kruskal-Wallis test indicated that the residues are not from the same populations and should not be combined when estimating the maximum residue level. Of the crops in this category, field trials with chilli pepper resulted in the greatest median residue level and greatest overall single-sample residue; however, the number of trials on chilli pepper is insufficient for making a group recommendation and the Meeting decided to make recommendations for the individual crops.

The Meeting estimated a maximum residue levels for sweet peppers at 0.4 mg/kg, for chilli peppers at 0.8 mg/kg, and for tomato at 0.2 mg/kg. Furthermore, the Meeting extrapolated the tomato data to eggplant and estimated a maximum residue level for eggplant at 0.2 mg/kg.

From the trials cited above, residues of CCIM and their associated HRs (from single samples) for assessing short-term dietary intake were as follows:

Sweet pepper (n=5): < 0.01 (4) and 0.012 mg/kg [HR = 0.014 mg/kg]

Chili pepper (n=3): 0.012 and 0.014 (2) mg/kg [HR = 0.017 mg/kg]

Tomato (n=15): < 0.01 (13), 0.01, and 0.015 mg/kg [HR = 0.02 mg/kg]; and by extension,

Eggplant: [HR = 0.02 mg/kg].

From the trials cited above, the combined residues of cyazofamid and CCIM, expressed as cyazofamid, and their associated STMRs for assessing long-term dietary intake were as follows:

Sweet pepper (n=5): 0.05, 0.07, 0.07, 0.09, and 0.24 mg/kg [STMR = 0.072 mg/kg]

Chilli pepper (n=3): 0.27 (2) and 0.33 mg/kg [STMR = 0.027 mg/kg];

Tomato (n=15): 0.02 (2), 0.04 (3), 0.05, 0.06 (5), 0.08, 0.09, 0.13, and 0.16 mg/kg [STMR = 0.06 mg/kg]; and by extension, Eggplant: [STMR = 0.06 mg/kg].

Leafy Vegetables (Including Brassica Leafy Vegetables)

The critical GAPs are from the registration of cyazofamid on the leafy greens crop subgroup in the USA (six foliar applications at 0.08 kg ai/ha on a 7–10-day interval with a zero-day PHI) and *Brassica* (Cole) leafy vegetables crop group in the USA (for mustard greens; one soil application at 0.753 kg ai/ha followed by five foliar applications at 0.08 kg ai/ha on a 7–10-day interval with a zero-day PHI). Supervised residue trials matching this GAP are available from Canada (head lettuce only) and the USA.

Mean field trial residues of cyazofamid in head lettuce from independent field trials matching the critical GAP (n=11) were: 0.070, 0.20, 0.26, 0.46, 0.63 (2), 0.73, 1.2, 1.5, 1.7, and 1.8 mg/kg.

Mean field trial residues of cyazofamid in leaf lettuce from independent field trials matching the critical GAP (n=11) were: 0.53, 0.76, 0.87, 0.89, 1.4, 1.8, 2.7, 2.8, 3.0, 4.0, and 4.4 mg/kg.

Mean field trial residues of cyazofamid in mustard greens from independent field trials matching the critical GAP (n=9) were: 1.4, 1.9, 3.3, 3.4, 3.5, 3.7, 5.5, 6.0, and 6.3 mg/kg.

Mean field trial residues of cyazofamid in spinach from independent field trials matching the critical GAP (n=10) were: 1.6, 2.0 (2), 2.2, 2.9, 3.3, 3.4, 3.6, 4.6, and 6.4 mg/kg.

Noting that the residue trials address crops in the Codex commodity designation Leafy Vegetables, the Meeting considered whether a group MRL is appropriate. The differences in median residue values across all four crops is greater than five-fold, indicating that a crop group recommendation is not appropriate. As median residue values for head lettuce, leaf lettuce, and spinach are within a five-fold range, the Meeting decided to make a recommendation for leafy vegetables, except Brassica leafy vegetables and to use data from mustard greens to make a recommendation for Brassica leafy vegetables.

Analysis of the residue data for lettuces and spinach by Kruskal-Wallis indicates that the residues are not from the same population and should not be combined when estimating the maximum residue level. Of these crops, the data from spinach has the highest median and highest residue.

On the basis of the data from spinach, the Meeting estimated a maximum residue level for Leafy Vegetables, except Brassica Leafy Vegetables at 10 mg/kg.

From the trials cited above, residues of CCIM and their associated HRs (from single samples) for assessing short-term dietary intake were as follows:

Head lettuce (n=11): < 0.010 (4), 0.01, 0.011, 0.013, 0.017 (2), 0.022, and 0.026 mg/kg [HR = 0.029 mg/kg];

Leaf lettuce (n=11): 0.011, 0.012, 0.016, 0.021, 0.025, 0.027, 0.037, 0.041 (2), 0.042, and 0.044 mg/kg [HR = 0.05 mg/kg];

Spinach (n=10): 0.029, 0.034, 0.045, 0.049, 0.05, 0.059, 0.088, 0.093, 0.12, and 0.14 mg/kg [HR = 0.15 mg/kg].

From the trials cited above, the combined residues of cyazofamid and CCIM, expressed as cyazofamid, and their associated STMRs for assessing long-term dietary intake were as follows:

Head lettuce (n=11): 0.08, 0.21, 0.27, 0.47, 0.64, 0.65, 0.74, 1.2, 1.5, 1.7, and 1.8 mg/kg [STMR = 0.65 mg/kg]

Leaf lettuce (n=11): 0.55, 0.80, 0.89, 0.93, 1.4, 1.8, 2.8, 2.9, 3.0, 4.1, and 4.5 mg/kg [STMR = 1.8 mg/kg];

Spinach (n=10): 1.6, 2.0, 2.1, 2.2, 3.0, 3.4, 3.5, 3.7, 4.8, and 6.6 mg/kg [STMR = 3.2 mg/kg].

For estimating dietary intake of the combined residues of cyazofamid and CCIM from leafy vegetables, except Brassica leafy vegetables, the data from spinach provide the highest residue estimate, with an STMR of 3.2 mg/kg.

For Brassica leafy vegetables, the Meeting estimated a maximum residue level of 15 mg/kg based on the data from mustard greens.

Residues of CCIM were (n=9): 0.032, 0.035 (2), 0.05, 0.053, 0.092, 0.11, 0.15, and 0.18 mg/kg. For assessing short-term dietary intake from Brassica leafy vegetables, the HR, from a single sample, is 0.19 mg/kg.

Combined residues of cyazofamid and CCIM in Mustard Greens were (n=9): 1.6, 2.0, 3.3, 3.5, 3.7, 4.0, 5.6, 6.1, and 6.4 mg/kg. For assessing long-term dietary intake from Brassica leafy vegetables, the STMR from that data set is 3.7 mg/kg.

Beans and beans, shelled

The critical GAP is from the registration of cyazofamid on beans (succulent podded and succulent shelled) in the USA (six foliar applications at 0.08 kg ai/ha on a 7–14-day interval with a zero-day PHI). Supervised residue trials in lima beans matching this GAP are available from the USA.

Mean field trial residues of cyazofamid in lima beans from independent field trials matching the critical GAP (n=6) were: < 0.010 (5) and 0.040 mg/kg.

Mean field trial residues of cyazofamid in snap beans from independent field trials matching the critical GAP (n=8) were: 0.018, 0.046, 0.059, 0.10, 0.12, 0.19, and 0.20 (2) mg/kg.

Noting that the residue trials in the USA address crops in the Codex commodity designation Legume Vegetables, the Meeting considered whether a group MRL is appropriate. Based on the spread in the median residue values, the Meeting determined that the residues from the trials are too dissimilar and that a group MRL is not appropriate.

The Meeting used the residue data from lima beans to estimate a maximum residue level for beans, shelled of 0.07 mg/kg.

From the trials cited above, residues of CCIM were (n=6): < 0.01 (6) mg/kg. For assessing short-term dietary intake from beans, shelled, the HR, from a single sample, is 0.01 mg/kg.

From the trials cited above, the combined residues of cyazofamid and CCIM, expressed as cyazofamid, were (n=6): 0.025 (5), and 0.06 mg/kg. For assessing long-term dietary intake from beans, shelled, the STMR from that data set is 0.025 mg/kg.

The Meeting used the residue data from snap beans to estimate a maximum residue level for beans, except broad bean and soya bean of 0.4 mg/kg.

From the trials cited above, residues of CCIM were (n=8): < 0.01 (8) mg/kg. For assessing short-term dietary intake from beans, except broad bean and soya bean, the HR, from a single sample, is 0.01 mg/kg.

From the trials cited above, the combined residues of cyazofamid and CCIM, expressed as cyazofamid, were (n=8): 0.04, 0.06, 0.07, 0.12, 0.13, 0.20, and 0.21 (2) mg/kg. For assessing long-term dietary intake from beans, except broad bean and soya bean the STMR from that data set is 0.125 mg/kg.

Carrot and potato

The critical GAP for carrots is from the registration of cyazofamid on carrots in the USA (five foliar applications at 0.175 kg ai/ha on a 14–21-day interval with a 14-day PHI). Supervised residue trials matching this GAP are available from Canada and the USA.

Mean field trial residues of cyazofamid in carrots from independent field trials matching the critical GAP (n=15) were: < 0.010 (9), 0.022 (2), 0.027, 0.029, 0.034, and 0.039 mg/kg. Carrot samples were stored frozen for 91 to 443 days prior to analysis. Stability of cyazofamid in carrots during frozen storage was not demonstrated (58% remaining at 374 days, no other time points sampled). As a result, the Meeting did not estimate a maximum residue level, HR, or STMR for carrot.

The critical GAP for potatoes is from the registration of cyazofamid on potatoes in Brazil (six foliar applications at 0.1 kg ai/ha on a 7–10-day interval with a seven-day PHI). The submitted residue trials conducted in Brazil did not match the critical GAP. However, supervised residue trials matching this GAP are available from the USA.

Mean field trial residues of cyazofamid in potatoes from independent field trials matching the critical GAP (n=23) were: < 0.010 (23). A single sample from an exaggerated rate (10-fold for the final application only) had a quantifiable residue of cyazofamid (0.02 mg/kg)

Based on those data and the results from the metabolism study, the Meeting estimated a maximum residue level for potato of 0.01* mg/kg.

From the trials cited above, residues of CCIM were: < 0.01 mg/kg. For assessing short-term dietary intake from potato, the HR, from a single sample, is 0.01 mg/kg.

From the trials cited above, the combined residues of cyazofamid and CCIM, expressed as cyazofamid, were (n=23): < 0.025 (23) mg/kg. Noting the low residue at the exaggerated rate, the Meeting decided to set the STMR at 0.01 mg/kg for assessing long-term dietary intake from potato.

Basil and hops

In basil, the critical GAP is from the registration in the USA (nine foliar applications at 0.088 kg ai/ha on a 10–14-day interval with a zero-day PHI). Mean field trial residues of cyazofamid in basil (sweet) from independent field trials conducted in the USA and matching the critical GAP (n=4) were: 2.5, 2.9, 7.2, and 9.4 mg/kg.

Stability of CCIM in sweet basil was not demonstrated (47% remaining at 284 days, the only time point analysed). As the data are insufficient for evaluating dietary intake, the Meeting is not making a recommendation for residues of cyazofamid in sweet basil.

In hops, the critical GAP is from the registration in the USA (six foliar applications at 0.06–0.08 kg ai/ha on a 7–10-day interval with a 3-day PHI). Mean field trial residues of cyazofamid in dried cones from independent field trials conducted in Canada and the USA and matching the critical GAP (with DAT ranging from 2 to 4 days; n=5) were: 2.5, 2.9, 3.2, 6.3, and 7.4 mg/kg.

Based on those data, the Meeting estimated a maximum residue level for hops (dried cones) of 15 mg/kg.

From the trials cited above, residues of CCIM were (n=5): 0.13, 0.17, 0.18, 0.24, and 0.44 mg/kg. For assessing short-term dietary intake from hops (dried cones), the HR, from a single sample, is 0.45 mg/kg.

From the trials cited above, the combined residues of cyazofamid and CCIM, expressed as cyazofamid, were (n=5): 3.1, 3.2, 3.6, 6.5, and 7.5 mg/kg. For assessing long-term dietary intake from hops (dried cones), the STMR from that data set is 3.6 mg/kg.

Fate of residues during processing

High-temperature hydrolysis

The Meeting received a study investigating the high-temperature hydrolysis of cyazofamid. Samples of aqueous buffered solutions were spiked with cyazofamid at ca. 1 mg/L and put under conditions simulating pasteurisation (90 °C, pH 4, 20 min.); baking, brewing, boiling (100 °C, pH 5, 60 min); and sterilisation (120 °C, pH 6, 20 min.). Solutions were analysed by HPLC-MS/MS prior to and after processing. Cyazofamid was readily hydrolysed to CCIM (ca. 80% for pasteurisation and 100% for both baking/brewing/boiling and sterilisation).

Based on the results of the high-temperature hydrolysis study, the Meeting assumed 100% yield in the conversion of cyazofamid to CCIM in all foods other than those specified as "raw" when conducting the short-term intake assessment for CCIM.

Residues after processing

In basil, the critical GAP is from the registration in the USA (nine foliar applications at 0.088 kg ai/ha on a 10–14-day interval with a zero-day PHI). Mean field trial residues of cyazofamid in dried basil from independent field trials conducted in the USA and matching the critical GAP (n=6) were: 9.7, 13, 14 (3), and 40 mg/kg

Stability of CCIM in basil (dry) was not demonstrated (59% remaining at 297 days, the only time point analysed). As the data are insufficient for evaluating dietary intake, the Meeting is not making a recommendation for residues of cyazofamid in basil (dry).

The Meeting received data depicting the concentration/dilution of residues during processing of grapes into raisins, must and wine; tomato into paste and puree; and potatoes into wet peel, chip, and flake commodities. Processed commodities were derived using simulated commercial practices. The residue data are supported by adequate analytical methods. Storage stability data demonstrate that residues of cyazofamid and CCIM are stable in those commodities under the conditions and storage periods used in the processing studies. Residues in raw and processed commodities are supported by adequate concurrent recovery data, with the exception of cyazofamid in raisins (67±10%) and CCIM in potato chips (68±4%).

Cyazofamid did not concentrate in any processed commodity. As no concentration of residues was observed, recommendations for maximum residue levels for grapes, tomatoes, or potatoes processed commodities are not necessary. The Meeting noted that for the potato commodities, residues were < LOQ in all samples and processing factors could not be calculated; however, the tubers used in the processing study were treated at an exaggerated rate such that quantifiable residues are not expected in processed commodities even if concentration is occurring upon processing.

For estimating short-term dietary intake, the Meeting based processing factors on the combined residues of cyazofamid (as CCIM equivalents) and CCIM in raw commodities and residues of CCIM only in processed commodities. When residues were < 0.01 in a sample, they were assumed to be 0.01 for purposes of deriving a processing factor.

For grapes, the combined residues of cyazofamid (as CCIM equivalents) and CCIM from field trials at the critical GAP were: 0.017, 0.033, 0.037, 0.050, 0.070, and 0.45 mg/kg, with an STMR of 0.044 mg/kg and an HR, from a single sample, of 0.47 mg/kg.

For tomatoes, the combined residues of cyazofamid (as CCIM equivalents) and CCIM from field trials at the critical GAP were: 0.017, 0.027, 0.030 (2), 0.033, 0.037, 0.044 (4), 0.054, 0.060, 0.075, and 0.11 mg/kg, with an STMR of 0.044 mg/kg and an HR, from a single sample, of 0.12 mg/kg.

For dried hops, the combined residues of cyazofamid (as CCIM equivalents) and CCIM from field trials at the critical GAP were: 2.1 (2), 2.4, 4.4, 5.0, and 5.1 mg/kg, with an STMR of 3.4 mg/kg and an HR, from a single sample, of 5.4 mg/kg.

For estimating long-term dietary intake, the Meeting based processing factors on the combined residues of cyazofamid and CCIM, expressed as cyazofamid, in raw and processed commodities. For all raw and processed commodities except potato, residues of parent or CCIM were quantifiable and processing factors could be derived. When residues were < 0.01 in a sample, they were assumed to be 0.01 for purposes of deriving a processing factor.

Residues in animal commodities

The Meeting has not made a determination as to the residue definitions for compliance and dietary intake for animal commodities. Furthermore, the Meeting did not receive animal feeding studies or residue data for livestock feedstuffs from some crops considered in this appraisal (grape: grape pomace, beans: vines). The Meeting did not make a recommendation for animal commodities.

RECOMMENDATIONS

Definition of the residue for compliance with the MRLs for plant commodities: *Cyazofamid*.

Definition of the residue for estimating long-term dietary intake from plant commodities: *Cyazofamid plus CCIM, expressed as cyazofamid*.

Definition of the residue for estimating short-term dietary intake from plant commodities (to be compared to the ARfD for CCIM; an ARfD was determined to be unnecessary for cyazofamid): *CCIM*.

Definition of the residue for compliance with the MRLs and for dietary intake for animal commodities: *Not defined.*

FUTURE WORK

As future work, the Meeting recommends that methods be developed to assay residues of CCBA (free and conjugated) in animal commodities, and that any such methods include suitable digestion steps for liver.

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Daily Intakes (IEDIs) of cyazofamid were calculated for the 17 GEMS/Food cluster diets using STMRs/STMR-Ps estimated by the current Meeting. The ADI for cyazofamid is 0–0.2 mg/kg bw. The calculated IEDIs for cyazofamid were 0–4% of the maximum ADI.

The Meeting concluded that the long-term intakes of residues of cyazofamid, when cyazofamid is used in ways that have been considered by the JMPR, are unlikely to present a public health concern.

Short-term intake

The International Estimated Short-Term Intakes (IESTI) of CCIM were calculated for food commodities and their processed commodities using HRs/HR-Ps or STMRs/STMR-Ps estimated by the current Meeting. The ARfD for CCIM is 0.2 mg/kg bw. The calculated maximum IESTI for CCIM was 90% of the ARfD for all commodities. The Meeting concluded that the short-term intake of residues of CCIM resulting from uses of cyazofamid, when cyazofamid is used in ways that have been considered by the JMPR, is unlikely to present a public health concern.

CYPRODINIL (207)

First draft prepared by Guibiao Ye, Institute for the Control of Agrochemicals, Ministry of Agriculture, P. R. China

EXPLANATION

Cyprodinil is a fungicide belonging to the anilinopyridine group. It is a systemic foliar and seed dressing fungicide that acts as an inhibitor of methionine biosynthesis. Cyprodinil has been registered in many countries to control a range of fungal diseases in cereals, grapes, pome fruit, stone fruit, strawberries, vegetables, field crops and ornamentals, and as a seed dressing for barley.

Cyprodinil was firstly evaluated by JMPR in 2003, when an ADI of 0–0.03 mg/kg bw/day was established. An ARfD was deemed to be unnecessary. A residue definition of cyprodinil was recommended for plant and animal commodities, for both compliance with MRLs and estimation of dietary intake. The residue is fat soluble.

At the Forty-sixth session of the CCPR (2014), cyprodinil was scheduled for evaluation of additional use patterns by the 2015 JMPR.

The Meeting received residue data for oilseed rape and potato, and the proposal to extrapolate from carrot to ginseng.

METHODS OF RESIDUE ANALYSIS

Plant matrices

Method REM 141.01

Method REM 141.01(Dieterle, 1989) was evaluated by the 2003 JMPR. Homogenized samples were extracted with aqueous methanol. The extract was cleaned-up on a cation exchange cartridge. HPLC (single-column or two column-switching systems) with UV detection (λ max 270) was used for the final measurement. The LOQ for plant material was 0.02-0.05 mg/kg. The validation data included a wide range of high-water content crops as well as cereal grains (starchy). As the method was used for the determination of cyprodinil residues in potatoes, no further validation was conducted.

Method number AG-631B

Method AG-631B (Williams, R.K. 1998), with minor modifications was evaluated by the 2013 JMPR. Additional validation on rape seed matrices (seed and meal) are included in the supervised trials. Rape seed and meal samples were extracted by shaking with a methanol/water mixture at room temperature. After centrifugation, a 20 mL aliquot was taken and 2 mL of 1 M HCl was added. The extract was eluted through a SPE column with a methanol/ammonia mixture. The eluent was evaporated to near dryness and reconstituted with methanol. The extract was brought to 10 mL with methanol and bottled water and then diluted to 100 mL final volume and analysed by LC/MS/MS (quantification transition: 226.1 → 93.1). The method was verified at an LOQ of 0.02 mg/kg and an LOD of 0.006 mg/kg for canola seed and meal.

The following modifications were made to the reference method:

1. The extracts were centrifuged at 5000 rpm instead of being filtered.

2. Diethylene glycol diethyl ether was not added.

3. Extracts were brought to 10 mL final volume instead of 2 mL final volume.

These modifications were made to improve the method's ruggedness and make it suitable for LC/MS/MS analysis.

Table 1 Recovery of cyprodinil from rape seed and rape seed meal using method AG-631B

Commodity	Fortification level (mg/kg)	No. of analyses (n)	Recovery (%)	Mean recovery (%)	% RSD	Reference (Author, Year)
Rape seed	0.02	4	73, 85, 82, 88	83	7.7	Williams, R.K. 1998
	0.1	2	79, 92			
	0.2	2	86, 76			
Rape seed meal	0.02	4	97, 88, 80, 86	97	12	Williams, R.K. 1998
	0.1	2	102, 113			
	0.2	2	104, 109			

Method AG-597B

The principle of method AG-579B (Campbell, D, D, 1996) for the determination of cyprodinil in oil is as follows: 10 g sample of rape seed oil samples were shaken with acetonitrile saturated with hexane. The partition was repeated four more times and the acetonitrile layers combined. The extract was evaporated to less than 5 mL and brought to 10 mL in acetonitrile. The extract was diluted to a suitable final volume and analysed by LC/MS/MS (226.0-108.2). The method was verified at an LOQ of 0.01 mg/kg and an LOD of 0.0033 mg/kg for refined oil.

Table 2 Recovery of cyprodinil from rape seed oil using method A-597B

Commodity	Fortification level (mg/kg)	No. of analyses (n)	Recovery (%)	Mean recovery (%)	% RSD	Reference (Author, Year)
Refined rape seed oil	0.01	4	107, 104, 92, 84	97	8.8	Campbell, D.D. 1996
	0.05	2	107, 89			
	0.1	2	96, 99			

Stability of pesticide residues in stored analytical samples

The stability of cyprodinil residues was investigated concurrently with sample storage as part of the analytical phase of the residue trials at intervals of 0, 3, 6 and 9 months frozen storage in rape seed, meal and oil. Cyprodinil residues are stable in rape seed, meal and oil stored frozen for at least 9 months.

Table 3 Recovery of cyprodinil in stored samples of rape seed and processed rape seed products

Matrix	Fortification lever(ppm)	Storage interval (months)				Reference
		0	3	6	9	
Rape seed	0.2	74	89	80	101	Sagan, K., 2009
Rape seed meal	0.2	99	107	97	78	
Rape seed oil	0.1	102	100	106	105	

Further storage stability data was evaluated by JMPR for the 2003 evaluation of cyprodinil. A study by Kissling (1995) evaluated the stability (at -18 °C) of incurred cyprodinil residues in grapes, apples, wheat ears, and wheat stalks, and of fortified residues in strawberries, potatoes, and wine. Acceptable stability was observed in all of these matrices over 24 months.

Additional storage stability data were also evaluated by the 2013 JMPR. Storage stability data for Avocado, Beans (dry), Blueberry, Broccoli, Cabbage, Mustard greens, Raspberry, Cantaloupe, Cucumber, Squash, Peppers, Tomato (fruit, puree, paste), Basil (fresh), Chives (fresh), Kiwifruit, Lettuce, Spinach, Lemon(dried pulp, juice, oil), Lychee, Parsley (fresh, dried), Carrot, Radish(top, roots), Strawberry, Watercress, Apple and Pear were determined concurrently with sample storage as part of the analytical phase of the residue trials. Cyprodinil was shown to be stable for periods up to 601 days in a wide range of frozen plant matrices.

USE PATTERN

Cyprodinil is registered in the Brazil for use on potatoes, Canada for use on oilseed rape and the USA for use on ginseng, and are summarized in Table 4.

Table 4 Registered uses of cyprodinil in Brazil, Canada and the USA

Crop	Country	Formulation		Application				PHI (days)
		g ai/kg	type	Method	(g ai/ha)	Water L/ha	No	
Potato	Brazil	750	WG	Foliar spray	250	500	4	7
Oilseed rape (canola)	Canada	375	WG	Foliar spray	365.6	>200	1	35
Ginseng	USA	375	WG	Foliar Spray	365.6	>140	4	7

RESULTS OF SUPERVISED RESIDUE TRIALS ON CROPS

The Meeting received information on cyprodinil supervised field residue trials for potatoes and oilseed rape.

Root and tuber vegetables

Potatoes

Three supervised trials with cyprodinil on potatoes were conducted in Brazil (two trials in 1997) and South Africa (one trial in 1992).

In trials conducted in South Africa, 5 foliar applications of cyprodinil (500 WP formulation) were applied at a rate of 175 or 300 g ai/ha. Samples of tubers were collected at PHIs of 0–63 days following the final application.

In Brazil, 5 or 6 applications of cyprodinil (750 WG formulation) were applied at rate of 250–500 g ai/ha). Samples of tubers were collected at PHIs of 0–63 days following the final application in each trial.

Samples were immediately frozen and maintained in frozen storage for periods of 82 to 329 days prior to extraction, and were analysed with the modified method REM 141.01

Oilseeds

Rape seed

Sixteen supervised trials with cyprodinil on canola (oilseed rape) were conducted in Canada in 2009. Fourteen of the trials were conducted in region 14 but at only nine field sites. Thus, there were only nine independent trials. One application of cyprodinil (WG formulation) was made at the rate of 365.6 g ai/ha with a PHI of 35 days, with adjuvant added. Samples of rape seed were collected at normal commercial harvest, 35 to 53 days after application.

Samples were immediately frozen and maintained in frozen storage for periods of up to 200 days prior to extraction. Residues of cyprodinil in seed and meal were determined using method AG-631B and residues of cyprodinil in oil were determined using method AG-597B.

Table 6 Summary of residue data from Canada supporting the Canada GAP for use of cyprodinil on oilseed rape

Location, Trial no., Year (Variety)	Application					PHI (days)	Crop Part	Residue (mg/kg)	Reference

LOQ for seed is 0.02mg/kg. LOQ for oil is 0.01mg/kg

FATE OF RESIDUES IN PROCESSING

The determination of cyprodinil residues in processed fractions of oilseed rape was included in the residue study conducted in Canada. The application rate of cyprodinil was 1098 g ai/ha, 3-times the label rate. The process included seed cleaning, seed pro-conditioning and flaking, seed cooking, pressing the flake to mechanically remove a portion of the oil, solvent extraction of the press-cake to remove the remainder of the oil, and desolventizing and toasting of the meal. No residues (<LOQ) were found in seed, meal and oil. Therefore, no processing factors can be established because no measurable residues were found in the seed samples before processing.

APPRAISAL

Cyprodinil was first evaluated for residues and toxicological aspects by the 2003 JMPR. An ADI of 0–0.03 mg/kg bw for cyprodinil was established, and an ARfD was concluded as unnecessary. The residue definition was established as cyprodinil for both compliance with MRLs and dietary risk assessment for both plant and animal commodities. The residue is fat soluble.

Cyprodinil was evaluated by 2013 JMPR for additional crops. A number of Codex Maximum Residue limits for cyprodinil were established. Cyprodinil was scheduled by the Forty-sixth CCPR meeting in 2014 for evaluation of residue data for additional crops by the JMPR.

Methods of analysis

The Meeting received two analytical methods for determination of cyprodinil residues in plant matrices which are relevant to this evaluation. The LOQ for the HPLC-MS/MS (226.01–93.10) methods for rapeseed and meal was 0.02 mg/kg, and for rape seed oil, 0.01 mg/kg.

Stability of residues in stored analytical samples

The Meeting received information on the storage stability of cyprodinil residues in plant matrices from trials conducted in conjunction with the residue studies submitted to the Meeting. These data and stability data from JMPR 2003 and 2013 covers the maximum storage period for samples in the residue studies submitted to this Meeting.

Residues of supervised trials on crops

The Meeting received supervised trial data for application of cyprodinil to oilseed rape, potatoes, and carrots, which was evaluated by 2013 JMPR.

Potato

Cyprodinil is registered in the Brazil for use on potatoes at a GAP of 4× 0.25 kg ai/ha and PHI of 7-days.

The residues of cyprodinil in potatoes from two trials conducted in Brazil and one trial in South Africa matching the Brazilian GAP were all < 0.02 mg/kg (LOQ). The meeting noted that three trials were insufficient to make a recommendation for a maximum residue level for potatoes.

Ginseng

The meeting received the request to extrapolate the maximum residue level from carrots to ginseng. The 2013 Meeting received supervised residue trials of carrots matching the US GAP. The Meeting noted that although the US GAP for ginseng is the same as that for carrots, the growth traits and cultivation practices are significantly different, and agreed not to extrapolate from carrots to ginseng.

Rape seed

Cyprodinil is registered in Canada for use on rape seed at a GAP of 1× 0.365 kg ai/ha and a 35-day PHI.

Nine independent residue trials were conducted in rapeseed at GAP in Canada. Residues in seed of rape seed at the 35 day PHI were all < 0.02 mg/kg (n=9).

Based on the residues from the Canadian trials, the Meeting estimated a maximum residue level of 0.02 mg/kg for seed of rape seed and an STMR of 0.02 mg/kg.

Processing studies

A processing study for oilseed rape was evaluated by the current Meeting in which the application rate of cyprodinil was 1098 g ai/ha, 3-times the label rate. No residues (< LOQ), were found in seed, meal and oil, and therefore no processing factors could be established.

Residues in animal commodities

Farm animal dietary burden

Dietary burden calculations incorporating all commodities considered by the current, 2003 and 2013 Meetings for beef cattle, dairy cattle, broilers and laying poultry are presented in Annex 6. The calculations are made according to the livestock diets of the USA/Canada, the European Union, Australia and Japan as laid out in the OECD table. The animal dietary burden is the same as the results from 2013 meeting, and the Meeting confirmed the previous recommendation of MRLs in animal products.

	US/CAN		EU		AU		Japan	
	Max.	Mean	Max.	Mean	Max.	Mean	Max.	Mean
Beef cattle	0.91	0.37	13.9	1.8	5.8	1.4	0.46	0.46
Dairy cattle	1.7	0.87	13.5	1.4	23.3	1.8	0.26	0.26
Poultry—broiler	0.49	0.49	0.80	0.54	0.12	0.12	0.066	0.066
Poultry—layer	0.49	0.49	4.1	0.76	0.12	0.12	–	–

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed are appropriate for establishing maximum residue limits and for an IEDI assessment.

Definition of the residue for plant and animal commodities for compliance with MRLs and for estimation of dietary intake: *cyprodinil.*

The residue is fat soluble

CCN	**Commodity**	**Recommended Maximum residue level (mg/kg)**		**STMR or STMR-P mg/kg**	**HR or HR-P mg/kg**
		New	**Previous**		
SO 0495	Rape seed	0.02		0.02	

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Dietary Intakes (IEDIs) of cyprodinil were calculated for the 17 GEMS/food cluster diets using STMRs/STMR-Ps estimated by the current Meeting and by the 2003 JMPR. The ADI is 0–0.03 mg/kg bw and the calculated IEDIs were 6–70% of the maximum ADI (0.03 mg/kg bw). The Meeting concluded that the long-term intakes of residues of cyprodinil, resulting from the uses considered by the current Meeting and by the 2003 JMPR are unlikely to present a public health concern.

Short-term intake

The 2003 JMPR decided that an ARfD was unnecessary and concluded that the short-term intake of cyprodinil residues is unlikely to present a public health concern.

DIFENOCONAZOLE (224)

First draft was prepared by Dr Anita Stromberg, National Food Agency, Uppsala Sweden

EXPLANATION

Difenoconazole is a systemic triazole fungicide and acts by inhibition of demethylation during ergosterol synthesis. It is applied by foliar spray or seed treatment and controls a broad-spectrum of foliar, seed and soil-borne diseases caused by *Ascomycetes*, *Basidiomycetes* and *Deuteromycetes* on a variety of crops. Difenoconazole was evaluated for the first time by JMPR 2007. The 2007 Meeting established an acceptable daily intake (ADI) of 0–0.01 mg/kg bw and an acute reference dose (ARfD) of 0.3 mg/kg bw. In 2007, 2010 and 2013, the JMPR evaluated the compound for residues and recommended a number of maximum residue levels.

Difenoconazole was listed by the 46th session of CCPR (2014) for evaluation for additional MRLs. The current Meeting received from the manufacturer additional analytical methods, processing data from soya beans, oilseed rape and rice, GAP information and residue trial data from uses on strawberry, avocado, soya beans, cotton, peanut, rice and oilseed rape (canola).

IDENTITY

The 2007 Meeting noted that the structural formula for difenoconazole contains two chiral carbons resulting in a *cis-trans* pair diastereoisomers. The current Meeting noted that the presented analytical methods not are stereo-selective for the *cis*- and *trans*- isomers

ANALYTICAL METHODS

The current Meeting received new analytical method descriptions and validation data for parent difenoconazole. Methods were validated for all crop matrices; the LOQ were 0.01 mg/kg for determination of difenoconazole with procedural recoveries by matrix in the range of 70–122% at various fortification levels. A summary of the analytical methods for difenoconazole is provided below.

Method, analyte	Matrix	Extraction	Clean-up	Detection, LOQ
Method REM 147.08 Difenoconazole	Plant material 2007 JMPR) Current Meeting: Validation data on oilseed rape seed, meal and refined oil.	Refluxing with methanol-ammonia for 2 hours. Elution with dichloromethane.	Solid-phase extraction (SPE)	LC-MS/MS Difenoconazole LOQ 0.01 mg/kg
Method POPIT MET.032 Difenoconazole	Plant material Validation data on soya beans and peanuts	high-speed homogenisation with a acetone/water mixture (2:1; v/v)	Filtration/centrifugation	HPLC-MS/MS Difenoconazole The ion transition m/z 406→251 is used for quantification LOQ 0.01 mg/kg

Plant materials

Oilseed rape (canola)

The analytical method REM 147.08 was validated for oilseed rape seed and the processed fraction meal and refined oil by Sagan, K (2012 SYN545192) for residues of difenoconazole with an LOQ of 0.01 mg/kg. The method REM 147.08 was reviewed by JMPR in 2007. The recovery (% recovery) and repeatability (RSD) is summarized in Table 1 below.

Table 1 Recovery and repeatability data for the method REM 147.08 for difenoconazole oilseed rape

Commodity	Fortification level (mg/kg)	No of analysis	Recovery (%)	Mean recovery (%)	% RSD
Oilseed Rape (seed)	0.010	4	81,121, 114, 112	107	17
	0.10	4	122, 118, 97, 102	110	11
	0.20	4	91 ,94 ,85	90	5.1
Oilseed Rape (meal)	0.010	3	98,89,100	96	6.1
	0.10	3	89, 103, 115	102	13
	0.20	3	85, 92, 84	87	5.0
Oilseed Rape (oil)	0.010	3	82, 100, 83	88	11
	0.10	3	98, 99,84	94	9.0

Other plant materials

The analytical method POPIT MET.032 was developed to determine and quantify difenoconazole in plant material by Vopi K *et al.* (2010 Syngenta file no. CGA169374_10882).

Residues of difenoconazole are extracted from plant matrices by high-speed homogenisation with an acetone/water mixture (2:1; v/v). The suspension is either filtrated (soya beans) or centrifuged (peanut) and brought to volume with extraction solvent. An aliquot of the extract is evaporated and reconstituted in acetonitrile/water (1:1; v/v). After filtration of the final sample solution, residues of difenoconazole are determined by liquid chromatography with tandem mass spectrometric detection (HPLC-MS/MS). Quantification is performed with calibration curves using 6 standard solutions (from 1×10^{-4} to 3.2×10^{-3} µg/mL, ½ to 16 times the LOQ). The ion transition m/z 406→251 is used for quantification. The method has a validated LOQ of 0.01 mg/kg for soya beans and peanut.

Table 2 Recovery and repeatability data for the method POPIT MET.032 for difenoconazole in soya beans and peanuts

Commodity	Fortification level (mg/kg)	No of analysis	Recovery (%)	Mean recovery (%)	% RSD
Soya (beans)	0.010	8	88; 91; 92; 93; 94; 96; 97; 99	94	3.8
	0.10	6	78; 83; 90; 92; 93; 95	89	7.5
	1.0	5	74; 77; 79; 79; 83	78	4.2
Peanut (kernels)	0.010	7	70; 72; 72; 72; 73; 74; 80	73	4
	0.11	5	70; 82; 83; 85; 90	82	9

The analytical method POPIT MET.033 was developed to determine and quantify difenoconazole in plant material by Maslowski, R *et al*. (2008 Syngenta file no. CGA169374_10881).

Residues of difenoconazole are extracted from plant matrices by high-speed homogenisation with an acetone/water mixture (2:1; v/v). The suspension is filtrated (cotton) and brought to volume by extraction solvent. After filtration of the final sample solution, residues of difenoconazole are determined by liquid chromatography with tandem mass spectrometric detection (HPLC-MS/MS). Quantification is performed with calibration curves using 6 standard solutions. The ion transition m/z 406→251 is used for quantification and the ion transition m/z 406-111 for confirmation. The method has a validated LOQ of 0.01 mg/kg for difenoconazole in avocado, cotton, peanut, rice, soya beans and strawberry.

The recovery (% recovery) and repeatability (RSD) of residues from parent difenoconazole in crop matrices in current evaluation for MRLs is summarized in Table 3 below.

Table 3 Recovery and repeatability data for the method POPIT MET.033 for difenoconazole in various plant matrices

USE PATTERN

Difenoconazole is a systemic fungicide which belongs to the triazole chemical group of fungicides. Information on registered uses including labels from countries trials had been carried out was provided to the Meeting by one manufacturer. The representative uses relating to crops under consideration for additional MRLs and revising some of the existing CODEX MRLs are summarized in the following table.

Table 4 Registered uses of difenoconazole from labels provided

Crop	Country	Application details								
		type	Met-hod	kg ai/ha	Water L/ha	Crop growth stage	No	Interval (days)	PHI	Comments
Straw-berry	USA	126 g ai/L SC	Foliar spray	0.129	> 94[a]; 140 [b]	Prior to disease onset when conditions conductive for disease	4	7-14	0	Not more than 2 sequential applications before alternating to another fungicide with different mode of action. max 0.21 kg ai/ha per crop and season
Avo-cado	Brazil	250 g ai/L EC	Foliar spray	0.050	500-1000	start at flowering, end when fruit is around 5 cm	4	14	14	ground/ aerial application
Soya bean	USA	126 g ai./L SC	Foliar spray	0.129	> 19[b]	Prior to disease onset when conditions conductive for disease	2	7-10	14	Do not feed soybean hay, forage or silage max 0.25 k g ai/ha per season
Rice	Italy	125 g ai/L SC	Foliar spray	0.125	200-400	BBCH 21-29[d]	2	-	28	ground application
Cotton	Brazil	250 g ai/L EC	Foliar spray	0.075	200-400	when first symptom occur	3	10-15	21	ground/ aerial application
Peanut	Brazil	250 g ai/L EC	Foliar spray	0.0875	100-200	when first symptom occur	3	-	22	ground/ aerial application
Oilseed Rape (canola)	Canada	250 g ai/L EC	Foliar spray	0.125	110-170[c]	BBCH 12-18[e] or BBCH 62-65[f]	1	-	30	ground/ aerial application max 0.125 kg ai/ha per season

[a] For aerial applications

[b] For ground applications

[c] When applying difenoconazole at typical herbicide timing it is recommended to use 50-110 L/ha water

[d] Between beginning and end of tillering.

[e] Apply during rosette stage between 2nd true leaf and bolting. (*Leptosphaeria maculans)* Virulent Black Leg

[f] Apply at 20-50% bloom *(Sclerotinia sclerotiorum)* Sclerotinia Stem Rot

Conditions of the supervised residue trials were generally well reported in detailed field reports. In most trials plots treated plots were not replicated but where results were reported from replicate plots, these are presented as individual values. Most field reports provided data on the sprayers used and their calibration, and reports provided data on plot size, residue sample size and sampling date. Although trials included control plots, no control data are recorded in the tables except where residues in control samples exceeded the LOQ. Residue data are recorded

unadjusted for % recovery. When residues were not detected they are shown as below the LOQ (e.g., < 0.01 mg/kg). Laboratory reports included methods validation with procedural recoveries from spiking at residue levels similar to those occurring in samples from the supervised trials. Data on duration of residue sample under storage were also provided. Residues and application rates have generally been rounded to two significant figures or, for residues near the LOQ, to one significant figure.

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

Residues values from trials conducted according to a maximum registered GAP with supporting trials have been used for the estimation of maximum residue levels. The results included in the evaluation of the MRL, STMR and HR is underlined.

The Meeting received information on supervised field trials involving difenoconazole for the following crops and commodities:

Group	Crop commodity	Portion of commodity to which MRL apply	Countries	Table No
FB, Berries and other small fruits	Strawberry, fruit	Whole fruit	USA	5
FI, Assorted tropical and sub-tropical fruits – inedible peel	Avocado, fruit	Whole commodity after removal of obviously decomposed or withered leaves	Brazil	6
Pulses,	Soya, seed	Whole commodity	USA	7
GC, Cereal grain	Rice, grain, straw forage	Whole commodity	Europe	8
SO, Oilseed	Cotton, seed	Whole kernel after removal of the seed	Brazil	9
	Peanut, whole plant	Whole kernel after removal of the seed	Brazil	10
	Oilseed rape, seed	Whole kernel after removal of the seed	Canada	11
Animal feeds	Rice forage		Europe	12
	Rice straw		Europe	13

Strawberry

Nine independent supervised residue field trials on strawberries were conducted in USA during growing season 2008-2009. Four foliar applications of difenoconazole (EC formulation) at a target rate of 0.129 kg ai/ha were made with a seven day interval. Duplicate samples (fruits) were taken seven days after the third application and immediately after the last (fourth) application. Samples were stored frozen for a maximum of eight months.

Analysis of difenoconazole was made using LC-MS/MS and method REM 147.08. The limit of quantification was 0.01 mg/kg and the mean recovery was in the range of 70–109% at fortification levels of (n=1–2) 0.01, 0.5, 1.0 and 2.0 mg/kg.

Samples were analysed for triazole metabolites by Analytical Method 160 using LC/MS/MS and Morse Laboratories, Inc. The limit of quantitation (LOQ) for all analytes (as respective parent equivalents) for strawberries was 0.01 mg/kg. The limit of detection (LOD) based on the smallest standard that can be detected is 0.0015 ng/kg. The mean recovery for the metabolites was triazole (87±8%), triazole alanine (92±7%) and triazole acetic (102±7%) at fortification levels (n=16) 0.01, 0.10, 0.02 and 0.5 mg/kg.

Avocado

Four independent supervised residue decline field trials were conducted on avocado in Brazil during growing season 2007-2008. Four foliar applications of difenoconazole (SC formulation) at a rate of 0.05 kg ai/ha were made with a fourteen day interval. Single samples (avocado fruits) were collected and stored frozen for a maximum of 8.9 months. This storage period is covered by the storage stability studies (24 months)

Analysis of parent difenoconazole was made using HPLC-MS/MS and method POPIT MET.033. The limit of quantification was 0.01 mg/kg and the mean recovery was between 84±2.2% to 91±1.2% at fortification levels of (n=2) 0.01, 0.11 and 2.2 mg/kg.

Soya beans (dry)

Eighteen independent supervised residue field trials on soya beans were conducted in USA during growing season 2008. Two foliar applications of difenoconazole (EC formulation) at a target rate of 0.129 kg ai/ha were made at an interval of seven to ten days. Duplicate samples of soya beans were collected except in the residue decline trials when single samples were taken. Samples were stored frozen for a maximum of 4.8 months. This storage period is covered by the storage stability studies (24 months).

Analysis of parent difenoconazole was made using LC-MS/MS and method REM 147.08. The limit of quantification was 0.01 mg/kg and the mean recovery was 100±11% (n=22) at fortification levels of 0.01–10.0 mg/kg.

Samples were also analysed for the triazole metabolites using LC/MS/MS and Morse Laboratories, Inc. (Analytical Method 160). The limit of quantitation (LOQ) for all analytes (as respective parent equivalents) for soybeans was 0.01 mg/kg. The limit of detection (LOD) for all metabolites based on the smallest detectable standard was 0.00003 µg/mL for 1, 2, 3-triazole and triazole alanine in all matrices. The LOD for triazole acetic acid was 0.00005 µg/mL in all matrices. The mean recovery for the metabolites was triazole (91±11%), triazole alanine (90±10%) and triazole acetic (99±7.4%) at fortification levels of 0.01 and 0.1 mg/kg (n=18).

nd = not detected

[a] Different due to different of 2.5 weeks difference in application times and different cultvars

R5 = BBCH 50-59Beginning Seed: Seed in one of the four uppermost nodes with fully developed leaves is 1/8 in. long.

R6 = BBCH60-69 Full Seed: Pod containing a green seed filling the pod cavity is present at one of the top four nodes.

R7 =BBCH 70-79 Beginning Maturity: One normal pod on the main stem has reached its mature pod colour. At this stage, the crop is safe from a killing frost.

Rice

Eight independent supervised residue field trials on rice were conducted in Italy in 2009 and 2010. Two foliar applications of difenoconazole (EC or SC) were made with a fifteen days interval at a target rate of 0.125 kg ai/ha. Duplicate samples of whole plant, grain and straw were collected and

maintained in frozen storage for periods up to 14 months for whole plants and 13 months for grain and straw. This storage period is covered by the storage stability studies (24 months)

Analysis of parent difenoconazole (on one of the duplicate sample) was made using LC-MS/MS and method REM 147.08. The limit of quantification was 0.01 and the mean recovery was 102±14% (whole plant), 108±12% (grain) and 105±10% for straw at fortification levels of (n=1–2) 0.01, 0.1 and 8 mg/kg.

Analysis of the metabolites was made using Syngenta method GRM053.01A for triazole metabolites T, TA, TAA and triazole lactic acid (TLA). The method is validated for cereals (including rice) whole plant, grain and straw with a LOQ of 0.01 mg/kg for each metabolite.

Cotton

Eight independent supervised residue field trials on cotton were conducted in Brazil during growing season 2006 and 2007/08. Four trials were made with four foliar applications of difenoconazole (SC formulation) at a target rate of 0.075 kg ai/ha, an interval of 14 days and sampling after 7, 4 and 21 days. An additional four trials were made with five foliar applications of difenoconazole (SC formulation) at a target rate of 0.075 kg ai/ha, an interval of 21 days (after the last two applications)

and sampling after 30 days. Single samples (cotton bolls) were taken and stored frozen maximum 8.1 months. This storage period is covered by the storage stability studies (24 months).

Analysis of parent difenoconazole in seeds was made using HPLC-MS/MS and method POPIT MET.033. The limit of quantification was 0.01 mg/kg for and the mean recovery was 84±5% at fortification levels of (n=8) 0.01 and 0.1 mg/kg.

Peanut

Eight supervised residue field trials on peanuts were conducted in Brazil during growing seasons 2008 and 2009/10. Four trials were made with six foliar applications (SC formulation) at a rate of 0.125 kg ai/ha. Single samples (peanut plants) were collected 14, 22 and 38 days after last application and after the plants were dried, the pods were removed from the plants and threshed using a small machine. The seeds were stored frozen at maximum 7.6 months. This storage period is covered by the storage stability studies (24 months).

Analysis of parent difenoconazole from seeds in these trials was made using method HPLC-MS/MS and method POPIT MET.033. The limit of quantification was 0.01 mg/kg and the mean recovery was between 84±3% to 89±2% at fortification levels of (n=5–7) 0.01 and 0.1 mg/kg.

An additional four field trials were conducted in Brazil during growing season 2007/08 with three foliar applications at rate of 0.0875 kg difenoconazole (EC formulation). Single samples (peanut plants) were sampled and peanut kernel stored frozen for a maximum of 4.5 months. The storage period is covered by the storage stability studies (24 months).

Analysis of parent difenoconazole from seeds in these trials was made using HPLC-MS/MS and method POPIT MET.032. The limit of quantification was 0.01 mg/kg and the mean recovery was between 73±3% to 82±9% at fortification levels of (n=5–7) 0.01 and 0.1 mg/kg.

Rape seed (Canola)

Thirteen independent supervised field trials on oilseed rape were conducted in Canada during growing season 2011. One foliar application (EC formulation) was made at the target rate of 0.125 kg ai/ha. Duplicate samples of were collected 30 days after the application. Rape seed samples were stored frozen for periods up to 4.7 months. This storage period is covered by the storage stability studies (24 months).

Analysis of parent difenoconazole from seeds in these trials was made using LC-MS/MS and method REM 147.08. The limit of quantification was 0.01 mg/kg for and the mean recovery was between 88±11% to 107±17% at fortification levels of (n=3–4) 0.01, 0.1 and 0.2 mg/kg.

FATE OF RESIDUES IN STORAGE AND PROCESSING

Residues after processing

As a measure of the transfer of residues into processed products, a processing factor was used, which is defined as:

Processing factor (Pf) parent difenoconazole =

$$\frac{\text{Residues in processed product (mg/kg)}}{\text{Residues in raw agricultural commodity (mg/kg)}}$$

Processing factor (PF) for each triazole metabolite =

$$\frac{\text{Residues in treated processed product – residues in untreated processed product (mg/kg)}}{\text{Residues in treated raw agricultural commodity (RAC) – residues in untreated RAC (mg/kg)}}$$

If residues in the RAC were below LOQ, no processing factor could be derived. In case of residues below the LOQ, but above the LOD in the processed product, the numeric value of the LOQ was used in the calculation. If residues in the processed product were below the LOD, the numeric value of the LOQ was used for the calculation but the PF was expressed as "less than" (e.g. < 0.5). If residues in the processed commodity were below what was found in untreated processed commodity no processing factor was calculated.

Soya beans

Two studies on the conduct of difenoconazole during processing of soya bean into meal, hulls and refined oil and one study for the processing into aspired grains was conducted by Willard, TR and Mäyer JT (2008, T002400-07). Field trials of soya bean was treated with two applications at a target rate of 0.65 kg ai/ha. Samples of soya beans were collected 14 days after the last application. Duplicate field samples and processed fractions were analysed for parent difenoconazole using method REM 147.08. LOQ for parent difenoconazole was 0.01 mg/kg and the mean recovery was in meal 108% at fortification level of (n=2) 0.01–5.0, in hulls 106% at fortification level of (n=2) 0.01–5.0, in refined oil 88% at fortification level of (n=2) 0.01–0.05 and in aspirated grain fraction (AEG) 112±6.6% at fortification level (n=4) 0.01–250 mg/kg- Each triazole metabolite was analysed using method No 160 rev.2 Morse Laboratories. LOQ for all triazole analytes were 0.01 mg/kg.

Samples of RAC (soya beans) were stored frozen for a maximum of 4.8 months and the duration of the storage for the processed fractions meals, hulls, refined oil and aspired grain fractions were 3.2, 5.5, 3.2 and 10.4 months, respectively.

Processing of meal, hulls and refined oil

Cleaned whole soybeans were fed into a roller mill to crack the hull and liberate the kernel. After hulling, the material was passed through an aspirator to separate hull and kernel material. The moisture content of the kernel material was determined and adjusted to 13.5%. Kernel material was heated to 71–79 °C and flaked in a flaking roll with a gap setting of 0.2–0.33 mm. Flakes were extruded in a continuous processor, where they were turned into collets by direct steam injection and compression. After extrusion, the collets were oven dried, placed in stainless steel batch extractors and submerged in hexane at 49–60 °C. After 30 minutes, the hexane was drained and fresh hexane was added to repeat the cycle twice.

The solvent was evaporated from the extracted flakes and the oil fraction to give meal and crude oil. The crude oil was treated with sodium hydroxide to remove free fatty acids. The neutralized oil was centrifuged and the supernatant, refined oil decanted.

Processing of aspirated grain fraction

To generate aspirated grain fractions (AGF), the samples were placed in a dust generation room containing a holding bin, two bucket conveyors, and a screw conveyor. As the samples were moved for 120 minutes in the system, aspiration was used to remove light impurities (grain dust). Light impurities were classified by sieving using 2.36, 2.0, 1.18, 0.85 and 0.425 mm sieves. After classification of each sample, the material collected through the 2.36 mm sieve was recombined to produce one aspirated grain fraction.

Residues determined in soya bean and processed fractions meal, hulls, refined oil and aspirated grain fraction are shown in table 14 and 15.

Pf: Processing factor

Treatment 1 Untreated control, one sample per trial

Treatment 2 Treated twice with 0.65 kg ai/ha at ca 7 day interval starting 28 days prior to harvest of mature seed

- not calculated due to a reduced amount in treated processed soya bean than in untreated processed soya bean, or not detected in treated or untreated processed soya beans.

AGF: Aspirated Grain Fraction

Rice

A study on the behaviour of difenoconazole during processing of rice was conducted by Yozgatli HP, and Breyer N (2010, S10-02953, No. A7402T_10217). Two field trials of rice were treated with two applications of difenoconazole with a target rate of 0.25 kg ai/ha. Samples of rice grain were collected at 21 and 28 days after the final application. Rice (grain) was processed into polished rice, parboiled rice, cooked rice and rice flour. Two mass-balance studies to determine the accountability of the residue and two follow-up studies were conducted to determine residue transfer on each process.

Field samples and processed fractions were analysed for parent difenoconazole using method REM 147.08 and LOQ was 0.01 mg/kg. The RAC (rice grain) and processed fractions were stored in the freezer ≤ 18 °C for a maximum of 17 months.

Cleaning and husking

Grain samples from the field were dried if required to achieve a moisture content of 12.1–14.2%. The rice was then cleaned using a sample cleaner. Shriveled (undeveloped and broken) grain was sorted out (< 1.9 mm). Samples of cleaned grain, shriveled grain and impurities were taken.

A portion of the cleaned grain was husked with a rubber husker. Samples of husks, brown rice and abrasion / broken grain were taken.

Polishing

Brown rice was processed into bran and polished rice. If the period between husking and polishing was more than 12 hours, an additional sample of brown rice was taken before polishing. The brown rice was then polished using a vertical shelling machine (abrasive decortication). Samples of bran / rub-off and polished rice were taken.

Parboiling

Samples of cleaned grain were taken before the parboiling process. The cleaned rice was steeped in water and heated to 76–85 °C. The steeped grain was stored in its closed container at room temperature and had a moisture content of 37.1–47.3 % at the end of the procedure (duration 3–4.4 h). Excess steeping water (which was not absorbed) was removed. A sample of the steeping water was taken.

The steeped grain was transferred to an autoclave and steamed at 104–115 °C for about 15 min. Samples of steamed grain and steaming water were taken before the steamed grain was transferred to the drying oven. The grain was dried for 16 h at temperatures between 36 °C and 88 °C until a final moisture content of 7.6–14.9 % was achieved. A sample of parboiled rice was taken.

The parboiled rice was husked using a rubber husker and samples of husks, parboiled brown rice and abrasion / broken grain were taken.

The husked parboiled brown rice was then polished using a vertical shelling machine. Samples of bran / rub-off and polished parboiled rice were taken.

Cooking

Samples of each type of rice were taken just before cooking.

Brown rice was cooked for 50–75 min in boiling water (97–100 °C) and a sample of cooked brown rice was taken. Brown parboiled rice was cooked for 65–85 min in boiling water (99–102 °C) and a sample of cooked parboiled brown rice was taken. Polished rice was cooked for 31–62 min in boiling water (98–100 °C) and a sample of cooked rice was taken. Polished parboiled rice was cooked for 48–68 min in boiling water (98–104 °C) and a sample of cooked parboiled rice was taken.

Milling flour

Samples of polished rice and polished parboiled rice were taken just before milling. Polished rice was milled using a cross beater mill and a sample of flour (polished rice) was taken. Similarly, polished parboiled rice was milled using a cross beater mill and a sample of flour (parboiled rice) was taken.

A summary flow chart of the overall processing scheme is given in Figure 1.

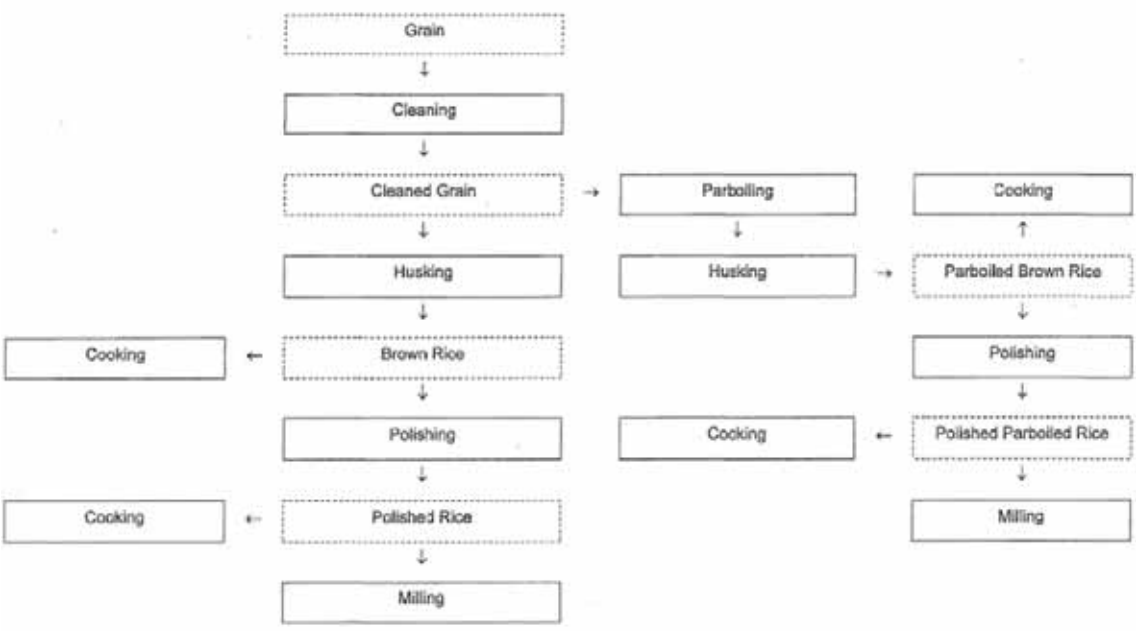

Figure 1 Processing Scheme for Rice grain

Rape seed

Two studies on the behaviour of difenoconazole during processing of rape seed into meal and refined oil was conducted by Sagen K (2011, CER 05903/11). Field trials of oilseed were treated with one application of the target rate 0.375 kg ai/ha. Samples were harvested 30 days after the application. Rape seed was used for the production of meal and refined oil. Field samples and processed fractions (single samples) were analysed for parent difenoconazole using method REM 147.08. The LOQ was 0.01 mg/kg. The duration of storage for the processed fractions press-cake meal and refined oil were 3.2 months and 1.6 months, respectively.

- Whole oilseed rape seeds were flaked
- Flakes were pressed to separate the oil
- The extracted meal was air dried
- A sample of air dried meal was heat treated to duplicate toasting of rape seed meal
- The pressed and extracted oils were combined
- The crude solvent oil and the centrifuged press oil were blended, acid degummed, refined, washed with water and bleached
- The bleached oil was deodorized.

Figure 2 Processing scheme for rape seed

APPRAISAL

Difenoconazole is a systemic triazole fungicide and acts by inhibition of demethylation during ergosterol synthesis. It is applied by foliar spray or seed treatment and controls a broad spectrum of foliar, seed and soil-borne diseases caused by Ascomycetes, Basidiomycetes and Deuteromycetes, on a variety of crops. Difenoconazole was evaluated for the first time by JMPR 2007. The 2007 Meeting established an acceptable daily intake (ADI) of 0–0.01 mg/kg bw and an acute reference dose (ARfD) of 0.3 mg/kg bw. Maximum residue levels for a number of commodities were recommended by JMPR in 2007, 2010 and 2013.

Definition of residues for plant products (compliance with MRLs and dietary intake assessment): *difenoconazole*.

Definition of residues for animal products: sum of difenoconazole and CGA 205375 (1-[2-chloro-4-(4-chloro-phenoxy)-phenyl]-2-(1, 2, 4-triazol)-1-yl-ethanol), expressed as difenoconazole.

Difenoconazole was listed by the Forty-sixth Session of CCPR (2014) for the review of additional maximum residue levels. GAP information with supporting residue studies in strawberries, avocadoes, soya beans, cotton, peanuts, rice and oilseed rape (canola) was evaluated by the present Meeting.

Methods of analysis

The analytical method used for determination of difenoconazole residues in samples derived from supervised field trials and processing studies in strawberries, soya beans, rice and oilseed was evaluated by previous Meetings.

Two new pre-registration methods for plant matrices were presented to the 2015 Meeting. In these methods difenoconazole is extracted by high-speed homogenisation with an acetone/water mixture (2:1). After clean-up the residues were determined by (HPLC-MS/MS).The method has a validated LOQ of 0.01 mg/kg for difenoconazole in avocadoes, cotton, oilseed rape including processed commodities, peanuts, rice, soya beans and strawberries. The methods were used for determination of difenoconazole residues in samples from supervised field trials on cotton and peanuts presented to the current Meeting.

Stability of pesticide residues in stored analytical samples

The stability of residues from difenoconazole in stored samples was evaluated by the 2007 Meeting. The periods of demonstrated stability cover the frozen storage intervals used in the residue trials for which maximum residue levels were estimated.

Results of supervised residue trials on crops

The Meeting received new supervised trial data for foliar application of difenoconazole (EC or SC formulations) on strawberries, avocadoes, soya beans, rice, cotton, peanuts and oilseed rape, and noted that residue data from rice, soya beans and oilseed rape also were provided to the 2007 JMPR.

The results from new trials and those previously reported by the 2007 JMPR which either matched the critical GAP, or when results could be proportionally adjusted to reflect GAP application rates, were considered in estimating maximum residue levels, STMRs and HRs for the commodities for which GAP information was available. The proportionality approach was considered to scale the results from trials where the application rates range from 0.3× GAP to 4× GAP and where all other parameters matched the critical GAP.

Strawberry

Data from supervised trials on strawberries from USA conducted in 2008 and 2009 were presented to the Meeting. The critical GAP in USA is maximum foliar applications up to 0.129 kg/ha, an application interval of 7–14 days and a PHI of 0 days. The maximum application rate for difenoconazole is 0.515 kg ai/ha per crop and season.

Strawberries belong to the high acid category and storage data covering this category was not evaluated by 2007 JMPR and not included in the residue trials. As difenoconazole has a pKa of 1.1 an estimation of maximum residue levels was not made.

Avocado

Four independent supervised trials from Brazil conducted in 2007 and 2008 were presented to the Meeting. The critical GAP in Brazil is four foliar applications of 0.05 kg ai/ha at BBCH 62–79 (starting at flowering until fruit is around 5 cm) and with intervals of 14 days. The PHI is 14 days.

The trials from Brazil (4× 0.05 kg ai/ha at BBCH 71–79, interval 14 days, PHI 14 days) matched the critical GAP. Residues of difenoconazole in avocado fruits 14 days after the last application were (n=4) 0.02, 0.05 (2) and 0.26 mg/kg. The highest residue of 0.26 mg/kg was measured in an individual fruit sample.

The Meeting estimated a maximum residue level, an STMR value and an HR value for difenoconazole in avocado of 0.6 mg/kg, 0.05 mg/kg and 0.26 mg/kg, respectively.

Soya bean (dry)

Twenty one supervised trials from USA conducted in 2008 were presented to the Meeting. The critical GAP in USA is two foliar applications of 0.129 kg ai/ha, with an interval of seven days and a PHI of 14 days.

Six trials from Brazil (2× 0.075 kg ai/ha and a PHI of 30 days) presented to the 2007 JMPR did not match the critical GAP.

Eighteen independent trials from USA (2× 0.129 kg ai/ha, interval 7–10 days, PHI 14 days) matched the critical GAP. Residues of difenoconazole in soya beans were (n=18) < 0.01(12), 0.012, 0.013, 0.019, 0.021, 0.04 and 0.087 mg/kg. The highest residue of 0.15 mg/kg was measured in individual seed samples.

The Meeting estimated a maximum residue level and STMR value for difenoconazole in soya bean seeds of 0.1 mg/kg and 0.01 mg/kg, respectively. The Meeting withdraws its previous recommendation of 0.02* mg/kg for maximum residue level for soya beans (dry).

Rice

Eight supervised trials from Europe (Italy) conducted in 2009 and 2010 were presented to the current Meeting. A registered label was not available to the Meeting and an estimation of a maximum residue level was not made.

Cotton

Eight independent supervised trials from Brazil conducted in 2006–2008 were presented to the Meeting. The critical GAP in Brazil is three foliar applications of 0.075 kg ai/ha, an interval of 10–15 days and a PHI of 21 days.

Four trials (5× 0.075 kg ai/ha, BBCH 13–81, interval 21 days, PHI 30 days) were not according to GAP. Samples were only taken 30 days after last application, and the applications were two more than specified in the critical GAP.

Four trials were made with four applications of 0.075 kg ai/ha starting from BBCH 71 up to BBCH 83 and a PHI of 21 days. These trials matched the critical GAP from Brazil. Residues

of difenoconazole in cotton were (n=4) < 0.01, 0.01 and 0.02 (2) mg/kg. An estimation of maximum residue levels was not made as four trials were considered insufficient.

Oilseeds

Peanut

Eight independent supervised trials from Brazil conducted in 2008–2010 were presented to the Meeting. The critical GAP in Brazil is three applications of 0.0875 kg ai/ha and a PHI of 22 day.

Four of the trials (3× 0.088 kg ai/ha, PHI 22 days) were according to the critical GAP and residues of parent difenoconazole were not detected. Another four trials (6× 0.125 kg ai/ha) were conducted as residue decline trials and residues of parent difenoconazole was not found.

As residues of difenoconazole not was detected at an exaggerated number of applications and application rates, the Meeting concluded a zero residue situation occurs after application of difenoconazole to peanuts in accordance with the Brazilian critical GAP.

Residues of difenoconazole in peanuts from eight independent trials matching GAP were (n=8) < 0.01 mg/kg.

The Meeting estimated a maximum residue level and STMR values for difenoconazole in peanut kernels of 0.01* mg/kg and 0 mg/kg, respectively.

Rape seed (canola)

Data from supervised trials on rape seed (canola) from Canada conducted in 2011 were presented to the Meeting. The critical GAP in Canada is one foliar application of 0.125 kg ai/ha and a PHI of 30 days.

Nine independent trials from Canada matching the critical GAP were available to the Meeting. Residues from difenoconazole in rape seed were (n=9) < 0.01, 0.011 (1), 0.015 (2), 0.033 (2), 0.038, 0.062 and 0.063 mg/kg.

The Meeting estimates a maximum residue level, and STMR value for difenoconazole in oilseed rape (rape seed) of 0.15 mg/kg and 0.03 mg/kg, respectively. The Meeting replaces its previous recommendation of 0.05 mg/kg for the maximum residue level for rape seed.

Animal feeds

Rape seed (canola), forage, fodder

Residue data for rape seed forage was not presented to the Meeting.

Soya bean

The Meeting noted that the GAP for difenoconazole in USA does not permit soya bean hay, forage or silage as animal feeds.

Rice whole crop (silage), and straw

Eight supervised trials from Europe (Italy) conducted in 2009 and 2010 were presented to the Meeting. Forage and straw samples were collected. A registered GAP was not available for rice. An estimation of maximum residues levels was not made.

Fate of residues during processing

The 2007 JMPR reported that difenoconazole was essentially stable during the hydrolysis conditions simulating food processing conditions and also estimated processing factors for a range of commodities. Relevant processing factors for difenoconazole and STMR-Ps for the commodities

considered at this Meeting and used for dietary intake and risk assessment or for estimating livestock animal burden are summarized below.

Raw agricultural commodity	Processed commodity	Processing factors [a] (mean)	RAC (mg/kg)	STMR-P
			STMR	mg/kg
Soya bean	RAC		0.01	
	Meal	0.38		0.004
	Hulls	2		0.02
	Oil (refined)	0.8		0.08
	AGF [b]	622		6.22
Rape seed (canola)	RAC		0.03	
	Meal	0.55		0.016
	Refined oil	0.05		0.002

[a] The processing factor is the ratio of the total residue in the processed item divided by the total residue in the RAC

[b] Aspirated grain fraction

The Meeting noted that in the studies available difenoconazole residues did not concentrate in food commodities during processing. In feed commodities however residues increased in soya bean hulls and soya bean aspirated grain fractions (AGF).

Residues in animal commodities

Estimated dietary burdens of farm animals

The dietary burdens for beef cattle and dairy cattle were calculated using the OECD diets listed in Appendix IX of the 2009 edition of the FAO Manual. Potential feed items included: almond hulls, cabbage heads and leaves, bean vines, carrot hulls, canola meal, grape pomace, pea vines, potato culls, potato process waste, soya beans, soya bean aspirated grain fraction, sunflower meal, and wheat grain and hay.

The estimated the dietary burden for cattle and poultry and were not significantly different from the dietary burdens estimated by the 2013 JMPR. The only additional feed item included was soya bean.

The Meeting confirmed the previous recommendations for animal commodities.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of residue for plant products (compliance with MRLs and dietary intake assessment): *difenoconazole.*

Definition of residue for animal products (compliance with MRLs and dietary intake assessment): sum of difenoconazole and CGA 205375 (1-[2-chloro-4-(4-chloro-phenoxy)-phenyl]-2-(1, 2,4-triazol)-1-yl-ethanol), expressed as difenoconazole.

The residue is fat soluble (2007 JMPR Meeting).

DIETARY RISK ASSESSMENT

Long-term intake

The IEDI of difenoconazole based on the STMRs estimated by this and previous Meetings for the 17 GEMS/Food regional diets were 7–70% of the maximum ADI of 0.01 mg/kg bw (see Annex 3 of the 2015 Report). The Meeting concluded that the long-term dietary intake of residues of difenoconazole is unlikely to present a public health concern.

Short-term intake

The ARfD for difenoconazole is 0.3 mg/kg bw. The International Estimated Short-Term (IESTI) of difenoconazole for the commodities for which STMR, HR and maximum residue levels were estimated by the current Meeting are shown in Annex 4 to the 2015 Report. The IESTI represented a maximum of 3% of the ARfD. The Meeting concluded that the short-term intake of difenoconazole residues from uses considered by the current Meeting was unlikely to present a public health concern.

ETHEPHON (106)

First draft prepared by Dr Yukiko Yamada, Ministry of Agriculture, Forestry and Fisheries, Tokyo, Japan

EXPLANATION

Ethephon, 2-chloroethylphosphonic acid, is a systemic plant growth regulator belonging to the phosphonate family. It is readily absorbed by the plant and releases ethylene, a natural plant hormone. Ethylene not only influences directly several physiological processes, such as ripening and maturation, but also stimulates the endogenous ethylene production. It has been registered in many countries for a variety of crops, including fruits, vegetables, cereals and oilseed crops.

Ethephon was first evaluated by JMPR in 1977 as a new compound, and has been reviewed for residues in 1978, 1983, 1985, 1994 (Periodic Review) and 1994. Currently there are 26 Codex MRLs for ethephon. It was listed in the Priority List by the 46th Session of CCPR in 2014 for toxicological and residue evaluation by the current Meeting in the CCPR Periodic Review Programme.

The Meeting received information on identity, metabolism and environmental fate, residue analysis, use patterns, supervised trials (on apples, cherries, grapes, figs, olives, pineapples, tomatoes, cereals, and cotton), processing, and animal feeding studies.

Formulations

Ethephon is mainly formulated as a soluble concentrate (SL). Concentrations are between 120 and 730 g/L. Combinations with chlormequat chloride or cyclanilide are also available for specific uses. Formulations are applied as foliar sprays by either ground or aerial equipment. Available formulations are listed below:

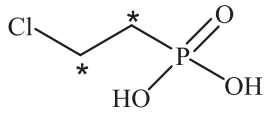
- Soluble liquid (SL) formulations containing either 120 g ai/L, 240 g ai/L, 250 g ai/L, 480 g ai/L, 660 g ai/L or 720 g ai/L
- Soluble liquid (SL) formulations containing a mixture of ethephon + chlormequat-chloride (150 g ai/L + 300 g ai/L or 180 g ai/L + 360 g ai/L ethephon + chlormequat-chloride, respectively)
- Suspension concentrate (SC) formulations containing a mixture of ethephon + cyclanilide (480 g ai/L + 60 g ai/L or 720 g ai/L + 45 g ai/L or 731 g ai/L + 49.5 g ai/L ethephon + cyclanilide, respectively)

METABOLISM AND ENVIRONMENTAL FATE

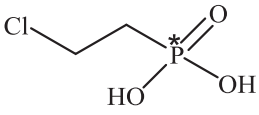
The following links code numbers and structure or description of the compounds appearing in the various metabolism and environmental fate studies.

Name or Code (MW)	IUPAC Name	Structure	Found in:
Ethephon (144.5) Syn: V-1283, S-1283, YI-5301, SCAL-5001	2-Chloroethylphophonic acid		Plants, Animals, Soils
HEPA (126.05)	(2-Hydroxyethyl)-phosphonic acid		Plants, Animals, Soils
Ethylene (28.05)	Ethylene		Plants, Animals
Phosphoric acid (94.97) or Phosphate anion	Phosphoric acid		Plants, Animals

The Meeting received information on plant and animal metabolism for ethephon, its environmental fate in soil and residues in rotational crops. The fate and behaviour of ethephon in plants, animals and soil were investigated using the radio-labelled ethephon with ^{14}C as shown in Figure 1. The radio-labelled ethephon with ^{32}P was also used in the metabolism study in pineapple.



1,2-^{14}C-ethephon ([U-^{14}C]-ethephon, ^{14}C-ethephon)



^{32}P-ethephon

Figure 1 Radio-labelled test materials used in the metabolism and environmental fate studies

In the metabolism and environmental studies, the total radioactive residues were expressed in ethephon equivalents unless otherwise stated.

Plant Metabolism

The Meeting received information on metabolism of ethephon in various plants (mostly fruit and seed crops) in support of supervised trials: pineapple, melon (cantaloupe), tomato, wheat, hazelnut and cotton. Information was also available from the published scientific literature on apple, peach, cherry, grape, squash and cucumber.

Pineapple

The metabolism of ethephon was studied in pineapple using [^{32}P]ethephon and [^{14}C]ethephon (Anonymous, 1968, ETH/M21, [M-188023-01-1]). The technical material used in the study was a mixture of 70% ethephon and 30% monochloroethyl ester. However, the monochloroethyl ester was later removed from all formulations intended for crop use and therefore its metabolism is not relevant for the current uses of ethephon.

In the first experiment, pineapple plants grown in the field were treated with an application to individual leaves of 300 mg of a formulation mixture containing [^{32}P]ethephon and its monochloroethyl ester approximately 5 months before harvesting of fruit. A separate group of pineapple plants was treated with 300 mg of a formulation mixture containing ^{32}P-sodium acid phosphate to investigate the uptake and distribution of phosphate, ethylene and chloride (all expected metabolites of ethephon) under the pH conditions normally found in plant tissues. Plants that were harvested with a longer PHI received a larger amount of ^{32}P-labelled compound due to the short half-life of ^{32}P (14.2 days).

One to 118 days after treatment, the above-ground portions were harvested. Samples were rinsed with water, homogenized and extracted with benzene and then methanol. The post-extraction solids were analysed for radioactivity by combustion. Liquid extracts were analysed by liquid scintillation counting (LSC).

On the day of application and three days after application (DAT), most of the radioactivity was recovered in the water wash. No radioactivity was found in the benzene extract or in the post-extraction solids. More than three days after treatment, little or no radioactivity was recovered in the water wash. On 118 DAT, approximately 40% of the radioactivity remained in the post-extraction solids, and was almost same for plants treated with [^{32}P]ethephon and with [^{32}P]phosphate.

TLC analysis of the water washes and methanol extracts showed complete degradation of ethephon in/on pineapple leaves long before formation of the fruits. No ethephon was found in immature fruits, or in fruits of leaves harvested 1 month before full maturity of the fruits.

In the second experiment, a pineapple leaf was spotted with a solution of [^{14}C]ethephon in methanol, and air-dried. Then the treated area was excised and sliced. The leaf slices were inserted into a sealed two-necked flask. A continuous stream of nitrogen was passed over the slices and led to an absorber tower containing a solution of 0.25 M mercuric perchlorate in perchloric acid to absorb [^{14}C]ethylene. The amount of [^{14}C]ethylene absorbed was determined by LSC for 8 consecutive days, after which time the leaf slices were freeze-dried, and the remaining radioactivity was determined by combustion.

Over the 8-day duration, 40.1% of the applied [^{14}C]ethephon was metabolized to [^{14}C]ethylene, and 36.3% of the applied radioactivity remained in the leaf. The low recovery is attributed to losses during freeze-drying.

In an additional static experiment, a treated pineapple leaf slice was cut into strips and placed in the centre annular ring of a Conway micro diffusion dish. A 0.5 mL aliquot of absorber solution was placed in the inner compartment and the apparatus sealed and left for 72 hours. The absorber solution was analysed by LSC. The leaf strips were extracted with methanol, the extract was diluted with water and then extracted with benzene. The methanol and benzene extracts were analysed by TLC, and the post-extraction solids were analysed by combustion. A portion of the methanol extract was treated with 5 N NaOH to convert the [^{14}C]ethephon to [^{14}C]ethylene. The resulting [^{14}C]ethylene was trapped in the perchlorate absorber and analysed by LSC.

After 72 hours, 25.2% of the applied [^{14}C]ethephon was converted to [^{14}C]ethylene. Of the radioactivity remaining in the leaf, 63.3% of the applied radioactivity (AR) was extracted with methanol, of which 40.1% AR reacted with NaOH to form [^{14}C]ethylene and was therefore characterized as [^{14}C]ethephon. TLC analysis of the methanol extract showed that parent ethephon was the only component of the residue, (Table 1).

Table 1 Recovery of ^{14}C- residues from an excised pineapple leaf slices following application of [^{14}C]ethephon (static experiment)

Fraction	% of Applied Radioactivity
[^{14}C]-ethylene	25.2
Methanol extract	63.3
Radioactivity evolved after treatment of methanol extract with NaOH (presumed to be [^{14}C]ethylene)	40.1
Benzene extract of methanol extract	< 0.1
Post-extraction solids	9.2

In the third experiment, nine pineapple plants were treated shortly (7, 14 or 21 days) before harvest of mature fruit with a spray application of [^{14}C]ethephon at 9 kg ai/ha, and transferred to uncoated cellophane chambers. Cellophane is impervious to ethylene but permeable to air and water vapour. In three of the boxes, glass tubing was inserted and connected to absorber towers filled with mercuric perchlorate-perchloric acid solution to absorb the ethylene evolved. Using a vacuum pump, air was passed through the chamber into the absorber towers at a rate of 1 air change/hour. The absorber solution was changed after 18, 46, 94, 118, 166 and 202 hours, and the radioactivity was determined by LSC. Plants were harvested after 1 hour to 21 days, and sectioned into fruit, top leaves, lower leaves and stump. The fruits were further sub-divided into crown, shell and bottom leaflets ('shell'), shell scrapings, fruit cylinder and core. Samples were frozen in dry ice and ground to a fine powder. The total radioactive residue in each fraction was determined by combustion analysis. Aliquots of each fraction were extracted with benzene and methanol, and the extracts were analysed by LSC. The radioactivity remaining unextracted was determined by combustion.

Very little or no radioactivity was found in the benzene extracts, and therefore these were not analysed further. Selected methanol extracts were analysed for ethephon by TLC. [^{14}C]Ethylene was evolved at an approximately constant rate from the treated plants. Little radioactivity was translocated into the pineapple flesh. TLC analysis showed that the bulk of the radioactivity remained in/on the plants and was found to comprise almost entirely unchanged [^{14}C]ethephon. An additional unidentified minor component of the ^{14}C-residue in pineapple shell and shell scrapings was also found in some stored standard solutions and was therefore postulated to be an impurity in the starting material rather than a metabolite. The distribution of residues in the pineapple fractions is shown in Table 2.

Table 2 Distribution of ^{14}C- residues in pineapple fractions

Application timing (days before normal harvest): Time after treatment	% of Total Radioactivity							
	Top third leaves	Shell	Shell scrapings	Stump	Cylinder	Core	Crown	Lower leaves
21: 45 hours	7.6	16.4	5.9	2.1	0.5	0.1	16.9	50.4
21: 6 days	20.5	23.9	3.7	1.4	0.9	0.1	9.8	39.3

Melon (Cantaloupe)

Melon plants grown under field conditions were treated with a foliar spray of an SL formulation followed by a localised application of [^{14}C]ethephon to the leaves proximal or distal to the peduncle

(fruit stalk), or directly to the melon rind covering about 40% of the surface area (Palmer, Lewis, Johnson and Smith, 1970, ETH/20, [M-188017-01-1]). The fruits were protected after treatment using a cheesecloth bag and were harvested after 3 days. Surface residues were removed by washing the treated leaves or melon rind with 20% aqueous methanol followed by two water washes. Each melon was separated into rind, flesh and seeds, the samples were cut into thin ribbons and then frozen. The remaining vines were collected and frozen. Samples were freeze-dried and ground into a fine powder, and then extracted with either benzene plus methanol, water and methanol/chloroform (2:1), or water and chloroform.

The methanol extracts from benzene and methanol were combined, acidified and concentrated by rotary evaporation. The concentrated extract was acidified, made up to volume with methanol, and ethyl ether added to precipitate the co-extracted plant material. The combined methanol/water extracts were concentrated by rotary evaporation, acidified, and ethyl ether added to precipitate the ether insoluble residue. This extraction scheme resulted in more complete extraction of radioactivity.

Radioactivity in the methanol, or methanol/water extracts was determined by LSC. Radioactivity in non-aqueous solvents and insoluble plant residues was determined by low beta gas flow counting. Metabolite profiling was performed by radio-TLC using cellulose or silica plates.

Surface washing removed 37.2–47.8% of the AR from the treated melons and 21.4–42.9% of the AR from the treated distal leaves. The treated proximal leaves senesced and desiccated rapidly and therefore two leaves were lost and a low recovery was obtained from the third leaf. Similar but less severe ageing of the proximal leaf was observed on other vines with ripened melons (Table 3).

Table 3 Radioactive residues recovered in surface washes following application of [^{14}C]ethephon to different portions of melon plant

Plant portion to which [^{14}C]ethephon was applied	% of Applied Radioactivity [a]
Melon fruit rind	37.2–47.8
Distal leaf	21.4–42.9
Proximal leaf	12.2 [b]

[a] Range of three replicates

[b] Value for one replicate only. Proximal leaf desiccated and shattered in two replicates.

The total recovered radioactivity from the melon fruits after surface-washing was 6.90% of the AR following application to the melon rind, 1.14% following application to the distal leaf and 1.70% following application to the proximal leaf (Table 4).

Table 4 Radioactive residues in melon sections following application of [^{14}C]ethephon

Plant portion to which [^{14}C]ethephon was applied	% of Applied Radioactivity [a]			
	Rind	Flesh	Seed	Total
Melon fruit rind [b]	6.35	0.06	0.15	6.90

Tomato

Tomato plants in outdoor plots were treated with a foliar application of [^{14}C]ethephon at 1.46 kg ai/ha and a water volume of 480 L/ha (Smith, 2002, CZ00E500, [M-240722-01-2]). The application timing was at the 'green mature' or 'colour break' stage of development. Tomato fruits were harvested on day 0 and 5 and 12 days after treatment (DAT). The 0 and 5 DAT samples were surface-washed with methanol, and then chopped and extracted with methanol. The 12 DAT samples were ground with dry ice and the total radioactivity was determined by combustion. The 12 DAT samples were subsequently extracted with methanol. Radioactivity in extracts was determined by LSC, and post-extraction solids were analysed by combustion analysis and LSC. Extracts were analysed by HPLC and TLC, and identification of ethephon and HEPA was performed by co-chromatography with reference standards.

The majority of the radioactive residue on 0 DAT was recovered in the surface wash, and most of the remainder was extracted with methanol. At 5 DAT, only 18% of the total radioactive residue (TRR) was recovered in the surface wash and the majority was extracted with methanol. Only 4.6% TRR remained unextracted. At 12 DAT, methanol extraction recovered 98% TRR, leaving only 2.3% TRR unextracted (Table 7).

Table 7 Total radioactive residues in tomato fruit after foliar application of [^{14}C]ethephon at 1.46 kg ai/ha

Fraction	0 DAT		5 DAT		12 DAT	
	mg/kg	% TRR	mg/kg	% TRR	mg/kg	% TRR
Methanol surface wash	6.5	83.7	0.31	18.4	Not performed	
Methanol extraction	1.3	16.0	1.3	77.1	1.1	97.8
Total extracted	7.8	99.7	1.6	95.5	1.1	97.8
Unextracted residue	0.025	0.4	0.078	4.6	0.026	2.3
TRR by extraction	7.8	100	1.7	100	1.2	106
TRR by combustion	Not performed		Not performed		1.1	100

The main component of the radioactive residue found in tomato fruit was ethephon (96, 70 and 59% TRR on 0, 5 and 12 DAT, respectively). The concentration of ethephon decreased over the time period in the study from 7.5 mg/kg at 0 DAT to 0.68 mg/kg at 12 DAT. The only significant metabolite was HEPA, amounting to 13–15% TRR in fruits of 5 and 12 DAT (Table 8). There were two other discernible metabolites that chromatographed close to HEPA, but both accounted for < 5% TRR and were not identified. The remainder of the unidentified radioactivity was polar in nature and did not exceed 8.5% TRR.

In tomato plants ethephon was metabolised by replacement of the chlorine in the 2-position with a hydroxy group to form HEPA; like in all other plants whose metabolism of ethephon was studied, the majority of the [^{14}C]ethephon applied was decomposed to volatile ethylene and phosphate.

Wheat

Wheat plants at the forage stage (BBCH 39) in outdoor plots were treated with a foliar application of [^{14}C]ethephon at a normal field rate of 0.36 kg ai/ha and at a 10× rate of 3.6 kg ai/ha in a water volume of approximately 250 L/ha (Smith, 2002, CZ00E501, [M-240723-01-1]). Samples were harvested on 0 (forage), 14 (hay) and 34 (grain and straw) DAT. The 0 and 14 DAT samples were surface-washed with methanol, and then chopped and extracted with methanol. The 34 DAT samples were homogenized and extracted with methanol. The post-extraction solids from the grain (1× and 10× rate) and straw (1× rate) were subjected to acid hydrolysis with 5% HCl, yielding an acid hydrolysate. The residual fibres were extracted with methanol and then acetonitrile, yielding a post-hydrolysis extract and non-extractable residue. Radioactivity in extracts was determined by LSC, and post-extraction solids were analysed by combustion analysis and LSC. The TRR in the 0 and 14 DAT samples were determined by extraction and combustion of the residue. The TRR in the 34 DAT samples was determined by combustion. Extracts were concentrated and analysed by HPLC and TLC, and identification of ethephon and HEPA was performed by co-chromatography with reference standards.

For both application rates at 0 DAT, about half the radioactivity was quickly absorbed into the leaves. On 14 DAT, only a small amount of the applied radioactivity remained on the leaf surface (1.1% TRR) and almost all the radioactivity was recovered in the methanol extract, with about 5% TRR remaining unextracted (Table 9).

On 14 and 34 DAT, the majority of radioactivity was recovered in methanol extracts of plant parts (hay and straw) regardless of the dose used; radioactivity was similarly distributed in methanol surface wash and methanol extract of forage on 0 DAT. Unextracted residues were about 5% in 14 DAT hay but 10% (1×) and 26% (10×) in 34 DAT straw.

Methanol extraction could recover only 28 and 22% TRR from grain (34 DAT) samples after the low and high doses. Acid hydrolysis of remaining solid with 5% HCl released 56 and 71% TRR and extraction of the post-hydrolysis solids with methanol and then acetonitrile further released a total of 9.9% and 4.3% TRR. This indicates the significance of conjugates in grains. Unextracted residues were 1.8–6.0% TRR.

Table 9 Total radioactive residues in wheat fractions after foliar application of [^{14}C]ethephon at 0.36 kg ai/ha (1× rate) or 3.6 kg ai/ha (10× rate)

TRR by combustion	Not performed		Not performed		3.39	100	22.45	100

At all harvest times, most of TRR was attributed to the sum of ethephon and HEPA, and were the only residues identified. In 0 DAT forage (1× rate), the recovered radioactivity was primarily unchanged ethephon (Table 10).

In the 14 DAT hay, the major radioactive residue was HEPA with 72% TRR and 3.7 mg/kg followed by ethephon with 20% TRR and 1.0 mg/kg in the methanol extract. In the 34 DAT straw, the major radioactive residue was ethephon at 62% TRR (47% TRR in methanol extract, 9.3% in acid hydrolysate and 5.9% TRR in extracts of post acid hydrolysis solid) and 1.5 mg/kg.

In 34 DAT grain, HEPA was found at a similar level as ethephon after the low dose: HEPA, 48% TRR (14% TRR in methanol extract, 29% TRR in acid hydrolysate and 5.5% TRR in extracts post-hydrolysis solid) and 0.51 mg/kg; and ethephon, 44% TRR (13% TRR in methanol extract, 26% TRR in acid hydrolysate and 4.4% TRR in extracts of post-hydrolysis solid) and 0.47 mg/kg. After the higher dose, approximately two times larger amounts of HEPA was found than ethephon (HEPA, total of 60% TRR and 2.0 mg/kg; and ethephon, total of 32% TRR and 1.1 mg/kg). No other metabolites exceeded 3% of TRR.

In total, in 14 and 34 DAT samples, 88–92% of the radioactive residue was identified as ethephon and HEPA, with no other single metabolite comprising more than 2.6% TRR.

In summary, ethephon is metabolised in wheat to form HEPA. The residue in 0 DAT wheat forage comprised mainly ethephon, with low levels of HEPA. In hay, grain and straw, the residue consisted of ethephon and HEPA; no other metabolites were identified.

Hazelnut (Filberts)

Two filbert trees (in the Codex Classification of Foods and Animal Feeds, the entry “Filberts” refers to “Hazelnuts” with the description, “among other *Corylus maxima*, Mill; and the “Hazelnuts”, include *C maxima* and *C. avellana*.) were treated with a foliar spray of non-radio-labelled ethephon at 1000 mg/kg and, six hours later, 2960 kBq [^{14}C]ethephon was applied to two branches of the trees (Anonymous, 1972, [M-188020-01-1]). One branch had 36 leaves and 9 nuts in husks, of which the upper surfaces of 18 leaves and two husks were treated. The other branch had 35 leaves and 11 nuts in husks, of which 15 leaves and three husks were treated.

The treated branches were separately enclosed in a screen cage wrapped in a plastic bag. Small holes in the bags allowed air to enter and flow through the bags. The bags were fitted with tubing which was connected to a gas trapping system consisting of an absorber containing water-saturated n-butanol and a mercuric perchlorate-perchloric acid solution to absorb ethylene. Air was drawn through the gas trapping system at a rate of 475 cm^3/minute. Ethylene absorption was continued for 7 days. [^{14}C]Ethylene in the absorber solution was measured using a liquid scintillation spectrometer.

Filbert nuts were harvested 7 and 14 DAT. Two different types of nut samples were collected: those treated directly on the husk, and those from limbs with treated leaves. Samples were frozen after collection. Nuts were separated into kernels, shells and husks and the samples were ground. TRR were determined by combustion analysis. The 7 DAT nutmeat was extracted by soxhlet extraction for 4 hours with benzene followed by methanol. The benzene extract did not contain any radioactivity and was discarded. The extracted residue was analysed by combustion.

The methanol extract was acidified, concentrated by rotary evaporation and then under nitrogen. The resulting extract was acidified, treated with diethyl ether and centrifuged. The resulting extract was concentrated, diluted with methanol and extracted with isooctane. The isooctane did not contain the radioactive residue and was discarded. The remaining methanol

extract was cleaned-up using a silica gel column and analysed by paper chromatography. The alkaline decomposition of the radioactive residue was investigated by treating an aliquot of the filbert extract with methanol/20% potassium hydroxide solution (1:1 v/v), by refluxing at 60 °C for 8 hours. A sample of control filbert extract was spiked with [^{14}C]ethephon and treated with alkali in the same way.

A significant amount of applied radioactivity was released over the 7 day period after treatment with [^{14}C]ethephon. The greatest amount of ethylene was release on the first day after treatment, gradually declining over the 7 day period (Table 11).

Only a small amount of the applied radioactivity was translocated onto the kernels (nutmeat) 7 DAT: 0.002 mg/kg and 0.87 mg/kg following application to the leaves and husk, respectively. The amount remaining in the kernels was even lower 14 DAT: 0.002 mg/kg and 0.14 mg/kg following application to the leaves and husk, respectively (Tables 12 and 13).

The 7 DAT nutmeat was extracted with benzene to remove the fats/oils. No radioactive residues were detected in the benzene fraction. Extraction with methanol released 98% of the TRR, with a further 1.6% remaining unextracted. After clean-up of the methanol extract, paper chromatography showed that the residue in nutmeat consisted of ethephon. No other radio-labelled component was detected. The presence of ethephon was confirmed by demonstrating that the radioactive residue in the nutmeat extract completely decomposed when treated with a strong base, as the alkaline treatment of [^{14}C]ethephon-spiked control extract confirmed this behaviour (of ethephon having been treated with a strong base).

Cotton

Cotton plants in outdoor plots were treated with a foliar application of [^{14}C]ethephon at a rate of 1.40 kg ai/ha in a water volume of approximately 500 L/ha (Smith, 2003, 601CZ, [M-240888-01-2]). The application timing corresponded to a 7 day PHI. Samples of treated cotton leaves were collected 0 DAT, immediately after the application had dried. The remaining plants were harvested 7 DAT according to normal agricultural practices, and separated into gin trash, lint and seed. The lint was not analysed further. The 0 DAT samples were surface-washed with acetonitrile, and then extracted with

acetonitrile. The mature (7 DAT) samples were frozen, ground and combusted to determine the TRR. The gin trash samples were extracted with methanol:water (9:1). The seed samples were extracted with methanol. The post-extraction solids from the gin trash and seed were hydrolysed with a mixture of concentrated HCl and water (1:7), yielding an acid hydrolysate. Radioactivity in extracts was determined by LSC, and post-extraction solids were analysed by combustion analysis and LSC. The TRR in the 0 DAT leaf samples was determined by extraction and combustion of the residue. The TRR in the 7 DAT samples was determined by combustion. Extracts were concentrated and analysed by HPLC, and identification of ethephon and HEPA was performed by comparison of retention times with radio-labelled reference standards. Identification was confirmed by TLC.

Radioactive residues recovered in leaves at 0 DAT (237 mg/kg) declined rapidly over 7 days after application. Gin trash and seed samples from 7 DAT (final harvest) contained TRR of 31.4 mg/kg and 0.82 mg/kg, respectively (Table). The percentage of residue extracted from leaves harvested 0 DAT by acetonitrile wash and extraction was relatively low (in total 62.5% TRR), but this extraction was used only for the residue levels at 0 DAT and to develop extraction methods for the 7 DAT samples. Methanol extraction of mature gin trash (with the addition of water at a ratio 1:9 of methanol) and seed proved very effective, recovering 89% TRR in gin trash and 82% TRR in seeds respectively. Acid hydrolysis with HCl:water (1:7) further recovered the majority of the remainder of the residue (11% TRR in gin trash and 17% TRR in seeds), leaving only 0.2% TRR remaining unextracted, potentially fibre-bound, in the gin trash and 1.2% in the cotton seed.

Table 14 Total radioactive residues in cotton after foliar application of [^{14}C]ethephon at 1.40 kg ai/ha

Fraction	Leaves, 0 DAT		Gin Trash, 7 DAT		Seeds, 7 DAT	
	mg/kg	% TRR	mg/kg	% TRR	mg/kg	% TRR

TRR by extraction	237.27	100	31.41	100	0.82	100
TRR by combustion	Not performed		31.41	100	0.82	100

The predominant radioactive residue in gin trash was ethephon at 93% TRR (84% TRR in the methanol:water extract and 9.3% TRR in acid hydrolysate) and 30 mg/kg and 78% TRR (66% TRR in the methanol extract and 12% in acid hydrolysate) and 0.64 mg/kg in seeds. HEPA was low at a total of 1.7% TRR and 0.52 mg/kg in gin trash and 9.6% TRR and 0.08 mg/kg in seeds. A total of 88–95% of the residue in these RACs was identified as ethephon and HEPA, with no other single metabolite comprising more than 1.9% of the residue.

[a] For leaves, only the surface wash was profiled

The majority of the ethephon applied to cotton is decomposed to volatile ethylene and phosphates. The metabolic pathway for ethephon in cotton was replacement of the chlorine atom in the 2-position with a hydroxyl function to give HEPA. The main residue found in cotton leaves, gin trash and seed was parent ethephon.

Data from Published Literature

Apple and Cherry (Edgerton and Hatch, 1972)

Radioactive ethephon labelled with ^{14}C was applied (500 ppm with 0.1% of Tween 20) to leaf and fruit surfaces of selected branches of apple and cherry trees 6 to 10 days before normal harvest dates. Samples were collected periodically following application and analysed with appropriate extraction and counting procedures. The level of radioactive ethephon increased in the fruit for about 48 to 72 hr, then decreased to a low level after 6 days. No intermediate metabolites were detected in the fruits. It was found that the majority of the ethephon in the fruits moved there from the application on adjacent leaves; relatively small amounts moved directly into the fruit from surface application. Radioactive ethylene was detected within 12 hr after application of the [^{14}C]ethephon on the leaf surfaces.

Cherry (Gilbert et al., 1975)

The metabolism of [^{14}C]ethephon was investigated after application to the leaves of cherry trees. In extracts from cherry leaves harvested 3 and 11 days after treatment, a metabolite was detected by TLC. The ratio of metabolite to ethephon was greater at 11 days than at 3 days after application. Based on the fact that the metabolite could also be chromatographed on an anion exchange resin column, it was suggested that the metabolite contains an intact phosphonic acid or other anionic group. Characterisation by mass spectrometry was not possible due to matrix interferences.

Peach (Giulivo et al., 1981)

The translocation and metabolism of 1,2-[^{14}C]ethephon was investigated in Andross peach trees at the end of Stage 1 of fruit development. [^{14}C]Ethephon was applied to the fruit surface or to the abaxial surface of the basal leaf of a developing shoot. Translocation did not occur following application to the fruit, but did occur following application to the leaf. TLC analysis indicated that the translocated radioactivity was associated with sugars. However the binding to sugars was not a metabolic reaction.

Grape

The translocation of [^{14}C]ethephon was investigated after spray application to grapevines (Weaver *et al*, 1972). At 7 days after treatment, 62% of the recovered radioactivity remained on the surface of the treated grape berries. In concentrated extracts of methanol-washed grape berries, parent ethephon was detected by TLC, but no radioactive metabolite was found. Application of ethephon to the first leaf above the cluster, or to a berry pedicel or peduncle, failed to result in measurable translocation of ethephon into the berries.

The uptake, translocation and fate of [^{14}C]ethephon in detached grapevine leaves and intact shoots was investigated (Nir and Lavee, 1981). Mature Perlette leaves were treated with [^{14}C]ethephon and the leaves put under constant fluorescent light (9 W/m^2) for 48–120 hours. Recovery of radioactivity from detached leaves was 53–61% after 48 hours, and reduced to 25% after 120 hours. Translocation was found to be mainly basipetal, and this was confirmed by autoradiography.

When young leaves near the apex of young detached cardinal shoots were treated with [^{14}C]ethephon, recovery after 48 hours was 85.5%. 7.5% remained on the leaf surface and 78% was extracted from the shoots. There was almost no translocation to other parts of the shoots.

Application of [^{14}C]ethephon to different sites on the upper parts of young growing shoots (cut surface, shoot apex and mature leaves) showed that translocation was very slight and after 4 hours, recovery was 58–72%. In mature leaves, only 2.4% of the radioactivity had penetrated the tissue, whereas 21–26% had penetrated the apical tissues. Translocation of [^{14}C]ethephon was very slight and most of the applied compound remained at the application site for many hours. No measurement of the loss of ^{14}C as volatiles was made.

Squash, Cucumber and Tomato (Yamaguchi et al, 1971)

The fate of [^{14}C]ethephon was investigated after application to squash, cucumber and tomato plants. At 7 days after application of a [^{14}C]ethephon solution to tomato leaves, about 15% of the radioactivity was recovered from the treated leaves and about 50% had been converted to [^{14}C]ethylene. About 12% of the radioactivity applied was translocated to immature fruits on the same branch. Analysis by paper chromatography showed that the radioactivity recovered from the fruit surface and tissue extracts comprised parent ethephon.

After injection of [^{14}C]ethephon into petioles of summer squash, more than 20% of the applied radioactivity was converted to [^{14}C]ethylene during the first day, followed by slightly less than 15% in the second day. There was a rapid decline in radioactivity in the petioles after the first day which was accompanied by translocation of radioactivity to other parts of the seedlings. One day after application, the radioactive residue comprised mainly ethephon. At 2 days after application the presence of an unknown metabolite was noted and at 6 days after treatment the amount of the unknown metabolite at the site of application was greater than that of ethephon. The translocated radioactivity was all in the form of the unidentified metabolite.

Four days after an application of [^{14}C]ethephon solution to cucumber leaves and fruits, about 40% of the total remaining radioactivity was found to be ethephon. No identification of characterization of the remaining 60% of the radioactive residue was performed.

This paper indicates that the main route of metabolism of ethephon in tomato is conversion to ethylene, and translocation of ethephon occurs. In contrast, in summer squash, besides the formation of ethylene, an unidentified metabolite is formed which is translocated to other parts of the plants whereas translocation of ethephon is not observed. In tomato tissue, the radioactive residue comprised [^{14}C]ethephon, but in squash seedlings much of the radioactivity was present in the form of the unidentified metabolite.

Walnut (Martin et al, 1972)

[^{14}C]Ethephon applied to a walnut leaflet was found to penetrate and translocate rapidly in young plants, but more slowly in older plants. The compound translocated to the kernel at higher levels when applied to a leaflet than when applied to the hull, but levels of radioactivity were low in both cases. Between 5–7 days after application, the amount of radioactivity in the kernel decreased markedly. It was concluded from the decrease in radioactivity that [^{14}C]ethephon in the leaves, hull, shell and kernel was metabolised. TLC analysis revealed the presence of [^{14}C]ethephon in leaf, hull and kernel extracts; however, no metabolites remained in the plant tissue that could be detected by TLC. No measurement of [^{14}C]ethylene was made in this study.

Proposed metabolic pathway of ethephon in plants

The metabolism of ethephon in a wide range of crops were studied. Information taken from published literature was also provided. Recent studies on tomatoes, wheat and cotton (2002–2003) and older studies (1968–1981) on apples, cherries, peaches, grapes, pineapples, cantaloupes, summer squash, cucumbers, tomatoes, filberts and walnuts showed similar metabolism of ethephon.

In the tomato study, the plants were foliarly-treated with 1.44 kg ai/ha of [^{14}C]ethephon. Parent ethephon was found to be the major residue component in tomato fruit harvested 0, 5 and 12 days after treatment. HEPA represented up to 15% of the total radioactive residue.

In the wheat study [^{14}C]ethephon was foliar sprayed at the rate of 0.36 kg ai/ha when the plants had reached the ligule stage (BBCH 39). At mature harvest, grain showed similar levels of parent ethephon and HEPA, whereas straw was found to contain higher levels of ethephon than of HEPA.

In the cotton study, the plants were treated with 1.40 kg ai/ha of [^{14}C]ethephon. The majority of the residue in cotton seed and gin trash harvested 7 days after treatment was parent ethephon. HEPA represented 1.7% of the total radioactive residue in gin trash and 9.6% in seed.

Overall, the main degradation route of ethephon was shown to involve decomposition of ethephon to ethylene and phosphates. The ethylene is rapidly released into the atmosphere while the phosphates are taken up in the natural phosphate cycle of the plant. However, part of the applied ethephon is metabolized according to a different metabolic pathway that results in the formation of the metabolite HEPA. HEPA is further metabolized by incorporation of the two carbon atoms in natural bio-molecules. The proposed metabolic pathway of ethephon in plants is presented below.

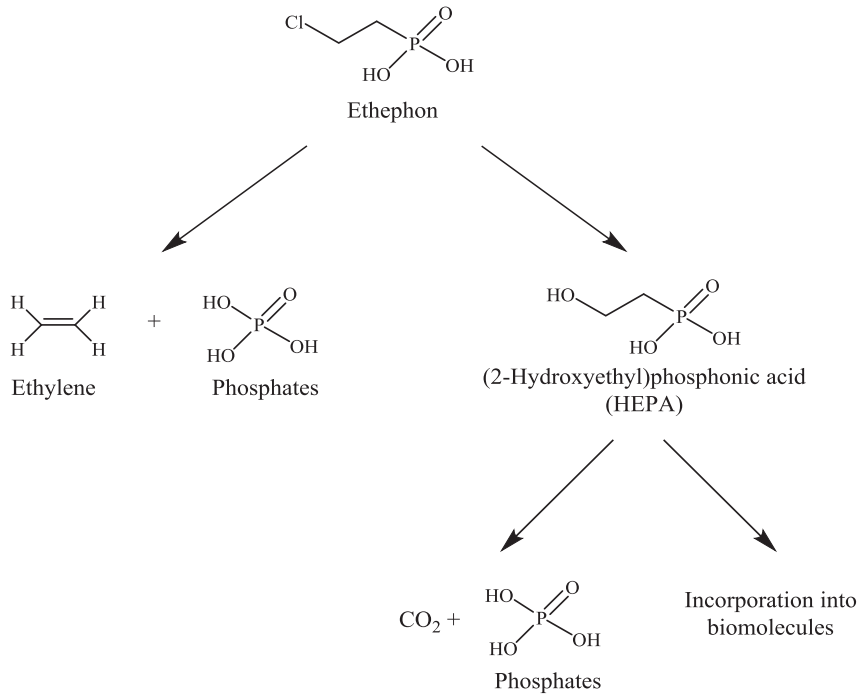

Figure 2 Proposed Metabolic Pathway of Ethephon in Plants

Animal Metabolism

The Meeting received information on the results of studies on lactating goats and laying hens which were fed [^{14}C]ethephon.

Metabolism studies on laboratory animals including rats were reviewed in the framework of toxicological evaluation by the current JMPR and the relevant information is summarized below.

Rat

After oral administration of ethephon to rats, absorption was rapid with a Tmax of 1.0–1.3 hours and 1.9–2.5 hours after a single oral dose of 50 or 1000 mg/kg bw, respectively. Six days after a single dose, tissue and carcass contained only 0.08% or less of administered radioactivity. Highest concentrations were found in liver and kidney. Radioactivity was excreted in urine (47–60%), expired air (18–21%, mainly ethylene) and faeces (4–6.5%), indicating that at least 65% of the administered dose was absorbed. Ethephon was mainly metabolized to ethylene and to a small extent to HEPA.

Lactating goats

The metabolism of ethephon in the lactating goat (Nubian and Alpine/Nubian cross) has been studied using [^{14}C]ethephon (Huhtanen *et al.*, 1984, ETH/M3, [M-187423-01-1]; Fisher, 2005, C046890, [M-223288-02-1]). The [^{14}C]ethephon was administered twice daily orally in capsules to two lactating goats for seven consecutive days. One dose followed the morning milking, and the other followed the afternoon milking. The goats received mean daily doses of 0.37 and 0.46 mg/kg bodyweight/day, respectively, equivalent to a dose level of approximately 10 ppm in the diet. A third goat served as a control animal.

Urine, faeces, milk and blood samples were collected daily. Milk samples were collected twice daily, in the morning and in the afternoon, approximately ten hours later, immediately prior to dosing. Selected milk sub-samples were separated into skimmed milk and milk fat by centrifugation. Whole blood samples were collected from each animal immediately prior to the afternoon dose. On Day 6, blood was collected from each goat at intervals of 0.25, 0.5, 1, 2, 4, 6, 8 and 10 hours after the morning dose. Volatile compounds were collected for 24 hours on the seventh day of the study. Carbon dioxide was trapped using 10% aqueous potassium hydroxide and ethylene was trapped using mercuric perchlorate solution. The animals were sacrificed approximately 16 hours after the final dose, and the following tissues were collected: liver, kidney, heart, composite fat, skeletal muscle, blood, and contents of the stomach and small and large intestine.

Radioactivity was quantified by LSC. Liquid samples (milk and urine) were analysed directly by LSC. Solid samples (tissues and intestinal contents) were analysed by oxidative combustion followed by LSC.

Freeze-dried sub-samples of liver were extracted with ether and then methanol. Extracts were radio-assayed and the remaining solids were analysed by combustion. Proteins and glycogen from the liver were isolated and analysed by combustion. Levels of ethephon in tissues, urine and milk were determined by base hydrolysis to ethylene which was trapped in a mercuric perchlorate solution.

A major proportion of the administered dose was released as volatiles in the form of ethylene (29% of administered dose) and CO_2 (2% of administered dose). Urinary excretion accounted for 19% and faecal excretion about 7% of the administered dose. Only 3.3% was excreted in milk and 3% remained in tissues on Day 7 (Table). The low total recovery (64%) was attributed to the difficulties in trapping large amounts of volatile compounds and the fact that volatile compounds were only collected over a 24 hour period.

Table 16 Distribution of radioactivity in tissues, milk and excreta from goats following oral administration of [^{14}C]ethephon at a nominal dietary concentration of 10 ppm for 7 days

Fraction	% of Administered dose
[^{14}C]ethylene [a]	29 [a]
$^{14}CO_2$ [a]	2.0 [a]
Urine	19
Faeces	6.7
Milk	3.3
Tissues	3.0
Gut contents	0.84
Total Recovery	64

[a] [^{14}C]ethylene and $^{14}CO_2$ were collected only over a 24-hour period on Day 7

Kidney and liver contained the highest total radioactive residue, at 1.2 and 1.0 mg/kg, respectively. TRRs in heart and muscle were low at 0.16 and 0.10 mg/kg, respectively, whilst fat contained a TRR of 0.50 mg/kg (Table).

Table 17 Average concentration of radioactive residues in tissues of goats sacrificed 16 hours after oral administration of [^{14}C]ethephon at a nominal 10 ppm for 7 days

Tissue	TRR, mg/kg
Kidney	1.2
Liver	1.0
Fat	0.50
Heart	0.16
Muscle	0.10

Average radioactive residue levels in whole milk were 0.28 mg/kg on Day 1, 0.36 mg/kg on Day 2 and 0.37 mg/kg on Day 3. Radioactive residue levels in milk increased until the afternoon milking on Day 3, where a plateau level of about 0.42 mg/kg was reached (Table). The milk fat fraction contained 45% of the radioactivity in milk. Radioactive residue concentrations in skimmed milk were 0.15–0.20 mg/kg, whilst those in milk fat were 3.03–4.18 mg/kg. As ethephon is hydrophilic and not expected to partition into fat, the residue in milk fat was attributed to incorporation of ^{14}C via [^{14}C]acetate into milk fats.

Table 18 Average concentration of radioactive residues in milk from goats during oral administration of [^{14}C]ethephon at a nominal 10 ppm for 7 days

Time, days	Average concentration, mg/kg
0.5	0.081
1.0	0.279
1.5	0.318
2.0	0.357
2.5	0.366
3.0	0.371
3.5	0.420
4.0	0.380
4.5	0.394
5.0	0.427
5.5	0.423
6.0	0.405
6.5	0.422
7.0	0.419

For the determination of ethephon, base degradation method was used to convert parent ethephon to ethylene. The analytical results indicate that no ethephon were present in fat, muscle, liver and milk. Kidney was the only tissue which yielded measurable levels of ethylene after base hydrolysis, equivalent to ethephon levels of 0.0085 mg/kg. Extraction of liver with ether released 5.3% TRR, extraction with methanol released a further 63.7% TRR, and 27.2% TRR remained in the post-extraction solids. Precipitation with trichloroacetic acid showed that 12.4% TRR in liver was associated with proteins. Radioactivity was also found to be associated with liver glycogen.

The incorporation of radiocarbon into liver protein, glycogen and fats as well as the elimination of $^{14}CO_2$ demonstrated that ethephon was incorporated into natural products possibly through an acetate-like intermediate. It was observed that radioactive carbon was present in milk fat and fat tissue, which indicates metabolic degradation of ethephon to a less hydrophilic compound.

The results show that significant amounts of the parent ethephon are degraded to ethylene and respired. The absence of parent ethephon in tissues demonstrated the complete metabolic degradation of ethephon, probably through an acetate-like intermediate. The study indicated that

there is low potential for transfer of residues of ethephon and/or its metabolites to milk, meat or meat by-products in ruminants after dietary exposure to ethephon.

Laying Hens

In the first study (Byrd, 1992, 9015C, [M-179283-01-1]), eight hens received daily oral capsule doses of [^{14}C]ethephon for five consecutive days at a rate equivalent to 53 ppm diet. Three hens in Group I were individually housed in metabolism cages designed to collect expired ethylene in a 2 M mercuric perchlorate trap solution and CO_2 in a 2 M sodium hydroxide solution. Five hens in Group II were individually housed in layer cages. Five other hens in Group III served as controls, and were individually housed in layer cages. Eggs were collected twice daily and excreta were collected once daily. Blood was collected prior to termination. Hens were terminated 22–23 hours after the final dose, and the following tissues collected: liver, kidney, muscle, fat, gastrointestinal tract and contents. A cage wash sample was collected after termination.

Liver, kidney, muscle, fat, yolk (Day 4) and excreta (Day 5) were freeze-dried and sequentially extracted with hexane and methanol using soxhlet extraction. The hexane and methanol extracts were pooled and the unextracted residues were subjected to enzyme hydrolysis (glucuronidase and sulphatase), and acid and base hydrolysis. The hydrolysates were extracted with dichloromethane but no radioactivity in any of hydrolysates partitioned into the organic layer. Radioactivity in extracts and hydrolysates was determined by LSC. Solid samples were analysed by combustion and LSC. Radioactivity in extracts was characterised by radio TLC.

The majority of the radioactivity (58% of the administered dose) was recovered as ethylene in the mercuric perchlorate trap solution. The identity of ethylene was confirmed by GC/MS headspace analysis. The amount of radioactivity trapped as $^{14}CO_2$ was negligible. A significant amount (26–30%) of the administered dose was recovered in the excreta. Radioactive residues in the CO_2 trap, eggs and tissues accounted for less than 1% of the total radioactivity administered (Table).

Table 19 Distribution of radioactivity in tissues, eggs and excreta from hens following oral administration of [^{14}C]ethephon at a nominal dietary concentration of 53 ppm for 5 days

Soxhlet extraction released the largest amount of radioactivity from all samples, except excreta. In excreta, the majority of the radioactivity was released by enzyme and acid hydrolysis. For all tissues, more than 75% of the residue was characterized. In liver and kidney, the radioactive residue was less readily extracted by solvent and 27% TRR in liver and 41% TRR in kidney remained unextracted. The extracted residue from liver and egg yolk could not be characterized by TLC due to the low amount of radioactivity in the extracts and interference from co-extractives.

The results indicate that the metabolism of ethephon proceeds almost exclusively by hydrolysis and dechlorination to ethylene, which is then expired. It appears that incorporation of the two carbon moiety into cellular components may result as no other radioactive metabolite could be isolated in tissue extracts.

In the second study (Schocken, 1995, 94-10-5526, [M-188154-01-1]), two groups (Groups II and III) of five hens received daily gavage doses of [^{14}C]ethephon for five consecutive days at a rate equivalent to 59 ppm diet (Group II) or 67 ppm diet (Group III). Five hens in Group II were individually housed in metabolism cages designed to collect expired ethylene in a 2 M mercuric perchlorate trap solution and CO_2 in a 2 M sodium hydroxide solution. Five hens in Group III were individually housed in layer cages. Three hens in Group I served as controls

and were individually housed in layer cages. Eggs were collected twice daily, and excreta were collected once daily. Blood was collected prior to termination. Hens were terminated 9–10 hours after the final dose, and the following tissues collected: liver, kidney, muscle, fat, gastrointestinal tract and contents.

Radioactivity in liquid samples was determined by LSC. Solid samples were analysed by combustion and LSC. [^{14}C]ethylene was confirmed by GC/MS headspace analysis of the mercuric perchlorate trap. $^{14}CO_2$ in the sodium hydroxide trap was determined by barium carbonate precipitation.

Fat and egg yolk samples were extracted with hexane/tetrahydrofuran. Other tissue samples were extracted with methanol/water. Fat and egg yolk were saponified with methanolic potassium hydroxide and analysed by LC/MS and/or HPLC to identify radio-labelled fatty acids, cholesterol and glycerol. The post-extraction solids from muscle, kidney, liver, egg white and egg yolk samples from Group III were digested with protease. Aliquots of hydrolysates were further hydrolysed with 6 N HCl. The protease and acid hydrolysates were profiled by HPLC to detect the presence of radio-labelled amino acids. The remaining solids were analysed by combustion.

The majority of the radioactivity was recovered in excreta, accounting for about one third of the administered dose. Radioactive residues in tissues accounted for 0.12–0.14% of the dose, with the highest concentrations in kidney (0.71–1.1 mg/kg) and liver (0.63–0.90 mg/kg) and lowest concentrations in fat (0.051–0.091 mg/kg) and muscle (0.051–0.058 mg/kg). Radioactive residues in egg white and egg yolk accounted for 0.03% and 0.07–0.10% of the dose, respectively. Due to leakage in the gas collection system, a total of only 2.7% of the administered dose was recovered in the expired volatiles trap (Table).

[a] Average concentration in whole eggs from Group II and Group III

Ethephon and HEPA were both identified in muscle, liver and kidney. Radioactivity in egg white and yolk was mainly incorporated into amino acids (57% TRR) and fatty acids/cholesterol (74–77% TRR), respectively. In organs, radioactivity was also incorporated into amino acids (up to 35% TRR in muscle). In fat, the only characterised fraction was fatty acids/cholesterol (39–44% TRR). The unknown fractions in Group III liver included a metabolite at 0.039 mg/kg, a multi-component peak (with no individual component exceeding 0.033 mg/kg) and a region of unidentified radioactivity (0.023 mg/kg) which could represent polypeptides. The unknowns in Group III kidney included two metabolites at levels of 0.015 and 0.045 mg/kg, as well as a multi-component peak (with no individual component exceeding 0.050 mg/kg) and a region of unidentified radioactivity (0.059 mg/kg) which could represent polypeptides. Unidentified residues in other Group III matrices were below 0.05 mg/kg. Bound residues from Group III samples, which had been subjected to protease hydrolysis in addition to solvent extraction, were all below 0.035 mg/kg (Table).

The radioactivity present in excreta was almost completely extracted with methanol. For the Group III samples which were treated with protease, a further 2.3% TRR was released by protease and 0.6% TRR remained bound. The major radioactive residue in excreta was ethephon, accounting for 83% TRR for the Group II hens and 88% TRR for the Group III hens, and represents the unabsorbed dose. The metabolite (2-hydroxyethyl)phosphonic acid (HEPA) accounted for 4.4–6.5% TRR. In the Group III excreta, an unknown metabolite was detected at 4.6% TRR. No radioactive amino acids, fatty acids/cholesterol or glycerol were detected.

nd = Not determined

The results indicate that ethephon metabolism in laying hens is postulated to involve the direct release of ethylene from parent ethephon, as well as the competitive removal of chlorine to form HEPA, which is further metabolised to release CO_2, and intermediates which can enter biochemical pathways, leading to the biosynthesis of proteins and lipids. The highest residue levels were found in liver, kidney and egg. Ethephon and HEPA were the major components of the residue in liver and kidney, whereas in egg yolk, most of the radioactivity was incorporated into fatty acids and cholesterol.

Proposed metabolic pathway of ethephon in animals

The metabolism of [^{14}C]ethephon was studied in lactating goats and laying hens. Orally administered [^{14}C]ethephon is rapidly eliminated either in the excreta or as [^{14}C]ethylene in expired air. The main route of metabolism is degradation/metabolism to [^{14}C]ethylene, and to a much lesser degree to $^{14}CO_2$.

A similar route of metabolism of ethephon to ethylene is seen in rats, goats and hens. In livestock, radioactivity was found in fat (fatty acids/cholesterol and glycerol), proteins (polypeptides and amino acids) and glycogen, demonstrating that metabolic degradation of ethephon through an acetate-like intermediate in the tricarboxylic acid cycle was occurring. Ethephon and the metabolite HEPA were found only at low levels in tissues. The proposed metabolic pathway of ethephon in animals is presented below.

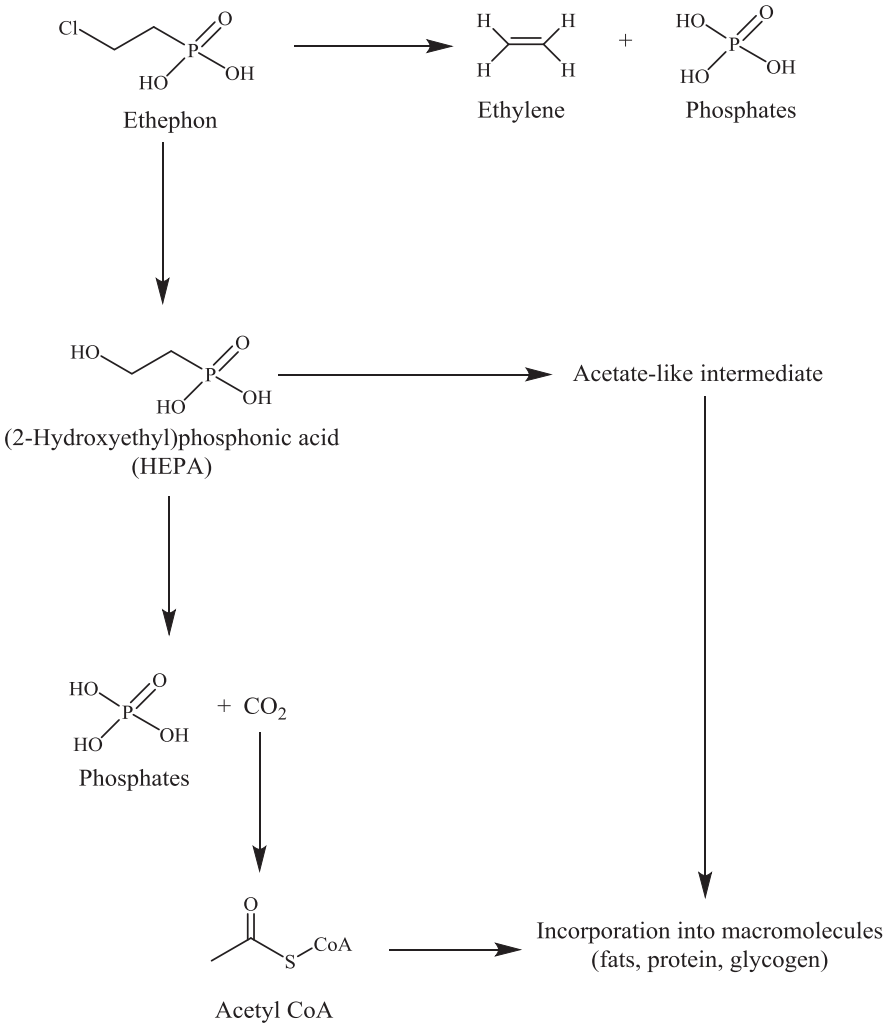

Figure 3 Proposed metabolic pathway for ethephon in animals

Environmental Fate in Soil

The Meeting received information on hydrolysis, photochemical degradation, aerobic and anaerobic degradation of ethephon in soil, photolysis of ethephon on soil, ethephon field dissipation, and residues in rotational crops.

Hydrolysis

The results of the hydrolysis study are summarized in the Physical and Chemical Properties section.

Photochemical degradation

The photolysis of ethephon in water was investigated under artificial sunlight in acetate buffer at pH 5 (Das, 1990, ISSI 89151, Bayer Ref: M-187634-01-1). [^{14}C]Ethephon was mixed with non-radio-labelled ethephon and dissolved in sterile acetate buffer and irradiated continuously using a xenon arc

simulated sunlight source (> 290 nm, 510.5 W/m^2) for up to 360 hours at 25 ± 1 °C; for control, ethephon in the acetate buffer was kept in darkness. Samples were taken at 0, 12, 36, 84, 168, 252 and 360 hours during irradiation. The samples were acidified immediately with HCl solution to prevent breakdown of ethephon during analysis. [^{14}C]ethylene was quantified by flushing the headspace with oxygen, and analysing the gas mixture by sample oxidation/LSC. The identity of ethylene was confirmed by GC-MS analysis of the headspace gases. The test solutions were evaporated to dryness and methylated with diazomethane for GC-MS analysis.

The mean recovery of radioactivity was 96.6% from the irradiated samples and 96.5% from the non-irradiated samples. The pH was confirmed in both the irradiated and non-irradiated samples. Microscopic analysis at 0 and 360 hours confirmed the sterility of the test solutions. GC-MS analysis confirmed the identity of [^{14}C]ethephon and [^{14}C]ethylene as the only major degradate in the test solution. [^{14}C]Ethylene was the only ethephon-related compound in the headspace.

The quantities of radioactive components in irradiated and non-irradiated test solutions of pH 5 buffer treated with [^{14}C]ethephon are presented in Table. In both irradiated and non-irradiated samples, [^{14}C]ethylene was the only major degradate. The calculated DT_{50} was 29.4 days for irradiated samples, and 51.4 days for non-irradiated samples.

Table 28 Recovery of radioactivity as [^{14}C]ethephon and [^{14}C]ethylene in an aqueous photolysis study

Time (hours)	Mean % recovery of total applied radioactivity

252	76.0	20.2	84.8	12.0
360	71.2	23.1	81.7	15.2

Aerobic degradation

In the first study, the aerobic degradation of ethephon was investigated in four soils for 180 days (Burr, 2001, C016772, [M-203033-01-1]). [^{14}C]Ethephon was applied to each soil at a rate equivalent to 2.24 kg ai/ha. The soils were incubated aerobically in the dark with 45% maximum water holding capacity at 10 °C or 20 °C under continuous air flow. Three traps containing a saturated solution of pyridinium hydrogen bromide per bromide (PHBPB) were used to collect [^{14}C]ethylene, and a 2 M KOH trap to collect $^{14}CO_2$. Soil samples were taken at 0, 1, 3, 7, 14, 27–28, 56–60, 77–80, 100–102, 120–123, 150–152 and 180 days after treatment. The soil was extracted with phosphoric acid followed by methanol.

The total recovered radioactivity decreased over time during the test (below 70% in the sandy loam, sandy silt loam and clay loam after approximately 102 days). This is probably due to problems with trapping [^{14}C]ethylene, caused by loss of dibromoethane (which is volatile) between trap removal and sampling.

Significant quantities of a volatile metabolite (ethylene) were found in the PHBPB traps, at up to approximately 60% applied radioactivity. Small amounts of (2-hydroxyethyl) phosphonic acid (HEPA) were detected in the soil samples (< 10% applied radioactivity), which is therefore regarded as a minor metabolite (Table 29).

Table 29 Recovery of radioactivity in soil after application of [^{14}C]ethephon

The rate of degradation of ethephon under aerobic conditions was also determined. Degradation of ethephon in soil under aerobic conditions depended on the pH of the soil and the temperature, being more rapid at higher pH values and at higher temperatures. The DT_{50} values at 20 °C ranged from 2.7 to 37.6 days. The DT_{50} value at 10 °C (for a clay loam soil) was slower (51.4 days) than the DT_{50} for the same soil at 20 °C (22.2 days). The DT_{50} and DT_{90} values for ethephon in aerobic soils are presented below in Table 30.

Table 30 DT_{50} and DT_{90} values of [^{14}C]ethephon in aerobic soils

Temp.	Clay loam (00/18) Soil pH 7.6.		Sandy loam (00/14) Soil pH 5.9.		Sandy silt loam (00/15) Soil pH 6.8.		Clay loam (00/16) Soil pH 6.9.

10 °C	51.4	254						

In the second study, the aerobic degradation of ethephon was investigated in a sandy loam soil for 30 days (Das, 1991, ISSI 90031, [M-187639-01-1]). [^{14}C]Ethephon was applied to the soil at a rate of 10.2 µg/g dry weight of soil. The soil was incubated aerobically in the dark with 75% maximum water holding capacity at 25 ± 1 °C under the airtight conditions. Soil samples were taken at 0, 1, 3, 7, 14, 21 and 30 days after treatment.

[^{14}C]Ethylene was quantified by flushing the headspace with oxygen (Headspace 1). The resulting gas mixture was fed through a NaOH solution (to capture $^{14}CO_2$) and then into a biological sample oxidiser. During oxidization, the [^{14}C]ethylene was quantitatively converted to $^{14}CO_2$ which was trapped in a scintillation cocktail. The soil was extracted with methanol and then with 1.0 N NaOH solution to hydrolyse the ethephon to ethylene. Immediately after addition of the NaOH solution, the vessels were sealed and the headspace contents sampled as described previously (Headspace 2). The headspace gases were analysed by GC-MS to confirm the identity of ethylene. Methanol soil extracts were methylated with diazomethane for GC-MS analysis. Alkaline soil extracts were neutralized and cleaned-up and then analysed in the same way as the methanol extracts.

The mean recovery was 97.3% of applied radioactivity. The oxygen content was 8.9 mg/L at the beginning and 8.7 mg/L at the end of the study, confirming aerobic incubation conditions. The results are summarized in Table 31.

Table 31 Recovery of radioactivity in sandy loam soil after application of [^{14}C]ethephon

21	21.4	15.0	46.0	3.4	10.8	24.8	96.6
30	0.3	8.5	63.5	4.4	14.6	4.7	91.4

GC-MS analysis showed that ethylene was the only compound in all the headspace fractions (Headspace 1 and 2). Ethephon and phosphoric acid were identified in the methanol extract of soil. HEPA was found in large quantities in the alkaline soil extract, but this may be an artefact caused by the alkaline extraction procedure.

The formation and detection of HEPA was investigated in more detail in a separate study (Lowden and Oddy, 2000, 202534, [M-198831-01-1]). Significant loss of radioactivity was found for [^{14}C]ethephon in 0.1 M or 1.0 M NaOH solutions after incubation at room temperature for 2 hours or 2 days. No loss of radioactivity was found in acidic solutions (0.1 M phosphoric acid or 0.1 M acetic acid). In tests to determine the best extraction solvent to use for soil, phosphoric acid gave the highest recoveries. Freeze-drying of the phosphoric acid extract gives a quantitative recovery of applied radioactivity. Methanol gives a poor recovery of radioactivity from soil samples. Extraction of soil with NaOH solution causes ethephon to transform to HEPA.

In the third aerobic degradation study, the degradation of ethephon was investigated in a soil different from those used by Burr for 44 days (Fitzmaurice, 2003, CX/02/32, [M-232779-01-1]). [^{14}C]Ethephon was applied to a clay loam soil at a rate of 2.24 µg/kg. The soil was incubated aerobically in the dark with 45% maximum water holding capacity at 20 °C under continuous air flow. $^{14}CO_2$ was trapped in an individual trap per flask and a merged trap prior to the air passing over a bed of cuprous oxide at 800 °C to convert volatile hydrocarbons to CO_2, which was trapped in two more CO_2 traps. Soil samples were taken at 0, 1, 3, 7, 14, 21, 38 and 44 days after treatment. The soil was extracted with acetonitrile/water (80:20 v/v) followed by 0.1 M phosphoric acid, and then washed with acetone.

Extracts were analysed by LSC, and post-extraction solids by combustion/LSC. The acetonitrile/water and acetone extracts were concentrated by evaporation and analysed by HPLC. Phosphoric acid extracts were concentrated by freeze-drying. Identification was by co-chromatography with ethephon and HEPA reference standards. Phosphoric acid extracts were analysed by LC-MS/MS for confirmation. The unextracted radioactivity was further characterized by fractionation of the soil organic matter. Volatile traps were treated with sodium carbonate chloride and barium chloride to characterize the radioactivity present.

The recovery of radioactivity ranged from 90.1–107.7% of applied radioactivity. Procedural recoveries ranged from 90.2 to 106.8%. The amount of extracted radioactivity decreased over time from an initial 98.8% to 16.3% on Day 44. Unextracted residues gradually increased to a maximum of 34% at Day 21 and were 27% at 44 days. The largest proportion of non-extracted radioactivity (12.6–19%) was associated with the fulvic acid soil fraction. The amount of radioactivity recovered as volatiles increased to 46.9% at Day 44. CO_2 evolution reached a maximum of 22.8% at Day 38. Ethylene accounted for 24.6% at Day 44.

Ethephon degraded from 98.7 to 10.8% of the applied radioactivity after 44 days. Minor amounts of HEPA (up to 1.6%) were detected. The presence of ethephon and HEPA was confirmed in the phosphoric acid extracts of Day 0 and Day 44. Ethylene was found at up to 25.6% of applied radioactivity. CO_2 and unextracted residues accounted for 22 and 27% of the

applied radioactivity after 44 days. Three unidentified polar degradates were found as minor metabolites (< 5%), (Table 32).

Table 32 Recovery of radioactivity in soil after application of [^{14}C]ethephon

Days after appl.	% of Applied radioactivity						
	Extracted residue	Ethylene trap	Unextracted Residue	CO_2	Total (mass balance)	Ethephon	HEPA
	Clay loam soil, 20 °C. Soil pH 7.9.						
0	98.8	n.d.	8.8	0.0	107.7	98.7	n.d.
1	90.3	3.6	13.2	0.01	107.2	90.2	0.10

7	54.6	12.2	25.9	3.2	95.8	52.4	0.98
14	38.8	15.2	32.1	12.4	98.6	36.2	0.05
21	30.4	18.0	34	15.7	98.0	28.2	0.04
38	18.6	22.8	27.1	22.8	91.4	15.0	0.43
44	16.3	25.6	27.0	22.3	90.2	10.8	1.56

The DT_{50} and DT_{90} were 6 days and 63 days, respectively. For the five soils for which the DT_{50} and DT_{90} were calculated above, the mean DT_{50} and DT_{90} values were 16.5 days and 93.8 days, respectively.

Anaerobic Degradation

The anaerobic degradation of ethephon was studied in a flooded clay loamy soil for 30 days (Oddy, 2001, C013378, [M-204496-01-1]). [^{14}C]Ethephon was applied to the soil at a rate equivalent to 2.24 kg ai/ha. The soil was incubated anaerobically in the dark at 20 ± 2 °C. Soil samples were taken at 0, 6 and 12 hours and 1, 2, 4, 7, 14 and 30 days after treatment. Four traps containing saturated solution of pyridinium hydrogen bromide per bromide (PHBPB) were used to collect [^{14}C]ethylene, and the fifth trap contained 2 M KOH to collect $^{14}CO_2$.

The extraction and recovery of radioactivity from anaerobic soil after application of [^{14}C]ethephon is summarized in Table 33. Recoveries were in the range 90–110% of applied radioactivity at all time-points, except at 2 days where the mean recovery was 86%. At the end of the incubation period, 94% of the applied radioactivity was found in the PHBPB traps. This was identified by GC-MS as dibromoethane from the reaction of ethylene with bromine. At 30 days, < 5% of the applied radioactivity was recovered in the water phase, the remaining radioactivity was found in the soil. Small amounts of HEPA (max 3.7% of applied radioactivity after 12 hours) were detected in the water phase. Ethylene was found in the water phase at up to 18.5% of applied radioactivity at 6 days. The amount of ethylene in the water phase declined to 0.4% after 14 days. Two minor metabolites were also detected.

Table 33 Extraction and recovery of radioactivity from an anaerobic soil after application of [^{14}C]ethephon

Time after application	% of Applied radioactivity							
	Water phase	% ethephon in water phase	Soil extract	% ethephon in soil extract	KOH trap (CO_2)	PHBPB trap (ethylene)	Unextracted residue	Total
0 hours	103.88	90.46	0.00	0.00	0.00	0.00	0.00	103.88
6 hours	89.00	66.05	8.14	7.90	0.00	3.09	1.11	101.33
12 hours	85.97	70.13	7.03	6.90	0.00	1.80	1.01	95.81
1 day	66.63	54.01	10.12	9.96	0.01	12.75	1.62	91.13
2 days	48.17	40.02	10.98	10.46	0.03	25.49	1.70	86.36
4 days	21.14	18.56	15.27	13.93	0.04	68.18	3.17	107.76
7 days	13.60	8.94	10.38	8.99	0.05	71.02	2.88	97.88
14 days	5.85	2.24	7.00	6.28	0.00	80.54	2.34	95.72
30 days	2.65	n.a.	2.67	n.a.	0.03	94.06	2.05	101.43

The major compound identified in soil was [^{14}C]ethephon. Five minor metabolites were detected in the soil at levels below 5% applied radioactivity.

The rate of degradation of ethephon under anaerobic conditions was determined. The DT_{50} and DT_{90} values for ethephon in an anaerobic soil system are presented below in Table 34.

Table 34 DT_{50} and DT_{90} values of [^{14}C]ethephon in an anaerobic soil system

Parameter	DT_{50} (days)	DT_{90} (days)
Anaerobic soil system	2.2	8.8

Soil Photolysis

The photolytic degradation of ethephon was studied on a clay loamy soil (Hatcher and Oddy, 2001, 202650, [M-199517-01-1]). [^{14}C]ethephon was applied to 1 cm thick layers of soil at a concentration equivalent to an application rate of 2.24 kg ai/ha. The soil layers was maintained at 45% of maximum water holding capacity under artificial sunlight from a xenon lamp at 20 ± 2 °C. A non-irradiated group was maintained in the dark at 20 ± 2 °C. Moistened CO_2-free air was supplied at a continuous rate, and the effluent air led through a series of four traps. Three traps containing saturated solution of PHBPB were used to collect [^{14}C]ethylene, and the last trap contained 2 M KOH to collect $^{14}CO_2$. Traps were replaced at 6, 12, 16 and 23 days after application. Duplicate soil samples were taken at 0, 1, 2, 5, 10, 21 and 30 days after treatment. Soil was extracted with 0.2 M phosphoric acid solution, the extracts neutralised and analysed directly by HPLC. Quantification of extracts and trapping solutions was done by LSC. Unextracted radioactivity in soil was analysed by combustion LSC.

Total recoveries of radioactivity for irradiated soils were in the range 76–106% of applied radioactivity. After 21 days, the mean recovery decrease to below 90%, probably due to incomplete trapping of ethylene by the PHBPB traps. The extraction and recovery of radioactivity from irradiated soil following application of [^{14}C]ethephon are presented in Table 35. For comparison, the extraction and recovery of radioactivity from non-irradiated soil following application of [^{14}C]ethephon are also presented.

In the irradiated experiment, after 30 days, 45.1% of the applied radioactivity was recovered in the phosphoric acid extract and 20.7% remained unextractable. 12.3% was found in the PHBPB traps and is attributed to ethylene. Small amounts of HEPA were detected in the soil extract, reaching a maximum of 10.6% applied radioactivity after 10 days, and decreasing to 8.7% after 30 days. The main component in soil was [^{14}C]ethephon. Four minor metabolites were detected in soil extracts at levels below 3% applied radioactivity.

At the end of the non-irradiated experiment, 49.4% applied radioactivity was recovered in the phosphoric acid extract and 19.6% remained unextractable. 7.8% was found in the PHBPB traps (ethylene). A further 5.7% was recovered in the KOH trap and characterised by precipitation as $^{14}CO_2$. The main component in soil was [^{14}C]ethephon, and small amounts of HEPA were detected in the extract (5.7% after 30 days). Three minor metabolites were detected in soil extracts at levels below 3% of the applied radioactivity

Table 35 Extraction and recovery of radioactivity from soil following application of [^{14}C]ethephon

Sampling time, days	% of applied radioactivity					
	H_3PO_4 extract	% ethephon in soil extract	KOH trap (CO_2)	PHBPB trap (ethylene)	Unextracted residue	Total
Irradiated						
0	100.52	99.11	0.00	0.00	0.80	101.32
1	96.80	90.62	0.00	0.27	2.85	99.92
2	96.03	87.95	0.00	0.80	3.42	100.25
5	89.91	76.76	0.02	2.85	8.79	101.57
10	72.96	59.08	0.05	4.52	15.12	92.64
21	54.74	43.51	0.99	7.29	18.34	81.35
30	45.14	32.55	0.50	12.25	20.68	78.56
Non-irradiated						

Sampling time, days	% of applied radioactivity					
	H_3PO_4 extract	% ethephon in soil extract	KOH trap (CO_2)	PHBPB trap (ethylene)	Unextracted residue	Total
0	100.52	99.11	0.00	0.00	0.80	101.32
1	95.84	89.90	0.08	1.13	3.22	100.26
2	92.42	86.44	0.00	0.51	4.32	97.26
5	83.29	77.74	1.08	2.91	8.67	95.95
10	71.08	62.99	2.21	4.30	14.87	92.46
21	59.90	51.96	4.97	5.69	16.96	87.51
30	49.40	40.47	5.67	7.78	19.60	82.45

The result indicates that the degradation pathway did not differ between the irradiated and non-irradiated soils. The rate of degradation of ethephon was slightly enhanced by irradiation. The DT_{50} and DT_{90} of [^{14}C]ethephon in non-irradiated and irradiated soil are shown below.

Table 36 DT_{50} and DT_{90} values of [^{14}C]ethephon in irradiated and non-irradiated soil

Parameter	DT_{50} (days)	DT_{90} (days)
Irradiated soil	16.5	57.8
Non-irradiated soil	20.7	74.4

Field Dissipation

The dissipation of ethephon was studied in three soils under field conditions in the USA (Norris, 1991, 41011, [M-187653-01-1]). The study was carried out over a period of four months under the growing conditions of tomatoes, cotton and spring wheat. Sites in the USA (California, North Carolina and Washington) were selected with plot areas of 960–1600 m^2. The field were tilled, the crops were planted and ethephon was applied at each location as follows:

Table 37 Dissipation of ethephon in soils

Trial location	Crop	Formulation	Application rate	Soil characterization (0–15 cm depth)
California	Tomato	SL, 22% ethephon	1.85 kg ai/ha	Loam, pH 7.8, 1.5% OM
North Carolina	Cotton	SL. 55% ethephon	2.25 kg ai/ha	Sand, pH 6.6, 0.7% OM
Washington	Spring wheat	SL, 40% ethephon	1.86 kg ai/ha [a]	Loamy sand, pH 7.1, 1.2% OM

[a] For the Washington site, the actual application rate was 3.3× the nominal rate of 0.56 kg ai/ha due to a calculation error

Crops were grown according to local standard agronomic practices. At the California and Washington trials sites, crops were irrigated in order to maintain a viable crop. Directly after application, 0–15 cm depth soil cores were collected. Soil cores collected at later intervals were segmented into 0–15, 15–30, 30–45, 45–60, 60–75 and 75–90 cm depth increments. After air-drying and sieving (2 mm), endogenous ethylene was removed from the soil samples. The soil was then subjected to alkaline hydrolysis to convert any ethephon present to ethylene, which was measured by GC analysis of the headspace.

The procedural recoveries for ethephon were in the range 63–104% (RSD 13%, n=78). The procedural recoveries were similar for soil from the three sites. In addition to the soil samples, filter paper strips placed in the field during application were analysed for evaluation of the application rate achieved.

Following application, residues of ethephon declined with time. Residues found in soil after application were 0.73–1.2 mg/kg, and assuming a soil density of 1.6 g/cm, fairly well matched the application rate as determined in the field (except for the Washington site). Residues declined to 0.01–0.03 mg/kg within 60–120 days. The majority of the residues were found in the top soil (0–15 cm), except for the Washington trial, which was attributed to excessive irrigation shortly after application, causing ethephon to penetrate into the soil as deep as 45–60 cm.

Dissipation seems to be temperature dependent, i.e. fastest in the south (North Carolina) and slowest in the north (Washington). Dissipation of ethephon in soil follows first order kinetics. The DT_{50} and DT_{90} values for dissipation of ethephon in soil under local field conditions are 6.8–20 days and 22–66 days, respectively (Table 38).

Table 38 DT_{50} and DT_{90} values for three USA soils

Location	Crop	Application rate, kg ai/ha	DT_{50}, days	DT_{90}, days	Function	Regression coefficient
California	Tomato	1.85	12 20	66	1st order linear 1st order non-linear	–0.986
North Carolina	Cotton	2.25	6.8 6.8	22	1st order linear 1st order non-linear	–0.964
Washington	Spring wheat	1.86	25 15	65	1st order linear 1st order non-linear	–0.986

Proposed degradation pathway in soil

Under aerobic, anaerobic and photolytic conditions, the route of degradation was similar with ethylene being formed as the major metabolite. Small amounts of HEPA and CO_2 are formed. The proposed degradation pathway of ethephon in soil is shown below.

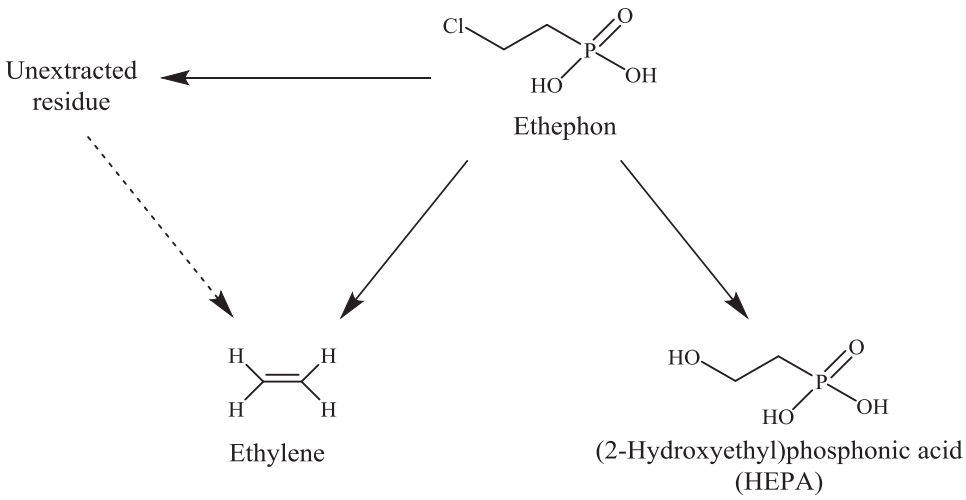

Figure 4 Proposed degradation pathway of ethephon in soil

Residues in Succeeding or Rotational Crops

A confined accumulation study on rotational crops was conducted with [^{14}C]ethephon using wheat, collards and radish (Miller, 1994, EC-91-158, [M-187425-01-1]). The test material was applied to bare plots in plastic containers containing a sandy loam soil, at an application rate of 2.36 kg ai/ha. Crops were planted into the treated soil at plant-back intervals (PBI) of 30, 120 and 379 days after treatment (DAT) after thorough manual mixing of soil (ca. 10 cm). Mature crops were harvested 54–62 days after planting (radishes), 68–91 days after planting (collards) and 110–158 days after planting (wheat). Immature wheat foliage was harvested 47–68 days after planting. Soil samples were collected at each planting and harvest interval. Total radioactive residues (TRR) in crops and soil were determined by combustion LSC.

Crop matrices were homogenized and subsequently extracted with hexane, ethyl acetate and methanol, and then by soxhlet extraction using acidified methanol. The extracts were combined and analysed using HPLC with UV and radiochemical detection. Radioactive components were co-chromatographed with ethephon and HEPA.

The unextracted residue was subjected to a sequential extraction procedure to give water-soluble polysaccharide (potassium phosphate extraction), starch (alpha-amylase digestion), protein (Pronase E digestion), pectin (sodium acetate/ EDTA extraction at pH 4.5), lignin (sodium chlorite digestion at 70 °C), hemi-cellulose (24% potassium hydroxide digestion) and cellulose (72% sulphuric acid digestion at 100 °C) fractions. These fractions were derivatized with phenyl hydrazine and oxidized to $^{14}CO_2$ in order to investigate the incorporation of [^{14}C]ethephon into biomolecules.

TRR in soil at a depth of 0–10 cm following application of [^{14}C]ethephon are summarized in Table 39. At 525 DAT, no detectable radioactive residue was observed in soil at a depth of 20–40 cm, and not more than 0.04 mg/kg was found at 10–20 cm depth.

Table 39 Total radioactive residues in soil at 0–10 cm depth after treatment with [^{14}C]ethephon

DAT	0	30	97	118	120	167	188	230	379	440	470	525
TRR in soil, mg/kg	2.0	1.5	1.2	0.71	0.69	0.73	0.86	0.94	0.33	0.20	0.23	0.22

TRRs in radishes, collards and wheat following application of [^{14}C]ethephon are summarized in Table 40. The highest TRRs were found in the 30 day PBI wheat straw (0.49 mg/kg) and grain (0.35 mg/kg), but in the 379 day PBI samples, 0.03 and 0.02 mg/kg, respectively. Extracted radioactive residues were low (< 50% of TRR) at all time points. Most of the extracted radioactivity from the crop matrices was released by extraction with methanol and the soxhlet extraction with acidified methanol, whereas hardly any radioactivity was extracted with hexane and ethyl acetate. The total extracted residue did not exceed 0.07 mg/kg in any sample analysed. Only the extracts containing residues above 0.01 mg/kg were subjected to HPLC analysis. Low levels of ethephon and HEPA were present in some extracts analysed (30 day PBI radish root and foliage, collard, wheat forage and straw, 120 day PBI radish root and wheat forage, and 379 day PBI wheat grain), and no unidentified metabolites were detected at significant concentrations.

Table 40 Total radioactive residues in rotational crops planted 30, 120 and 379 days after soil application of [^{14}C]ethephon

Crop matrices	Harvest time	TRR	Solvent-extracted radioactive residue [a]	
	DAT	mg/kg	mg/kg	% TRR
30 day PBI				
Radish foliage	98	0.07	0.03	33
Radish roots	98	0.07	0.02	38
Collards	117	0.11	0.03	35
Immature wheat forage	98	0.14	0.05	43
Wheat grain	188	0.35	0.02	8.1
Wheat straw	188	0.49	0.07	15
120 day PBI				
Radish foliage	174	0.07	0.02	29
Radish roots	174	0.06	0.03	49
Collards	188	0.05	0.02	42

Wheat straw	230	0.19	0.05	24
379 day PBI				
Radish foliage	441	0.01	< 0.01	11
Radish roots	441	0.00	< 0.01	21
Collards	470	0.01	< 0.01	1.4
Immature wheat forage	441	0.01	< 0.01	0.6
Wheat grain	523	0.02	0.01	23
Wheat straw	523	0.03	< 0.01	21

[a] Sum of extractions with hexane, ethyl acetate, methanol and acidified methanol

All crop samples contained radioactive residues in the post-extraction solids. In general, 30 day PBI wheat contained the highest unextracted residues. In these samples, the cellulose fractions from wheat grain and straw were 0.07 mg/kg (20% TRR) and 0.12 mg/kg (25% TRR), respectively. Radioactivity in other biomolecule fractions was found to be lower, (Table 41).

Overall, [^{14}C]ethephon residues declined steadily in soil. Radioactivity in mature plant samples paralleled or decreased at an even faster rate compared to the soil levels. In plant extracts, no radioactive peaks greater than 0.01 mg/kg were detected. Very low levels of ethephon and HEPA were detected in radishes, collards and wheat. Most of the radioactivity in the crop samples was attributable to incorporation into natural plant constituents.

The metabolism in rotational crops is similar to that seen in primary crops, with degradation to HEPA and natural incorporation into biomolecules.

Residue analytical methods

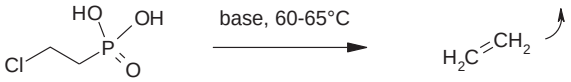
The Meeting received information on analytical methods together with validation data for residues of ethephon in plant, and animal matrices.

The analytical methods presented in this section are based on three different principles:

Ethylene-release method

This method was widely used in studies performed in the USA, and involves base hydrolysis of the residue to ethylene, with measurement of the released ethylene by GC-FID. The samples are first heated in a solution of tartaric acid in order to remove the endogenous ethylene. Thereafter the solution is made basic and heated again in capped bottles which allow headspace samples to be collected. By this procedure the ethephon present in the samples decomposes to ethylene, which is

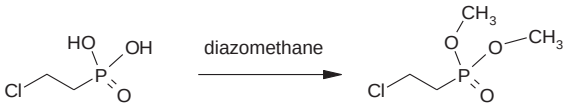
determined by headspace GC/FID. The released ethylene allows the ethephon residues in the sample to be quantified. The LOQ is typically 0.02–0.10 mg/kg.



ethephon **ethylene**

Derivatisation to methyl ester method

This method was used in the earlier studies performed in Europe and involves extraction with methanol and derivatisation of the ethephon residue with diazomethane to give the methyl ester, with measurement by GC-NPD or GC-FPD in phosphorus mode. The LOQ is typically 0.05–0.20 mg/kg.



ethephon **ethephon dimethyl ester**

LC-MS/MS method

This is a highly specific method which has been used in the more recent studies and involves extraction of the ethephon residue, sample clean-up and measurement by LC-MS/MS. The LOQ is typically 0.05 mg/kg.

Detailed descriptions of all these analytical methods are presented below. Validation data for methods on plant and animal matrices are summarized in Table 42.

Analytical Methods for Determination of Ethephon Residues

Analytical methods for plant matrices

Method: 11-94 (Ethylene release method) (Nygren, 1994, 11-94, [M-188198-01-1])

Analyte:	Ethephon	GC-FID	
LOQ:	0.10 mg/kg in fig, 0.02 in pineapple, 0.07 mg/kg in cotton seed,		
Description:	The ground sample is placed in a 250 mL pressure bottle with a crown cap that has a provision for withdrawing a headspace sample with a syringe. An aqueous tartaric acid-surfactant solution is added. The bottle is then capped, heated to about 60 °C and periodically agitated to drive any endogenous ethylene from the sample. After one hour heating, the cap is removed and the bottle is flushed with a gentle stream of nitrogen to remove any released ethylene. The sample is allowed to cool to room temperature. Trisodium phosphate, sufficient to make the sample basic, is added. The bottle is immediately capped and heated for one hour with periodic agitation to convert any ethephon residues into ethylene. The ethylene accumulates in the headspace and is quantified by gas chromatography with flame ionisation detection.		

Method: Union Carbide, 1981 (Diazomethane method) (Conn, 1992, SARS-89-24, [M-187553-01-1])

Method title “Detailed Method of Analysis for Residues of (2-Chloroethyl)Phosphonic Acid (Ethephon) in Wheat and Barley Grain, Straw and Milling Fractions”			
Analyte:	Ethephon	GC-FPD	
LOQ:	0.05 mg/kg in wheat grain and straw		

Description:	This method is the predecessor of SOP 90074 Samples are hard-frozen, ground and freeze-dried. Grain samples are soxhlet extracted with methanol for 4 hours. Straw samples are soxhlet extracted with 1% citric acid in methanol for 4 hours. The pH is adjusted by the addition of 10% methanolic hydrochloric acid. An aliquot of the extract is concentrated, 10% methanolic HCl added and solid materials precipitated by the addition of diethyl ether. After centrifugation and concentration of the liquid extract to ca. 1 mL, the ethephon residues are methylated with diazomethane. Straw samples are subjected to an additional clean-up step using a florisil column. The thus formed ethephon dimethyl ester is measured by means of gas chromatography with flame photometric detection.

Method: SOP–90070 (Diazomethane method) (Nygren, 1990, SOP–90070, [M-163159-01-1])

Analyte:	Ethephon	GC-FPD or GC-NPD	
LOQ:	0.05 mg/kg in wheat grain and straw, 0.02 in tomato		
Description:	This method is essentially the same as Method SOP 90074. Samples are hard-frozen, ground (in case of solid matrices) and freeze-dried. Samples are soxhlet extracted with methanol for 4 hours. The pH is adjusted by the addition of 10% methanolic hydrochloric acid. An aliquot of the extract is concentrated, 10% methanolic HCl added and solid materials precipitated by the addition of diethyl ether. After centrifugation and concentration of the liquid extract to ca. 1 mL, the ethephon residues are methylated with diazomethane. The thus formed ethephon dimethyl ester is measured by means of gas chromatography with either flame photometric detection in the phosphorous mode or with nitrogen phosphorus detection. Minor adjustments of the general procedure may be necessary to adapt for individual crops.		

Method: SOP 90069 (Diazomethane method) (Nygren, 1991, 89-REN-WA-S, [M-187529-01-1])

Analyte:	Ethephon	GC-NPD	
LOQ:	0.01 mg/kg in macadamia nuts		
Description:	Samples are hard-frozen, ground and freeze-dried. Samples are soxhlet extracted with methanol for 4 hours. The pH of the extract is adjusted by the addition of 10% methanolic hydrochloric acid. The acidified extract is frozen overnight to solidify the extracted lipid material. The methanolic solution is separated from the lipid material, concentrated and the solid materials in the extract precipitated by the addition of diethyl ether and separated by centrifugation. The resulting extract is concentrated and residues of ethephon methylated with diazomethane. The ethephon dimethyl ester is analysed by gas chromatography with nitrogen phosphorus detection.		

Method: SOP 90074 (Diazomethane method) (Eckert, 1992, Report: RP-01-89I, [M-187521-01-1])

Analyte:	Ethephon	GC-FPD	
LOQ:	0.05 mg/kg in wheat grain and straw		
Description:	Samples are hard-frozen, ground and freeze-dried. Grain samples are soxhlet extracted with methanol for 4 hours. Straw samples are soxhlet extracted with 1% citric acid in methanol for 4 hours. The pH is adjusted by the addition of 10% methanolic hydrochloric acid. An aliquot of the extract is concentrated, 10% methanolic HCl added and solid materials precipitated by the addition of diethyl ether. After centrifugation and concentration of the liquid extract to ca. 1 mL, the ethephon residues are methylated with diazomethane. Straw samples are subjected to an additional clean-up step using a florisil column. The thus formed ethephon dimethyl ester is measured by means of gas chromatography with flame photometric detection in phosphorus mode.		

Method: SOP 90075 (Diazomethane method) (Eckert, 1992, RP-01-89J, [M-187525-01-1])

Analyte:	Ethephon	GC-FPD	
LOQ:	0.05 mg/kg in cotton seed		

Description:	Cotton seed, hulls and meal: Samples are hard-frozen, ground and freeze-dried. Samples are soxhlet extracted with methanol for 4 hours. The pH of the extract is adjusted by the addition of 10% methanolic hydrochloric acid. An aliquot of the extract is concentrated, 10% methanolic HCl added and solid materials precipitated by the addition of diethyl ether. After centrifugation and concentration of the liquid extract to ca. 1 mL, the ethephon residues are methylated with diazomethane. The resulting ethephon dimethyl ester is analysed by gas chromatography with flame photometric detection in phosphorus mode or alkali flame thermionic detection. Cottonseed oil and soapstock: Samples are extracted by vortex mixing with 1% methanolic citric acid for 1 minute. After centrifugation, the upper methanol phase is removed and reserved, and the extraction procedure repeated a further two times. The combined methanol extracts are concentrated and solid materials precipitated by the addition of diethyl ether. After centrifugation and concentration of the liquid extract to ca. 1 mL, the ethephon residues are methylated with diazomethane. The resulting ethephon dimethyl ester is analysed by gas chromatography with flame photometric detection in phosphorus mode or alkali flame thermionic detection.

Method: Analytical methods for pesticide residues in foodstuffs, Sixth edition, June 1996: Ethephon (Diazomethane method) [M-208923-01-1])

Analyte:	Ethephon	GC-FPD	
LOQ:	0.1 mg/kg		
Description:	This is an official method for determination of ethephon in foodstuffs of plant origin, which has been published by the Dutch General Inspectorate for Health Protection. This method is similar to method SOP 90070 except that ethyl acetate is used as an extraction solvent instead of methanol. The ground samples (50 g) are extracted with ethyl acetate (400 mL) in presence of sulphuric acid, magnesium sulphate and sodium sulphate. An aliquot of the extract (100 mL) is methylated with diazomethane and then concentrated on a rotary evaporator. The ethephon dimethyl ester present in the final extract is measured by means of gas chromatography with flame photometric detection in the phosphorus mode. If necessary the final extract can first be cleaned up by treatment with charcoal.		

Method: HVA 12/89 (Diazomethane method) (Maestracci, 1998, R&D/CRLD/AN/msa/9816152, [M-165702-02-1])

Analyte:	Ethephon	GC-FPD	
LOQ:	0.10 mg/kg in pineapple (skin and flesh), cotton (seed and lint)		
Description:	Samples are extracted by homogenization with methanol, filtered, and the extraction repeated. The combined extract is concentrated and made up to a known volume with methanol. An aliquot of the extract is diluted with diethyl ether and acidified with acetic acid. The ethephon is methylated with diazomethane and residues determined by gas chromatography with flame photometric detection in the phosphorus mode. Quantification is done by external standardisation.		

Method: HVA SOP 10071 (Diazomethane method) (Fuchsbichler, 2002, HVA SOP 10071, [M-210331-01-1])

Analyte:	Ethephon and HEPA	GC-FPD	
LOQ:	0.05 mg/kg		
Description:	Samples are extracted by homogenization with methanol, filtered, concentrated and made up to a known volume with methanol. An aliquot of the extract is liquid/liquid partitioned into diethyl ether, the diethyl ether dried with sodium sulphate and evaporated to 1–2 ml. Ethephon and HEPA are methylated with diazomethane and residues determined by gas chromatography with flame photometric detection in the phosphorus mode. Quantification is done by external standardisation. For sweet pepper, an additional clean up on silica gel is necessary prior to GC-determination.		

Method: V5229/01 (LC-MS/MS method) (Kerkdijk, 1994, V5229/01, [M-226290-01-1])

Analyte:	Ethephon and HEPA	LC-MS/MS	
LOQ:	0.05 mg/kg in apple, cherry and sweet pepper		
Description:	Samples are extracted by high speed blending with demineralized water. The extract is centrifuged and filtered to give a clear supernatant. The pH of the supernatant is adjusted to pH 4–5 using 1 N formic acid solution. A further clean-up is performed by solid phase extraction (SPE) using SDB1 columns. The resulting eluate is analysed by liquid chromatography with tandem mass spectrometric detection (LC/MS/MS) in the negative electrospray mode. Ethephon is monitored by means of the MS/MS transition at m/z 142.9 → 107.0 (^{35}Cl isotope) and HEPA at m/z 124.9 → 94.9.		

Method: 00902 (LC-MS/MS method) (Oel & Bardel, 2005, MR-128/04, [M-247578-01-1])(Independent-laboratory-validated)

Analyte:	Ethephon	LC-MS/MS	
LOQ:	0.05 mg/kg in tomato, wheat grain, orange, olive		
Description:	Residues of ethephon are extracted from plant material by high speed blending with methanol/water/formic acid (90/10/0.1, v/v/v). For dry matrices (e. g. cereal grain) the sample must be soaked prior to blending and some cysteine hydrochloride is added to extraction solvent. For dry matrices it is also possible to use microwave extraction instead of high speed blending. After concentration to dryness the extract is reconstituted in water/methanol/formic acid (80/20/0.5, v/v/v). The reconstituted extract is analysed by liquid chromatography with tandem mass spectrometric detection (LC/MS/MS) using a triple-quadrupole apparatus that is operated in the negative electrospray mode. Ethephon is monitored by means of the MS/MS transitions m/z 143 → 107 (^{35}Cl isotope) and/or m/z 145 → 107 (^{37}Cl isotope). Satisfactory chromatographic separation is achieved on a C_{18} column with polar embedding (Synergi Fusion-RP 80Å, 150×4.6 mm, 4 µm). Elution is performed using water/methanol (80/20, v/v) acidified with 0.5% formic acid as the mobile phase.		

Method: 00918 (LC-MS/MS method) (Oel & Bardel, 2005, MR-173/04, [M-248933-01-1])

Analyte:	Ethephon and HEPA	LC-MS/MS	
LOQ:	0.05 mg/kg in cereal green material, grain and straw		
Description:	The residues of ethephon and HEPA are extracted from cereal green material, straw, and grain by high speed blending with methanol/water/formic acid (50/50/0.1, v/v/v). Samples of straw and grain must be soaked prior to blending. Alternately it is possible to extract residues from cereal grain by microwave extraction using the same solvent mixture. The raw extracts are cleaned-up on an SPE Bond Elut ENV cartridge. For determination of ethephon and HEPA an aliquot of the eluate is concentrated to dryness and reconstituted in 0.01% formic acid. The final extracts are measured by liquid chromatography with tandem mass spectrometric detection (LC/MS/MS) using a triple-quadrupole apparatus that is operated in the negative electrospray mode. Satisfactory chromatographic separation is achieved an ion chromatography column (Metrosep A Supp 4) with an aqueous solution of ammonium carbonate (15 mmol/L) as mobile phase. Ethephon is monitored by means of the MS/MS transition m/z 143 → 107, while HEPA is monitored by means of the MS/MS transition m/z 125 → 95.		

Method: 00903 and 00903/E001 (LC-MS/MS method) (Oel & Bardel, 2005, MR-131/04, [M-254165-01-1])

Analyte:	Ethephon and HEPA	LC-MS/MS	
LOQ:	0.05 mg/kg in grapes, apple, tomato, olives and processed fractions		
Description:	Apple and grape samples are extracted by soaking and then high speed blending with 0.01% formic acid. The extract is filtered under vacuum to give a clear supernatant. Tomato matrices are extracted by soaking and then high speed blending with 0.01% formic acid. Celite is added to the extract, which is then filtered under vacuum to give a clear supernatant. The filtered extract is cleaned-up by solid phase extraction (SPE) using Bond Elut ENV columns. The resulting eluate is filtered and analysed by liquid chromatography with tandem mass spectrometric detection (LC/MS/MS) in the negative ion mode. Ethephon is monitored by means of the MS/MS transition at m/z 143 → 107 (^{35}Cl isotope) and HEPA at m/z 125 → 95. The method can be performed using either internal or external standards.		

Method: 01429 (LC-MS/MS method)(Schulte and Sruskus, 2015, MR-14/100)

Analyte	Ethephon and HEPA	LC-MS/MS	
LOQ:	For both compounds: 0.01 mg/kg in cereal grains and 0.05 mg/kg in cereal green material and straw		
Description:	The residues were extracted from cereal green material by blending two times with methanol. For cereal straw and grain the residues were extracted by blending three times with methanol followed by hydrolysis/extraction with a mixture of hydrochloric acid (32%)/water (1/7, v/v) at 50 °C overnight. After addition of isotopically labeled internal standards the extracts were analysed by HPLC-MS/MS using a cation exchange column (e.g. Luna SCX 5 µm, 150 × 2 mm) in the HILIC (Hydrophilic Interaction Liquid Chromatography) mode. The mass spectrometer was operated in the negative ionization mode using the mass transitions m/z 142.9 → 106.8 for the quantitation of ethephon and m/z 125.0 → 94.8 for the quantitation of the metabolite HEPA.		

Method Validation

Validation data of the methods used for determining ethephon in plant and animal commodities from related studies are summarized below.

Table 42 Summary of Method Validation

Matrix	Analyte	Fortification, mg/kg	n	Recovery (%)		% RSD	Method	Reference
				Range	Mean			
Plant commodities—ethylene release method								
Barley grain	Ethephon	0.16 0.8 2	4 4 4	88–97 92–100 95–102	94 96 98	4.8 3.5 3.4	11-94 (EC-92-228)	Nygren, 1993, EC-92-228, [M-179285-01-1]

Analytical methods for animal matrices

Method: 18980A 9-REN-74-76 (Ethylene release method) (Leonard, 1993, EC-92-198, [M-187997-01-1])

Analyte:	Ethephon	GC-FID	
LOQ:	0.01 mg/kg in meat, milk and egg		
Description:	This is the same as method 11-94, with some minor modifications for analysing animal tissues. The sample is placed in a pressure bottle with a crown cap that has a provision for withdrawing a headspace sample with a syringe. Water and an aqueous tartaric acid-surfactant solution are added. The bottle is then capped, heated to 60–65 °C and periodically agitated to drive any endogenous ethylene from the sample. After one hour heating, the headspace gases are released, the sample shaken for 5 minutes and then incubated at 60–65 °C with periodic agitation for a further 30 minutes. After shaking for a further 5 minutes, the cap is removed and the bottle is flushed with a gentle stream of nitrogen to remove any released ethylene. The sample is allowed to cool to room temperature. Trisodium phosphate, sufficient to make the sample basic, is added. The bottle is immediately capped and heated for one hour at 60–65 °C with periodic agitation to convert any ethephon residues into ethylene. The ethylene accumulates in the headspace and is quantified by gas chromatography with flame ionisation detection.		

Method: 11-94 (Ethylene release method) (Nygren, 1994, 11-94, [M-188198-01-1])

Analyte:	Ethephon	GC-FID
LOQ:	0.002 mg/kg in milk and eggs, 0.01 mg/kg in tissues	
Description:	The sample is placed in a pressure bottle with a crown cap that has a provision for withdrawing a headspace sample with a syringe. Water and an aqueous tartaric acid-surfactant solution are added. The bottle is then capped, heated to 60–65 °C and periodically agitated to drive any endogenous ethylene from the sample. After one hour heating, the headspace gases are released, the sample shaken for 5 minutes and then incubated at 60–65 °C with periodic agitation for a further 30 minutes. After shaking for a further 5 minutes, the cap is removed and the bottle is flushed with a gentle stream of nitrogen to remove any released ethylene. The sample is allowed to cool to room temperature. Trisodium phosphate, sufficient to make the sample basic, is added. The bottle is immediately capped and heated for one hour at 60–65 °C with periodic agitation to convert any ethephon residues into ethylene. The ethylene accumulates in the headspace and is quantified by gas chromatography with flame ionisation detection. A radiovalidation performed using poultry liver containing incurred residues of [^{14}C]ethephon. The sample was analysed twice using the ethylene-release method. Both analyses indicated a residue level of 0.048 mg/kg. The same sample was analysed using a radiometric technique, which yielded an ethephon concentration of 0.041 mg/kg. The two values therefore are in good agreement, indicating that the ethylene-release method adequately determines the concentration of ethephon residues in animal tissues.	

Method: 00995 (LC-MS/MS method) (Bardel, 2006, MR-054/06 and Amendment 1, [M-274047-02-1])

Analyte:	Ethephon	LC-MS/MS	
LOQ:	0.01 mg/kg in milk, 0.05 mg/kg in meat (muscle), fat, kidney and egg		

Description:	Residues of ethephon are extracted from milk, fat, meat, and kidney by high speed blending with methanol/water/formic acid (90/10/0.1, v/v/v). Residue extraction from egg samples is performed according to a similar procedure, except that some cysteine hydrochloride is added to the extraction solvent. In all cases the extract is cleaned-up on a styrene divinyl benzene SPE column (Varian Bond Elut ENV), concentrated to dryness and reconstituted in water/methanol/formic acid (80/20/0.5, v/v/v). The reconstituted extract is analysed by liquid chromatography with tandem mass spectrometric detection (LC/MS/MS) using a triple-quadrupole apparatus that is operated in the negative electrospray mode. Ethephon is monitored by means of the MS/MS transitions m/z 143 → 107 (^{35}Cl isotope) and/or m/z 145 → 107 (^{37}Cl isotope). Satisfactory chromatographic separation is achieved on a C_{18} column with polar embedding (Synergi Fusion-RP 80Å, 150×4.6 mm, 4 µm). Elution is performed using water/methanol (74/26, v/v) acidified with 0.5% formic acid as the mobile phase.

Multi-residue Methods

DFG S 19

The applicability of multi-methods has been investigated (Fuchsbichler, 2000, HVA 24/00, [M-184660-01-1]). Multi-residue methods for products of plant origin typically involve extraction with acetone or ethyl acetate. Ethephon is known to be a very hydrophilic compound but it is also readily soluble in acetone and ethyl acetate (solubility > 600 g/L).

Wheat grain was chosen as crop material for the experimental assessment. The samples were fortified with ethephon at 2 or 10 mg/kg. Two variants of the German multi-residue method DFG S19 were investigated. Extraction was performed with acetone/water (2:1, v:v). The extract was cleaned-up by liquid/liquid partition. Depending on the variant of the method, this was done either with dichloromethane or with a mixture of cyclohexane and ethyl acetate. At this stage, the organic phase was dried with sodium sulphate and reacted with (trimethylsilyl) diazomethane in order to methylate any ethephon residues. The methylated extracts were analysed by gas chromatography with flame photometric detection (GC/FPD). There was no ethephon dimethyl ester, indicating that the extraction procedure was not appropriate to ethephon. The same result was found when blank reagents were fortified at the beginning of the procedure. Therefore, the problem was not due to any effect of the crop matrix. In order to demonstrate the accuracy of the derivatisation reaction, control samples and reagent blanks were fortified with ethephon after the extraction step. In this case the concentrations determined by GC/FPD were between 84% and 105% of the theoretical value, therefore validating the derivatisation procedure.

An alternate extraction procedure was investigated similarly. The samples were homogenised with ethyl acetate and sodium sulphate. The extracts were filtered and reacted with (trimethylsilyl) diazomethane. The amounts of ethephon dimethyl ester determined by GC/FPD were less than 30% of the theoretical value. This was a better result than with the DFG S19 extraction procedure, but still insufficient to develop a reliable method.

The study shows that instead of using diazomethane it is possible to perform the methylation with (dimethylsilyl) diazomethane, which is a less hazardous reagent. However, acetone and ethyl acetate are not suitable extraction solvents for ethephon. The extraction procedures used in the classical multi-residue enforcement methods therefore do not work for ethephon.

Storage Stability under Frozen Conditions

Plant commodities

The stability of ethephon residues in commodities has been investigated in high water content commodities (apples, cherries, melons, peppers and tomatoes), high acid content commodities (grapes, blackberries and pineapples), high starch content commodity (wheat) and high oil content commodities (walnuts and cotton) stored under frozen conditions. In all studies on raw agriculture commodities except on wheat and cotton seed, 20 g homogenized control samples were fortified with ethephon. In studies on wheat and cotton seed, 10 g, 5 g and 10 or 5 g of homogenized wheat grain, wheat straw and cotton seed, respectively, were fortified. In studies on apple juice and cottonseed oil, 25 g and 10 g of control samples were fortified.

The stability of ethephon residues has also been investigated in freeze-dried commodities stored at room temperature (apples, cherries, grapes, blackberries, pineapples, melons, peppers, tomatoes and walnuts) because freeze-drying is part of analytical methods. All stored samples were spiked prior to freeze-drying but, for procedural recovery, samples were spiked after freeze-drying.

Conditions and results of storage stability studies are summarized in Table 44 (under frozen conditions) and Table 45 (freeze-dried samples at room temperature). Percent of ethephon remaining was not corrected for procedural recoveries.

1.

The results showed that ethephon was stable for at least the following periods under frozen conditions:

Table 46 Summary of storage stability of ethephon in various plant matrices under frozen conditions

Matrix	Storage temp., °C	Stable period (at least)	Note
Apple	–20 (–18 to –26)	24 months	Longest period tested
Sweet cherry	–15	24 months	Longest period tested
Grape	–20 (–18 to –26)	24 months	Longest period tested
Blackberry	–20 (–18 to –26)	24 months	Longest period tested
Pineapple fruit	–20 (–18 to –26)	24 months	Longest period tested
Pineapple forage	–20 (–18 to –26)	24 months	Longest period tested
Cantaloupe	–20 (–18 to –26)	36 months	Longest period tested
Sweet pepper	–15	24 months	Longest period tested
Tomato	–20 (–18 to –26)	24 months	Longest period tested
Wheat grain	–20 (–18 to –26)	24 months	Longest period tested
Wheat straw	–20 (–18 to –26)	24 months	Longest period tested
Walnut	–15	3 months	Not conclusive due to analytical uncertainty
Cottonseed	–20 (–18 to –26)	25 months	Longest period tested (some uncertainty)
Apple juice	–20	12 months	Longest period tested
Cottonseed oil	–20	12 months	Longest period tested

Ethephon was shown to be stable during storage at room temperature after freeze-drying for the longest period tested (24 months) in apples, sweet cherries, grapes, blackberries, pineapple fruit, and tomato samples.

However, ethephon was stable up to only 9 months in pineapple forage, 4 months in cantaloupe, and 6 months in sweet pepper samples during storage at room temperature after freeze-drying. Due to significant analytical uncertainty, it was also not possible to determine storage stability of freeze-dried walnut samples at room temperature.

Animal Commodities

A storage stability study was conducted on meat, milk and eggs in 1992–1993 (Leonard, 1993, EC-92-198, [M-187997-01-1]).

Bovine meat was trimmed, and ground to homogeneity. Eggs were removed from their shells and beaten to a homogenous mixture. Milk was used as received. The prepared control samples (40 g) were fortified with ethephon at a concentration of 0.10 mg/kg and then stored frozen at about –20 °C. Samples were analysed using the ethylene release method 18980A 9-REN-74-76

The results showed that ethephon was stable when stored frozen (actual temperature: –10 to –23 °C) for the longest periods tested: in milk for 4 months, in meat 12 months and in eggs 15 months.

USE PATTERN

Ethephon is registered in many countries for use on cereals (wheat, barley, rye and rice) to increase resistance to lodging through straw shortening and strengthening; fruits and vegetables to promote

fruit maturity (early and uniform ripening and colouring of mature fruits); and on cotton to promote uniform boll opening and enhance defoliation.

Ethephon is mainly formulated as a soluble concentrate (SL). Combinations with chlormequat chloride are also used for cereals, and combinations with cyclanilide are used for cotton. Formulations are applied as foliar sprays by either ground or aerial equipment, except for applications to figs in Brazil where ethephon is applied directly to fruits using brushes or other equipment for even distribution.

For the purposes of estimating maximum residue levels, only the registered uses in countries relevant for the submitted supervised trials are recorded in Table 48.

For cereals, where there is a long interval between application and harvest, PHIs are often not given on the label. The PHI is described by the vegetative growth between applications; the labels give the growth stage at application. Therefore for cereals in the table below, both the PHI (where available) and the application timing (growth stage at application) are given.

Table 48 Registered Uses of Ethephon

Crop	Country	Form. Ethephon conc Type	Application				PHI (days)/Application timing Notes
			Max rate, g ai/ha	Max. Spray conc., g ai/hL	Water volume (L/ha)	No. (max g ai/ha/ season)

RESIDUES RESULTING FROM SUPERVISED TRIALS

Supervised trials have been conducted on the following crops: apples, cherries, grapes, figs, olives, pineapples, tomatoes, cereal grains (wheat, barley and rye) and cotton. The results of these supervised trials are summarized in the following tables:

Crop Group	Commodity	Country/Region, year of trials	Table No.
Pome fruit	Apple	Europe, 2000, 2002, 2006, 2007	49
Stone fruit	Cherries	Europe, 2000, 2002, 2009	50
Berries and other small fruits	Grapes	Europe, 1995, 2006, 2009	51
Assorted tropical and sub-tropical fruits—edible peel	Fig	Brazil, 2004, 2005	52
	Olive	Europe, 2007, 2008	53
Assorted tropical and sub-tropical fruits—inedible peel	Pineapple	Brazil, 1994, 1997, 2005 Costa Rica, 1998 Côte d'Ivoire, 1997, 1999 USA, 1989	54
Fruiting vegetables, other than cucurbits	Tomatoes	Europe, 1999, 2000, 2001, 2004 USA, 1989, 1990, 1991, 2005	55

In addition to the description and details of the field trials and analytical methods, each study report includes procedural recoveries and in some cases a summary of the method validation.

In the trials where multiple analyses are conducted on a single sample, the mean value is reported. Where multiple samples were taken from a single plot, the mean residue value is reported. Where results from separate plots with distinguishing characteristics such as different formulations, varieties or treatment schedules were reported, results are listed for each plot.

Results have not been corrected for concurrent method recoveries. Residues and application rates have generally been rounded to two significant figures or, for residues near the LOQ, to one significant figure. Residue values from the trials conducted according to the maximum GAP were used for the estimation of maximum residue levels. Those results included in the tables are underlined. Where a higher residue value was obtained at a later PHI, the higher value has been used.

Apple

A total of eighteen supervised trials were conducted on apples in France, Germany, the UK, Italy, Spain, Portugal and Greece. A 480 g/L SL formulation was applied as a foliar spray at BBCH 78–89 at a rate of 0.35–0.42 kg ai/ha. In studies 00-551 and 00-550, residues of ethephon were determined using method HVA SOP 10071. In study 02R792, residues of ethephon were determined using method V5229/01. In studies RA-2514/06 and RA-2576/07, residues of ethephon were determined using method 00903, supplement E001. The maximum period of storage of frozen samples was 406 days at < –18 ºC.

Cherries

A total of fifteen supervised trials were conducted on cherries in France, Italy, Spain, Greece, Belgium and the Netherlands. A 480 g/L SL formulation was applied as a foliar spray to cherry trees at BBCH 76–89 at a rate of 0.35–0.36 kg ai/ha. In general, residues were determined in the whole fruit at earlier time points, and in the pitted fruit at the last time point, and the residue in the whole fruit was calculated. Whether whole fruit or pitted fruit was analysed is specified in the following Table. In the trials conducted in 2000, residues of ethephon were determined using method HVA SOP 10071. In the trials conducted in 2002, residues of ethephon were determined using method V5229/01. In the trials conducted in 2009, residues of ethephon were determined using method 00903, supplement E001. The maximum period of storage of frozen samples at < –18 ºC was 483 days.

Grapes

Ten supervised trials were conducted on grapes in France. A 180 g/L SL formulation was applied once as a foliar spray to grape vines at BBCH 83–85 at a rate of 0.45–0.47 kg ai/ha. In the trials conducted in 1995, residues of ethephon were determined using the analytical method referenced in "Analytical Method for Residues of Pesticides" Part II-89, 5th Edition, SDU Publishers, The Netherlands (1988). This method is similar to SOP 90070 and was validated on grapes prior to use. The LOQ was 0.10 mg/kg. In the trials conducted in 2006 and 2009, residues of ethephon were determined using method 00903, supplement E001. The maximum period of storage of frozen samples at < –18 ºC was 447 days.

Fig

Six supervised trials were conducted in 2004–2005 on figs in Brazil. For the trials conducted in 2004, brush application was carried out with a 240 g/L SL formulation at the harvest growth stage. For the trials conducted in 2005, application used a 720 g/L SL formulation at the harvest growth stage. In the trials conducted in 2004, residues of ethephon were determined using the analytical method referenced in "Analytical Methods for Pesticide Residues in Foodstuffs" 6th Edition, part II, The Netherlands, 1996, with some modifications. In the trials conducted in 2005, residues of ethephon were determined using the analytical method 11-94. The maximum period of storage of frozen samples at < –20 ºC was 8 months.

Olives

Eight supervised trials were conducted in 2007–2008 on olives in Spain. In the 2007 trials, a 480 g/L SL formulation was applied twice as a foliar spray to olives trees at BBCH 79–81 at a rate of 0.35–0.41 + 0.47–0.50 kg ai/ha and a 7-day interval between applications. In the 2008 trials, a 480 g/L SL formulation was applied twice as a foliar spray to olives trees at BBCH 78–87 at a rate of 0.48 + 0.62 kg ai/ha and a 7–8 day interval between applications. In the trials conducted in 2007, residues of ethephon were determined using method 00903. In the trials conducted in 2008, residues of ethephon were determined using method 00903, supplement E001. The maximum period of storage of frozen samples at < –18 ºC was 12 months for olives, 7 months for table olives and 11.5 months for oil.

Pineapple

Pineapple plants may be treated early to induce flowering or close to harvest to induce ripening/colouration of the pineapple fruit. The pre-flowering application is not expected to result in measurable residues. Treatment for fruit ripening/colouration close to harvest (typical PHI 1–14 days) is the most critical use and will result in the highest residues in the fruit. In the trials conducted in Brazil, Costa Rica and Côte d'Ivoire, pineapples have been treated close to harvest for fruit ripening/colouration.

Five supervised trials were conducted in Brazil. The plots were sprayed with a 240 g/L SL formulation once at 0.96 kg ai/ha or 1.92 kg ai/ha. All samples were analysed using ethylene release method (Method 11-94 for the 2005 trials). The maximum period of frozen storage of frozen samples was 1.5 months.

Two supervised trials have been conducted in 1998 in Costa Rica. The plots were sprayed with a 480 g/L SL formulation at an application rate of 1.59 kg ai/ha. Samples were separated into flesh and peel, after removal of the crown. The maximum period of storage of frozen samples at < –18 ºC was 3 months.

Two supervised trials were conducted in 1997 and 1999 in Côte d'Ivoire. The plots were sprayed with a 480 g/L SL formulation at a rate of 1.43–1.44 kg ai/ha.

Samples of peel and flesh of pineapple fruit from trials in Costa Rica and Côte d'Ivoire were analysed using method HVA 12/89. Residues in whole fruit were determined by calculation

from the residues in peel and flesh. The maximum period of storage of frozen samples was 6 months.

Six supervised trials have been conducted in 1989 in the USA (Hawaii). Four trials were conducted in Oahu, and two in Maui (no specific description about the locations). Each plot was divided into three subplots which were sprayed with a 480 g/L SL formulation at a rate of 2.24 + 1.12 kg ai/ha or 2× 2.24 kg ai/ha. Samples were analysed using method SOP 90070. The maximum period of storage of frozen samples was 11 months.

[a] Results of three subplots. The highest residue concentration is selected.

Tomato

A total of twelve supervised trials were conducted on outdoor (field) grown tomatoes in Greece, Italy, Portugal and Spain. A total of nine supervised trials were conducted on indoor tomatoes in France, the Netherlands and Spain in 1999, 2000 and 2001. A 480 g/L SL formulation was applied as a foliar spray to outdoor (field) tomatoes at BBCH 84–89 at a rate of 1.68 kg ai/ha, or to indoor tomatoes at BBCH 60–89 at 1.42–1.47 kg ai/ha. In the 1999–2001 studies, residues of ethephon were determined using method HVA SOP 10071. In the 2004 study, residues of ethephon were determined using method 00903, supplement E001. The maximum period of storage of frozen samples was 642 days (21 months).

Twelve supervised trials were conducted in 1989–1991 on outdoor (field) grown tomato and three trials in 2005 on indoor tomato in the USA. A 240 g/L SL formulation was applied as a single foliar spray to outdoor (field) tomatoes at a rate of 1.73–2.14 kg ai/ha, or to indoor tomatoes at 1.38–1.42 kg ai/ha. In one field tomato trial (89-138), ethephon had been applied prior to the trial commencing, and the total ethephon application rate was 2.43 kg ai/ha. Residues of ethephon from the trials reported in 1991, 1992 and 2008 were determined using method SOP 90070. Residues of ethephon from the trials reported in 1995 were determined using method EC-92-228 (ethylene release method). The maximum period of storage frozen samples at –15 °C was 26 months.

Table 55 Ethephon residues in tomatoes resulting from supervised trials in Europe and the USA.

[a] Mean residue. Analytical results of replicate samples were in parentheses

[b] Can be divided into two applications (i.e., seasonal max, 1.92)

Cereal grains

Barley

A total of fifty-three supervised trials were conducted in Europe with a foliar spray:

- Fourteen at a rate of 1× 480 g ai/ha, application at BBCH 45–51 (one trial at BBCH 55), (determination using method HVA SOP 10071)
- Eight trials at a rate of 1× 225 g ai/ha, application at BBCH 39–41, (determination using method 00918)
- Ten trials at a rate of 1× 380 g ai/ha, application at BBCH 37–39, (determination using method 00918)
- Five trials at a rate of 1× 670–720 g ai/ha (nominal rate 720 g ai/ha), application at BBCH 37–39 (determination using method 00918).

In all studies, the maximum period of storage of frozen samples at around –18 °C was 14 months.

A total of 16 new trials were conducted to determine the magnitude of the residues of ethephon in/on barley (grain, green materials and straw) after one spraying application with ethephon SL 480 during the 2013 and 2014 seasons with one foliar application in Europe:

- Eight trials at a rate of 480 g ai/ha at BBCH 39
- Eight trials at 480 g ai/ha at BBCH 51.

The samples were stored frozen (–18 °C) for a maximum of 647 days. In these sixteen trials residues of ethephon and HEPA were determined by Method 01429, HPLC-MS/MS method in which grains and straw were extracted first with methanol and then by a mixture of concentrated hydrochloric acid and water (1/7, v/v) at 50 °C to convert conjugated ethephon and HEPA to free ethephon and HEPA. The extracts and acid hydrolysates were combined for analysis.

Table 56 Ethephon residues in barley grains resulting from supervised trials in Europe

Rye

Nine supervised trials were conducted in 2006–2007 in France, UK, Sweden and Germany. A 480 g/L SL formulation was applied as a foliar spray to rye at BBCH 49 at a rate of 0.67–0.72 kg ai/ha. Samples of green material were collected after 0, 7 and 20-21 days, ears and rest of plant after 42–49 days, and mature grain and straw after 70–103 days. Residues of ethephon were determined using method 00918.

The maximum period of storage of frozen samples at –18 °C was 11.4 months.

Wheat

A total of forty-three supervised trials were conducted in Europe with one foliar application:

- Nine trials at a rate of 480 g ai/ha, application at BBCH 37–39 (method HVA SOP 10071)
- Five trials at a rate of 480 g ai/ha, application at BBCH 49–51 (method HVA SOP 10071)
- Eight trials at a rate of 375 g ai/ha, application at BBCH 37 (one trial at BBCH 41–45), (method 00918)
- Five trials at a rate of 670–720 g ai/ha (nominal rate 720 g ai/ha), application at BBCH 39 (one trial at BBCH 49) (method 00918).

In all above studies, the maximum period of storage of frozen samples at around –18 °C was 12.2 months.

During the 2013 and 2014 seasons, a total of 16 trials were conducted in Europe to determine the magnitude of the residues of ethephon in/on wheat, soft (grain, green materials and straw) after one spraying application with Ethephon SL 480:

- Eight at a rate of 480 g ai/ha at BBCH 51
- Eight at a rate of 480 g ai/ha at BBCH 39.

Residues of ethephon in trials in 2013 and 2014 were determined by Method 01429, HPLC-MS/MS method in which grains and straw were extracted first with methanol and then by a mixture of concentrated hydrochloric acid and water (1/7, v/v) at 50 °C to convert conjugated ethephon and HEPA to free ethephon and HEPA. The extracts and acid hydrolysates are combined for analysis.

The samples were stored frozen (–18 °C) for a maximum of 713 days.

Supervised trials in USA

Sixteen supervised trials were conducted in wheat.

In the 1981 trials, a 480 g/L SL formulation was applied as a single foliar broadcast spray to wheat at a rate of 0.56–0.59 or 0.84 kg ai/ha. Application was made at the early-late boot growth stage. Residues of ethephon were determined using a method similar to SOP 90074, entitled “Detailed Method of Analysis for residues of (2-Chloroethyl)Phosphonic Acid (Ethephon) in Wheat and Barley Grain, Straw and Milling Fractions”, dated December 1981.

In the 1989 trials, a 480 g/L SL formulation was applied as a single foliar spray to wheat at a rate of 0.56 kg ai/ha. Application was made at the late boot to inflorescence emergence growth stage. Residues of ethephon were determined using the same method as above.

The samples were stored frozen at approximately –20 °C for the maximum period of storage was 5 months for the 1981 study and 29 months for the 1989 study.

[a] Mean residue. Analytical results of replicate samples were in parentheses.

Cotton seed

A total of ten supervised trials were conducted in Greece and Spain. A 540 g/L SC formulation was applied as a foliar spray to cotton at a nominal rate of 1.44 kg ai/ha (actual rate range 1.41–1.53 kg ai/ha). In the trials conducted in Greece in 1993 and 1995, an additional plot was treated at a nominal rate of 2.88 kg ai/ha (actual rate range 2.79–2.93 kg ai/ha). In the 1993–1995 studies, residues of ethephon were determined using method HVA 12/89. In the 2008 study, residues of ethephon were determined using method 00918. The maximum period of storage of frozen cotton seed samples, except described below, at < –18 °C was 14 months.

In trial 93739GR1, samples were stored at room temperature for 3 months and then frozen (–20 °C) for 13 months prior to analysis. As storage stability data indicate that residues of ethephon are not stable in cotton seed when stored at room temperature, these data will not be considered in the estimation of maximum residue level. In trials 94681SE1, 94681SE2 and 94681SE3, samples were stored in a cold room for 1 month and then frozen (–20 °C) for 4 months prior to analysis.

A total of forty-one supervised trials were conducted in the USA. In the 1989 trials, a 720 g/L SL formulation was applied as a single foliar spray to cotton at a rate of 2.24 kg ai/ha by ground or aerial application. Residues of ethephon were determined using method SOP 90075. In the 1993 trials, a 540 g/L SC formulation was applied as a single foliar spray to cotton at a nominal rate of 2.24 kg ai/ha by ground application. Residues of ethephon were determined using method EC-92-228. In the 1994 trials, a 540 g/L SC formulation was applied as a single foliar

spray to cotton at a nominal rate of 2.24 kg ai/ha by ground application. Residues of ethephon in seed and gin trash were determined using method EC-92-228. The maximum period of storage of frozen samples at < –10 °C was 12 months for seed and 6.3 months for gin trash.

A total of seven supervised trials were conducted in Brazil. In the 1996 trials, a 480 g/L SL formulation was applied as a foliar spray to cotton at a nominal rate of 1.44 kg ai/ha in one plot and at 2.88 kg ai/ha in the other. In the 2006 trials (HR06BR008-P1 to -P4), a 540 g/L SC formulation was applied as a foliar spray to cotton at a nominal rate of 1.20 kg ai/ha. Residues of ethephon were determined using method 11-94 (ethylene release). The maximum period of storage of frozen samples at < –10 °C was 12 months.

Primary feed commodities

Barley forage and straw

Thirty-seven supervised trials have been conducted in barley in Europe.

Table 63 Ethephon residues in barley forage and straw resulting from supervised trials in Europe

Wheat forage and straw

Twenty-six supervised trials have been conducted in wheat in Europe and sixteen supervised trials have been conducted in wheat in the USA, which support the use on wheat in Canada.

FATE OF RESIDUES IN STORAGE AND IN PROCESSING

Information and Data from Residues in Processed Commodities

The Meeting received information on hydrolysis relevant to food processing; and processing of apples, grapes, olives, tomatoes, barley, wheat, and cotton seed to their respective processed commodities.

Hydrolysis

The hydrolytic behaviour of ethephon was investigated under conditions relevant to major food processing operations such as pasteurization (20 minutes at 90 °C, pH 4), brewing, baking and boiling (60 minutes at 100 °C, pH 5) and sterilisation (20 minutes at 120 °C, pH 6) using [^{14}C]ethephon (Selzer, 2002, CP02/001, [M-211072-01-1).

[^{14}C]Ethephon was spiked into citrate buffer solutions which were adjusted to the required pH-value with sodium hydroxide. For each set of conditions there were two trials at a spiking level of 0.1 mg/L and two trials at a level of 1.0 mg/L. The spiked buffer solutions were heated in closed stainless steel reaction vessels using either a water bath or an autoclave. The heating time was measured from the moment when the temperature inside the vessels reached the required value. At the end of the fixed time the vessels were immersed immediately in an ice bath. After cooling, the outlets of the vessels were connected to a series of adsorption bottles containing a saturated solution of pyridinium hydrobromide perbromide (PHB) and the headspace gas was passed through the bottles in order to trap the ethylene formed during the test.

The total radioactivity remaining in the buffer solutions and the radioactivity trapped in the bottles were measured by LSC. The individual compounds present in the buffer solutions were identified and quantified by HPLC against reference standards. In order to characterize the radioactive compounds released in the gaseous phase, a series of trials was performed under the same conditions with unlabelled ethephon and the gaseous phase was analysed by GC/FID.

The overall radioactivity recovery was in the range of 82 to 95%, except in three trials where the recovery was only about 50% because of losses during the gas trapping procedure (Table 70).

Under the conditions representative of pasteurization, more than 80% of the ethephon remained unchanged and about 10% was decomposed to ethylene. Besides the parent compound, very small amounts of HEPA and an unknown compound were formed in the buffer solution. Under the conditions representative of brewing, baking, boiling and sterilization, degradation of ethephon was complete. Based on the trials which gave acceptable overall recoveries, at least 75% of the substance was decomposed to ethylene. The buffer solutions contained small quantities of HEPA and an unknown compound, but these amounted to less than 10% of the initial radioactivity.

Table 70 Quantification and characterization of radioactivity recovered under hydrolysis conditions simulating processing

Simulated process	Initial level of ethephon	Total radioactivity recovered (%[a])	Radioactivity in solution (%[a])				Ethylene (%[a])
			Total	Ethephon	HEPA	Unknown	
Pasteurisation (90 °C, pH 4, 20 min)	0.1 mg/L	93.0	83.31	80.29	1.46	1.56	9.67
	1.0 mg/L	93.4	82.55	80.74	0.93	0.66	10.82
Baking, brewing, boiling (100 °C, pH 5, 60 min)	0.1 mg/L	82.6	6.94	n.d.	4.70	2.24	75.64
	1.0 mg/L	85.7	8.76	n.d.	7.86	0.90	76.93

Simulated process	Initial level of ethephon	Total radioactivity recovered (%[a])	Radioactivity in solution (%[a])				Ethylene (%[a])
			Total	Ethephon	HEPA	Unknown	
Sterilization (120 °C, pH 6, 20 min)	0.1 mg/L	51.2 [b]	11.72	n.d.	2.66	5.44	39.45 [b]
	1.0 mg/L	82.6	4.14	n.d.	2.91	1.23	78.45

[a] All results are expressed as percentage of initial radioactivity and represent the mean of two replicates, except for brewing, baking and boiling at 1.0 mg/L, for which the results of only one trial are shown, due to low overall recovery in the other trial (49.0% of initial radioactivity).

[b] For sterilisation at 0.1 mg/L both trials resulted in low overall recoveries, probably due to a leak in the gas trapping system and underestimation of the ethylene released.

Apples

The first study was conducted in the USA during 1989–1990 on processing of apples harvested at a DALT of 7 days in one trial in Washington into juice and wet and dry pomace (Nygren, 1990, USA89E32, [M-187583-01-1]). Apples were stored frozen prior to processing. The processing procedure consisted of first washing the thawed apples. The use of frozen apples resulted in a high yield of juice end compared to normal commercial processing attributed to the partial destruction of cell walls during freezing. A flow chart of the processing operations is shown below with analysed fractions underlined.

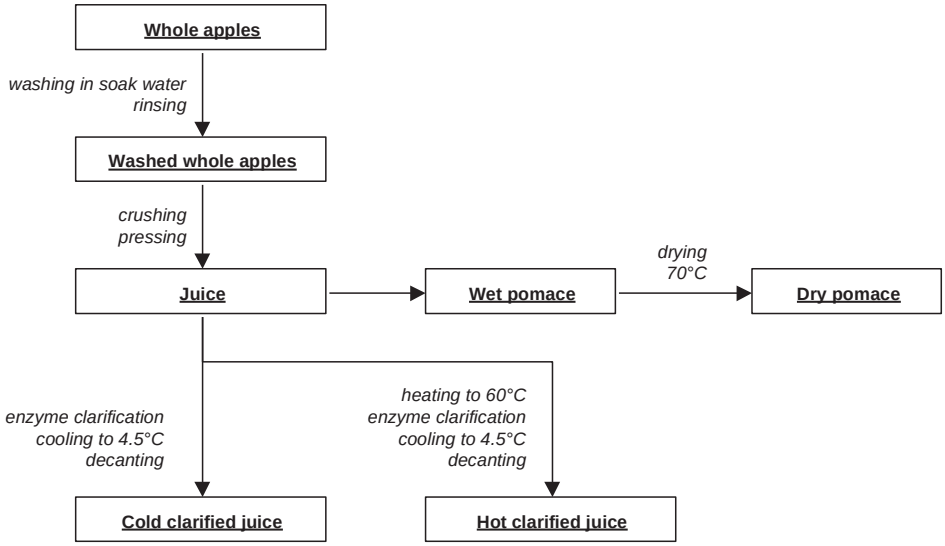

Figure 5 Apple processing

Residues of ethephon were determined using method SOP 90070. The LOQ was 0.05 mg/kg in apples and processed fractions. In the method validation, recoveries at fortification levels of 0.20–2.0 mg/kg were 104% in fruit, 76–85% in wet pomace, 105% in dry pomace, 98% in fresh juice, 64–107% in cold clarified juice and 95% in hot clarified juice.

The samples were frozen after collection (< –16 °C) and stored frozen until extraction and analysis. The maximum period of storage was 13 months for apple fruit and 9 months for processed commodities.

Residues determined in apple fruit and processed fractions are shown in Table 71. Results indicate that ethephon residues concentrate from whole fresh fruit to juice with processing factors

between 1.24 (fresh juice) and 1.57 (cold clarified juice). This result may be accounted for by the high water solubility of ethephon. A processing factor of almost 2 was observed in dried pomace as compared to whole fresh fruit. This indicates that part of the ethephon residues were eliminated during the drying process, probably due to co-sublimation with the water.

Table 71 Residues of ethephon in apple fruit and processed commodities

Commodities	Ethephon, mg/kg	Processing factor
Apple fruit (RAC)	0.37	1.0
Washed apple fruit	0.28	0.8
Wet pomace	0.24	0.6
Dry pomace	0.73	2.0
Fresh juice	0.46	1.2
Cold clarified juice	0.58	1.6
Hot clarified juice	0.56	1.5

The second study was conducted in Europe during 2003 on processing of apples harvested at a DALT of 14 days in a total of four trials in Europe (two in Italy, one in Portugal and one in Spain) into apple sauce, juice and wet and dry pomace (Bardel, Hoffmann & Eberhardt, 2005, RA-3610/03, [M-254102-01-1]). Apples were stored frozen prior to processing. Apples were partially defrosted and washed with tap water before processing.

The apples were then crushed and pressed into raw juice and wet pomace. The juice was filtered and subjected to ultrafiltration for 2–4 hours at room temperature. The resulting cleared juice was filtered to obtain clear apple juice, and pasteurised in glass bottles to give pasteurised juice.

The washed and thawed apples were cut into small pieces manually with a knife and then placed in a stainless steel pot. Water was added and the apples heated until all fruit parts were soft (cooking time 20 minutes at 96–99 °C). The apples were then crushed using a stainless steel food mill to remove cores and peel (pomace) and yield raw sauce. The pomace was discarded. The raw apple sauce was filled into a preserving bottle and pasteurised to give pasteurised sauce.

Residues of ethephon were determined by method 00903/E001 using LC-MS/MS. The LOQ was 0.05 mg/kg in apples and processed fractions. In the method validation, mean recoveries at fortification levels of 0.05–0.5 mg/kg were 104% in fruit, 104% in juice, 92% in pomace, 99% in washings and 96% in sauce/raw stewed fruit.

The samples were frozen after collection (< –14 °C) and stored frozen until extraction and analysis. The maximum period of storage was 462 days (< 16 months) for apple fruit and 71 days (2.3 months) for processed commodities.

Residues determined in apple fruit and processed fractions are shown in Table 72. At harvest, residues in apples were 0.06–0.63 mg/kg. Residues in the processed commodities were < 0.05–0.41 mg/kg in apple sauce, < 0.05–0.30 mg/kg in juice and < 0.05–0.71 mg/kg in wet pomace. Processing factors were calculated to be, 0.4–< 0.8, < 0.4–< 0.8 and 0.3–1.1, for apple sauce, juice and wet pomace, respectively.

Grapes

The first study was conducted in the USA on processing of grapes harvested at a DALT of 42–47 days in six field trials in California during 1978 into dried grape and raisin waste (Harrison, 1979, 279C2, [M-188057-01-1]). Ethephon was applied as a foliar spray to Thompson seedless grapes at a rate of 0.56 kg ai/ha. The processing procedure is not reported.

The samples of grape berries, dried grapes and raisin waste were analysed according to the analytical method (AmChem Products Inc., 1975). The LOQ was 0.01 mg/kg. The mean recovery at a fortification level of 0.20 mg/kg in grapes was 107% (RSD 15.5%), at 0.40 mg/kg in dried grapes was 105% (RSD 4.6%), and at 10.0 mg/kg in raisin waste was 102% (RSD 8.9%).

The samples were stored frozen (–34 °C) until they were freeze dried, and the freeze-dried samples then stored frozen (–12 °C) or at ambient temperature. The maximum period of storage was 5 months.

Residues determined in grapes, dried grapes and raisin waste are shown in Table 73. Results give variable processing factors ranging between 0.79 and 8.5 for dried grapes and 19 and 82 for raisin waste. Considering the relationship of concentrations apple wet pomace and apple dry pomace, it is likely that the processing factor for dried raisin would be higher than 1.

[a] Mite infested trial

Another study was conducted in 1995 on processing of grapes harvested at DALT of 35–38 days in two field trials in France to must and red wine (Grolleau, 1997, EA950185, [M-188232-01-1]).

The samples were shipped refrigerated (approximately 5 °C) to the processing facility on the day of collection in order to start immediately with the wine preparation procedure. The vinification procedure is shown below. Alcoholic fermentation takes about 4 weeks, malolactic fermentation about 3 weeks and clarification about 8 weeks. Several oenological additives were used in the process: potassium metabisulphite, yeast (*Saccharomyces cerevisiae*), sugar, lactic bacteria (*Leuconostoc oenos*), gelatine and metatartaric acid.

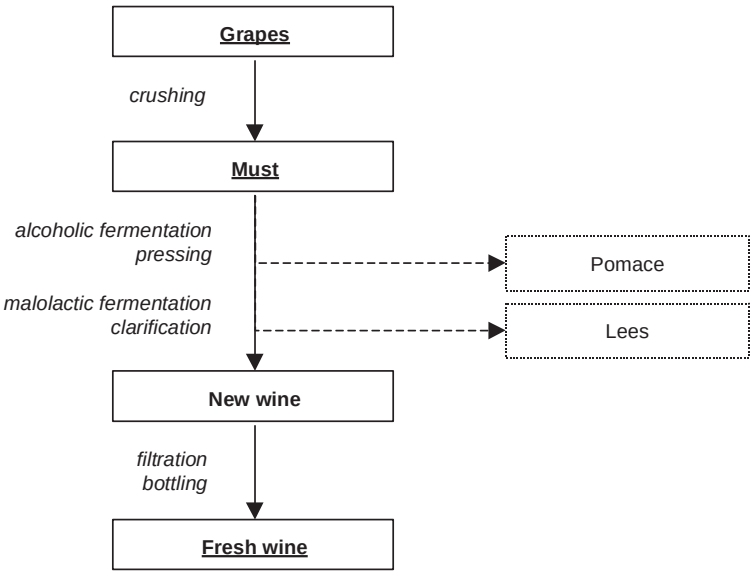

Figure 6 Processing of grapes to red wine

The samples of grape, must and red wine were analysed using the analytical method referenced in “Analytical Method for Residues of Pesticides” Part II-89, 5th Edition, SDU

Publishers, The Netherlands (1988). This method involves extraction with methanol, methylation with diazomethane and determination by GC/FPD and is similar to SOP 90070, and was validated on grapes prior to use. The LOQ was 0.10 mg/kg. Procedural recoveries at fortification levels of 0.10–2.0 mg/kg in grapes were 70–93% (mean 79%, RSD 9.9), at 0.10–0.25 mg/kg in must were 70–90%, and at 0.10–0.50 mg/kg in wine were 90–123%.

The samples were frozen after collection and stored frozen (< –18 ºC) until extraction and analysis. The maximum period of storage was 4 months for grapes and must, and 9 days for wine (after bottling).

Residues determined in grapes, must and red wine are shown in Table 74. The concentrations of ethephon in must were found to be comparable to or slightly lower than the concentrations in whole fruit. A concentration from fruit to wine was found, with processing factors of 1.4 and 2.1.

Table 74 Residues of ethephon in grapes, must and red wine (Grolleau, 1997)

Trial	Processed commodities	Ethephon, mg/kg	Processing factor
EA950185-FR01 France, 1995 (variety Syrah)	Grapes (RAC)	0.37	
	Must	0.34	0.9
	Wine	0.77	2.1
EA950185-FR02 France, 1995 (variety Grenache)	Grapes (RAC)	0.25	
	Must	0.17	0.7
	Wine	0.36	1.4

Two additional studies were conducted in 2003 in which processing of grapes from four trials in Europe (one in Germany, two in France and one in Greece) to raw juice and wine (Bardel & Hoffmann, 2005, RA-3680/03 and Amendment 1, [M-249278-02-1; Bardel & Hoffmann, 2005, RA-3681/03 and Amendment 1, [M-249332-02-1).

Juice was prepared through the following procedure: grapes were destemmed, washed and crushed, and the mash pressed to give raw juice and wet pomace. The raw juice was depectinised by heating for approximately 30 seconds at 80–85 °C, cooled and treated with pectolytic enzyme for 1 hour at room temperature. The cooled juice was filtered and pasteurised, and a juice sample collected.

Wine was prepared through the following procedure: grapes were crushed and destemmed, and the mash heated to 80 °C and then cooled down to fermentation temperature. The mash was pressed in a cloth press, and a sample of the resulting pomace collected. The must was filled into vessels and potassium hyposulphite and bentonite added. After clarifying, the must was decanted from the lees and a sample of must collected. Alcoholic fermentation was started by the addition of pure-culture yeast. After fermentation (approximately 6 weeks), the yeast was removed by decanting and filtration. The young wine was sulphited and finished for 2 months (trial R 2003 0468/4) and for 3 days (trials R 2003 0971/6, R 2003 0469/2 and R 2003 0973/2). The wine was filtered and bottled, and samples of bottled wine collected.

The samples of grapes and processed commodities were analysed using method 00903, which was validated prior to use. The LOQ was 0.05 mg/kg. Mean procedural recoveries at fortification levels of 0.05–0.5 mg/kg were 95% (RSD 5.9) in grapes, 99% (RSD 15.2%) in must, 103% (RDS 4.1%) in wine, 81% (RSD 5.7%) in pomace and 114% (RSD 4.2%) in juice.

The samples were frozen after collection and stored frozen (< –18 ºC) until extraction and analysis. The maximum period of storage was 14 months.

Residues determined in grape, juice, pomace, must and wine are shown in Table 75. The ethephon concentrations in juice, pomace and must were found to be comparable to or lower than those in whole fruit. The processing factors were in the range 0.5–1.1 for juice, 0.4–1.1 for wet pomace, 0.8–1.0 in must and 0.7–1.5 in wine.

Olive

A study was conducted in 2007 on processing of olives harvested at a DALT of 11 days in four trials in Spain to table olives and olive oil (Fernandez, 2009, 07 D OL BY P/A, [M-352734-01-1]).

Table olives: Olives were placed into a 2–4% NaOH solution and oscillated for 5–8 hours. Afterwards, the olives were immersed in water for 12–20 hours to eliminate the NaOH from the fruit. After watering, the olives were put into a 10% NaCl solution to give table olives.

Olive oil: Olives were washed in tap water, and the washed olives then milled to a pulp. The pulp was mixed in a thermo-malaxer for approximately 30 minutes. Boiling water was added after the first 20 minutes of mixing, to give a water:pulp ratio of 1:1. The mixture was pressed into a liquid phase (oil and water) and solid phase (press cake). The liquid phase was decanted and centrifuged and the raw oil separated. Filtration of the raw oil yielded virgin oil. Soda was added to raw oil and the mixture heated to 60–70 °C for 30 minutes. The oil was separated from the sediment (soap) by filtration to give refined oil.

Residues of ethephon were determined using method 00918. The LOQ was 0.05 mg/kg. Procedural recoveries at fortification levels of 0.05–5.0 mg/kg in olives were within the acceptable range of 70–120%, RSD < 20%. Procedural recoveries at fortification levels of 0.05–0.50 mg/kg in oil were within the acceptable range of 70–120%, RSD < 20%.

The samples were frozen after collection and stored frozen (–18 ºC) until extraction and analysis. The maximum period of storage was 7 months for olives RAC and 7 months for table olives.

Residues determined in olives, table olives and oil are shown in Table 76. Concentrations of ethephon were 1.6–4.3 mg/kg in olive RAC. There is no significant transfer of residues of ethephon into the processed commodities, and residues in table olives and virgin and refined oil were < 0.05 mg/kg in all trials.

Tomato

A study was conducted in 1989 on processing of tomatoes harvested at a DALT in 3 days of trials in the USA (California) to juice, paste and puree (Nygren, 1991, USA89E30, [M-187599-01-1]).

The processing was performed using commercial equipment and each of the processed fractions generated was to industry specifications. A simplified flow chart of the processing is shown in the following Figure. The tomato processed fractions collected were fresh whole tomatoes, washed whole tomatoes, wet pomace, dry pomace, canned fresh juice, canned puree, canned paste and canned juice reconstituted from tomato concentrate.

Residues of ethephon were determined using method SOP 90070. The LOQ was 0.02 mg/kg and the method was validated prior to use. The mean procedural recovery at a fortification level of 0.2 mg/kg in tomatoes was 109% (n=9), and recoveries at 0.5 mg/kg in processed commodities were 70–105%.

The samples were frozen after collection (–15 °C) and stored frozen until extraction and analysis. The maximum period of storage was 17 months.

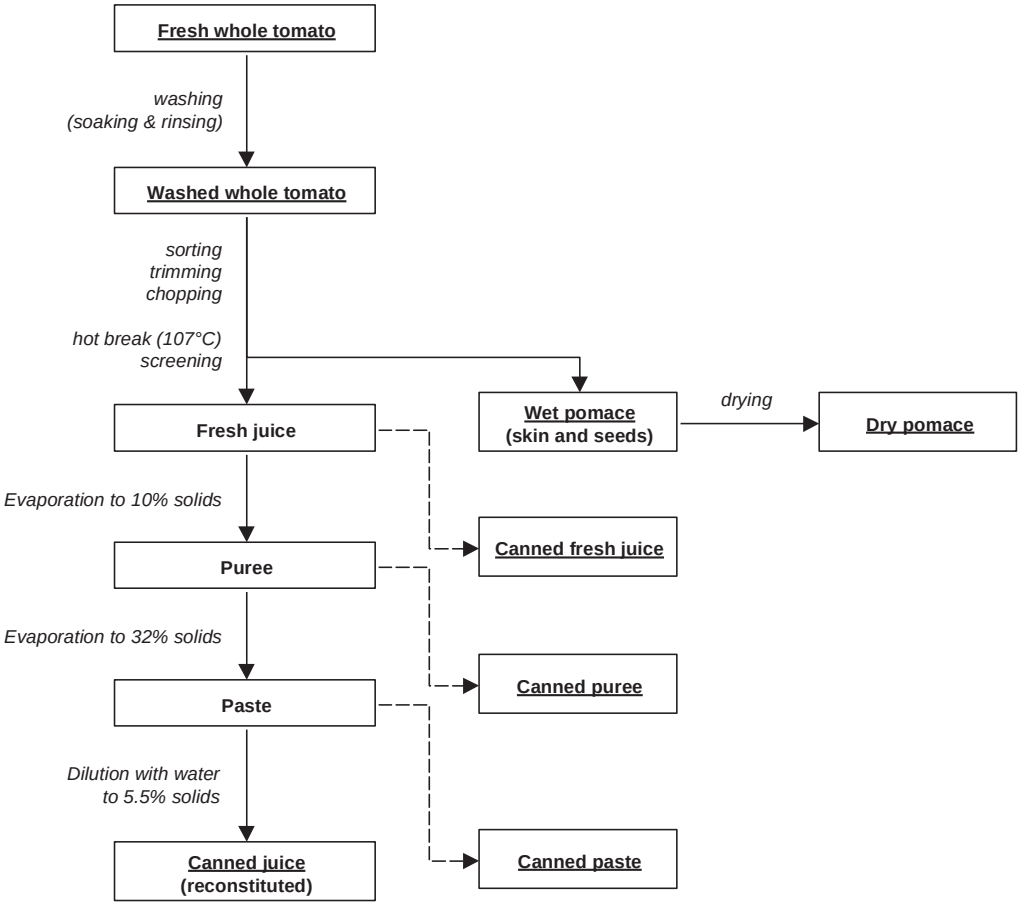

Figure 7 Tomato processing

Residues determined in fresh whole tomato and the tomato processed commodities are shown in Table 77. Ethephon did not concentrate in tomato processed commodities except in dry pomace which has a processing factor of 1.9. The data indicate that ethephon was lost during the preliminary processing, probably by heating.

Table 77 Residues of ethephon in processed tomato commodities (Nygren, 1991)

Trial	Commodities	Ethephon, mg/kg	Processing factor
89-138 CA, USA, 1989 (variety 1643)	Tomatoes (RAC)	0.73	1.0
	Washed fruit	0.68	0.93
	Wet pomace	0.38	0.52
	Dry pomace	1.39	1.9
	Canned fresh juice	0.25	0.34
	Canned puree	0.44	0.60
	Canned paste	0.55	0.75
	Canned juice from concentrate	0.29	0.40

In a published paper, processing of tomato into tomato paste was studied in Italy (Bolzuni & Leoni, Industria Conserve, *60*, 1985, pp 183, [M-188387-01-1). In this study, two lots of tomatoes (approximately 100 kg) containing incurred residues were processed using a procedure commonly used in industrial facilities. Following washing and chopping, the tomatoes were heated to 90 °C and passed through a sieve (opening Ø 0.6 mm) in order to remove seeds and skin. The juice obtained was concentrated into paste by heating at 55 °C under reduced pressure.

Finally, the paste was heated at 90 °C, canned and pasteurised. The samples of canned paste were stored for 9 months prior to analysis.

Analysis was by a method involving freeze drying, extraction with methanol, methylation using diazomethane and determination by means of GC/NPD. Mean procedural recoveries at fortification levels of 0.4 and 2.0 mg/kg in tomatoes were 86–95%, and at 0.2 and 1.0 mg/kg in tomato paste were 75–86%.

Residues determined in fresh whole tomatoes and tomato paste are shown in Table 78. The initial concentrations in the two lots of tomato were 0.27 and 0.36 mg/kg decreasing to 0.13 and 0.21 mg/kg, respectively, in paste with processing factor of 0.5 and 0.6 respectively.

Table 78 Residues of ethephon in tomato paste

Trial	Commodities	Ethephon, mg/kg	Processing factor
Trial 1 (variety UC 82)	Tomatoes (RAC)	0.27	
	Tomato paste	0.13	0.5
Trial 2 (variety UC 82)	Tomatoes (RAC)	0.36	
	Tomato paste	0.21	0.6

A study was conducted in 2004 on processing of tomato from three trials (Spain, Portugal and Italy) to juice, puree and preserve (Bardel, 2005, RA-3065/04, [M-262300-01-1]).

Preparation of juice: Tomatoes were washed in water, and samples of the washing water and washed tomato fruits collected. The washed tomatoes were cut into small pieces and heated with water (100 mL water/kg tomatoes) to 98–100 °C for 15–30 minutes. After this blanching process, the tomato pulp was passed through a strainer to separate raw juice and wet pomace. Sodium chloride was added to the raw juice, and sample of raw juice collected. One part of the raw juice was used for the processing into preserves. The rest of the raw juice was filled into preserving cans and pasteurised. After pasteurisation, a sample of juice was collected.

Preserves: Frozen tomatoes were washed in water and the peel removed. Samples of peel, peeling water and peeled fruits were collected. The peeled tomatoes were filled into preserving cans and raw juice added. The tomato preserves were pasteurised and a sample of tomato preserves collected.

Purée: Tomatoes were washed and then cut into small pieces. The cut tomatoes were heated with water (100 mL water/kg tomatoes) to 98–100 °C for 25–35 minutes. After this blanching process, the tomato pulp was passed through a strainer to separate raw juice and wet pomace. After the addition of sodium chloride, the raw juice was separated into raw purée and tomato liquid by centrifugation. The raw puree was filled into preserving cans and pasteurised. After pasteurisation, a sample of purée was collected.

Residues of ethephon were determined using method 00903, supplement E001. The LOQ was 0.05 mg/kg. The mean procedural recovery at fortification levels of 0.05–5.0 mg/kg in tomatoes was 103% (RSD 3.9%, n=10), at 0.05–0.5 mg/kg in juice was 103% (RSD 2.9%, n=8), at 0.05–0.5 mg/kg in puree was 98% (RSD 3.3%, n=8) and at 0.05–5.0 mg/kg in wet pomace was 90% (RSD 3.5%, n=7).

The samples were frozen after collection (–15 °C) and stored frozen until extraction and analysis. The maximum period of storage was 225 days (7.4 months).

Residues determined in fresh whole tomato and the tomato processed commodities are shown in Table 79. Ethephon did not concentrate in juice, preserves or puree. Residues were 0.30–0.57 mg/kg in fresh tomatoes, and decreased after processing to < 0.05–0.06 mg/kg in juice, < 0.05 mg/kg in puree and < 0.05–0.12 mg/kg in preserve.

Barley

A study was conducted on processing of barley grains obtained at a DALT of 49 days from a trial in Canada during 1981 to hulls and pearl barley (Harrison, 1981, 10223, [M-187972-01-1]).

Barley grain was milled into pearls as a batch operation. After pearling, the hulls and pearls were separated by sifting. Pearls were ground on a small plate grinder prior to analysis.

Residues of ethephon were determined using a method similar to SOP 90074. The LOQ was 0.05 mg/kg. The average recovery rate in wheat and barley grain at 0.2 mg/kg was 102% (RSD 17%, n=14). The recovery at 0.2 mg/kg in barley hulls was 114%, and in pearls was 99%.

The samples were frozen after collection at approximately –20 °C and stored frozen for 4 months.

Residues determined in barley processed commodities are shown in Table 80. In barley pearls, the ethephon concentration was slightly lower than in the corresponding raw agricultural commodity, while ethephon concentration in hulls was higher with a processing factor of 1.6.

Table 80 Residues of ethephon in barley grain and processed commodities

Trial	Commodities	Ethephon, mg/kg	Processing factor
Canada (variety Bruce)	Barley grain (RAC)	0.62	
	Barley pearls	0.54	0.9
	Barley hulls	1.01	1.6

Wheat

A study was conducted on processing of wheat grains harvested at a DALT of 65 days from one field trial in the USA (Texas) during 1989–1990 to dust, middlings, bran, flour, red dog and germ and shorts (Conn, 1992, SARS-90-24P, [M-187550-01-1]).

Wheat grain samples were processed to simulate industrial practice as closely as possible. The total quantity processed was approximately 81 kg. A simplified flow chart of the processing is shown in the following Figure.

Residues of ethephon were determined using a method similar to SOP 90074. The method involved Soxhlet extraction with methanol, precipitation of interfering materials, methylation using diazomethane and determination by means of GC/FPD. The LOQ was 0.1 mg/kg in red dog and 0.05 mg/kg for wheat grain and all other processed fractions. The average recovery rate at fortification levels of 0.05–1.0 mg/kg was 80% in wheat grain, 97% in dust, 73% in bran, 104% in low grade flour, 66% in patent flour, 60% in shorts and germ, and 74% in red dog. The overall average recovery was 79% (n=15).

Samples were in frozen storage for less than 1 month between harvest and processing and for no longer than 5 months between processing and analysis.

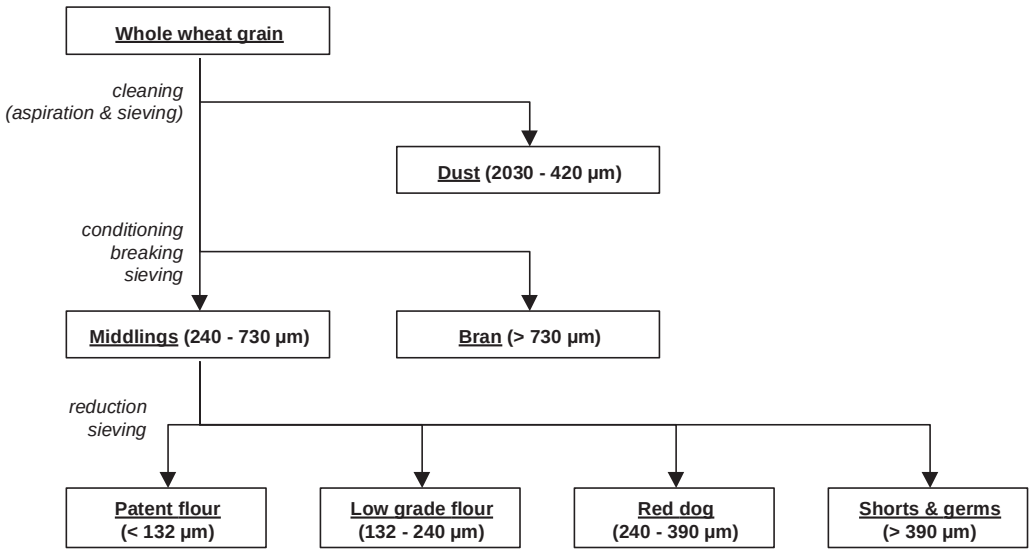

Figure 8 Wheat grain processing

Residues determined in wheat grain and the processed commodities are shown in Table 81. In middlings, low grade flour and patent flour, the residue levels were less than the LOQ (0.05 mg/kg). Measurable residues were found in unprocessed grain, grain dust, bran, shorts and germ and in red dog. Limited concentrations of ethephon residues occurred in bran, shorts and germs, and in red dog, with processing factors of less than 1.5.

Table 81 Residues of ethephon in wheat grain and processed products (Conn, 1992)

Trial	Commodities	Ethephon, mg/kg	Processing factor
USA (Texas) (variety Mitt)	Wheat grain (RAC)	0.17	
	Grain dust	0.10	0.6
	Bran	0.23	1.4
	Middlings	< 0.05	< 0.3
	Low grade flour	< 0.05	< 0.3
	Patent flour	< 0.05	< 0.3
	Shorts and germ	0.25	1.5
	Red dog	0.20	1.2

A second study was conducted on processing of wheat from a trial in Canada during 1981 to bran, flour, germ and shorts (Harrison, 1981, 10223, [M-187972-01-1]). Wheat grain was harvested at a PHI of 53 days.

The wheat grain sample was first brought to 15% moisture content and then milled using an automatic laboratory mill, which separated the ground grain into bran, flour, and a mixture of shorts and germ. The shorts and germ fraction was then manually separated into shorts and germ.

Residues of ethephon were determined using the same method as in the study above. The LOQ was 0.05 mg/kg. The average recovery rate in wheat and barley grain at 0.2 mg/kg was 102% (RSD 17%, n=14). The recovery at 0.2 mg/kg was 98% in shorts, 112% in germ, 84% in flour and 96% in bran.

The samples were frozen after collection at approximately –20 °C and stored frozen for less than 2 months.

Residues determined in wheat processed commodities are shown in Table 82. In wheat flour the residue level of ethephon was lower than in the corresponding raw agricultural commodity. Concentration of ethephon residues occurred in bran, shorts and germ with processing factors in the range of 2.0 to 3.5.

Table 82 Residues of ethephon in wheat grain and processed products (Harrison, 1981)

Trial	Commodities	Ethephon, mg/kg	Processing factor
Canada (variety Frederick)	Wheat grain (RAC)	0.35	
	Wheat bran	1.21	3.5
	Wheat flour	0.02	0.1
	Wheat shorts	0.78	2.2
	Wheat germ	0.71	2.0

A third study was conducted on processing of wheat from a trial in Canada during 1984 into bran and flour (Nygren, 1985, 866R11, [M-187977-01-1]). Three separate grain samples were processed into bran and flour. The shorts and germ fractions were combined during processing to a whole wheat flour fraction.

Residues of ethephon were determined using the same method as above. The method was validated by determination of the recovery rates for control samples fortified at 0.20 mg/kg. The recovery rates were good: 74% in grain, 79% in bran, 85% in flour and 84% in shorts and germ.

The samples were stored frozen (< –34 °C) for less than 12 months.

Residues determined in wheat processed commodities are shown in Table 83. Ethephon concentrations were lower in wheat flour in unprocessed grain. Ethephon residues occurred in bran as well as in shorts and germs (combined to whole wheat flour) with average processing factors of 3.1 and 2.7, respectively. These results compare well with those obtained in the previous study. A material balance is provided in the report which shows that the residues

measured in the milled fractions accounted for 78 to 86% of the residues determined in the corresponding unprocessed wheat grain samples.

Table 83 Residues of ethephon in wheat grain and processed products (Nygren, 1985)

Trial	Commodities	Ethephon, mg/kg	Mean processing factor
Canada (variety Augusta)	Wheat grain (RAC)	0.07, 0.10, 0.07 (mean 0.08)	
	Wheat bran	0.20, 0.22, 0.30 (mean 0.24)	3.1
	Wheat flour	0.02, 0.03, 0.02 (mean 0.02)	0.2
	Whole wheat flour (germ + shorts)	0.25, 0.18, 0.19 (mean 0.21)	2.7

Cotton seed

A study was conducted on processing of cotton seed from a trial in the USA (Louisiana) in 1993–1994 to oil and pomace (Lee, 1994, USA93I04R, [M-203874-01-2]). Three replicate samples (approximately 72 kg each) were harvested by hand 7 days after treatment.

The cotton was processed in such a way as to simulate industrial practice as closely as possible. However, due to the sample size, a batch process was adopted (as opposed to a continuous operation). A simplified flow chart of the processing is shown in the following Figure with analysed fractions underlined. The kernel (with some hull material) was heated (66–76 °C), flaked (82–114 °C) and then exposed to hexane (49–60 °C) to remove the crude oil from the flakes. After the crude oil and the hexane mixture was adjusted to the proper ratio, the crude oil was refined by heating up to 49 °C with sodium hydroxide. Thereafter the soapstock was separated by centrifugation and heated to about 70 °C in order to remove solvent. The refined oil was obtained from the liquid phase by evaporating the hexane. As the refined oil had a dark colour, it was refined again.

Residues of ethephon were analysed by ethylene release with method EC-92-228. The LOQ was 0.07 mg/kg for seed and processed commodities. Procedural recoveries at fortification levels of 0.07–6.0 mg/kg were 95% (RSD 3.2%, n=7) for seed, 108% (RSD 14.6%, n=5) for hulls, 101% (RSD 10.3%, n=5) for meal, 99% (RD 6.7%, n=7) for crude oil, 93% (RSD 14.1%, n=8) for soapstock and refined soapstock) and 100% (RSD 6.0%, n=8) for refined and re-refined oil.

The samples were frozen after collection at < -10 °C and stored frozen until extraction and analysis. The maximum period of storage was 12 months.

Residues determined in the ginned cottonseed and the cottonseed processed fractions are shown in Table 84. The mean ethephon residue level in ginned cottonseed amounted to 4.96 mg/kg. There was no concentration in any of the analysed processed fractions. Mean ethephon concentrations amounted to 0.35 mg/kg in hulls, 0.12 mg/kg in meal and 0.13 mg/kg in soapstock. Ethephon concentrations in crude and refined oil were less than the limit of quantification of 0.07 mg/kg. The data suggest that a significant part of the ethephon residue decomposes during processing.

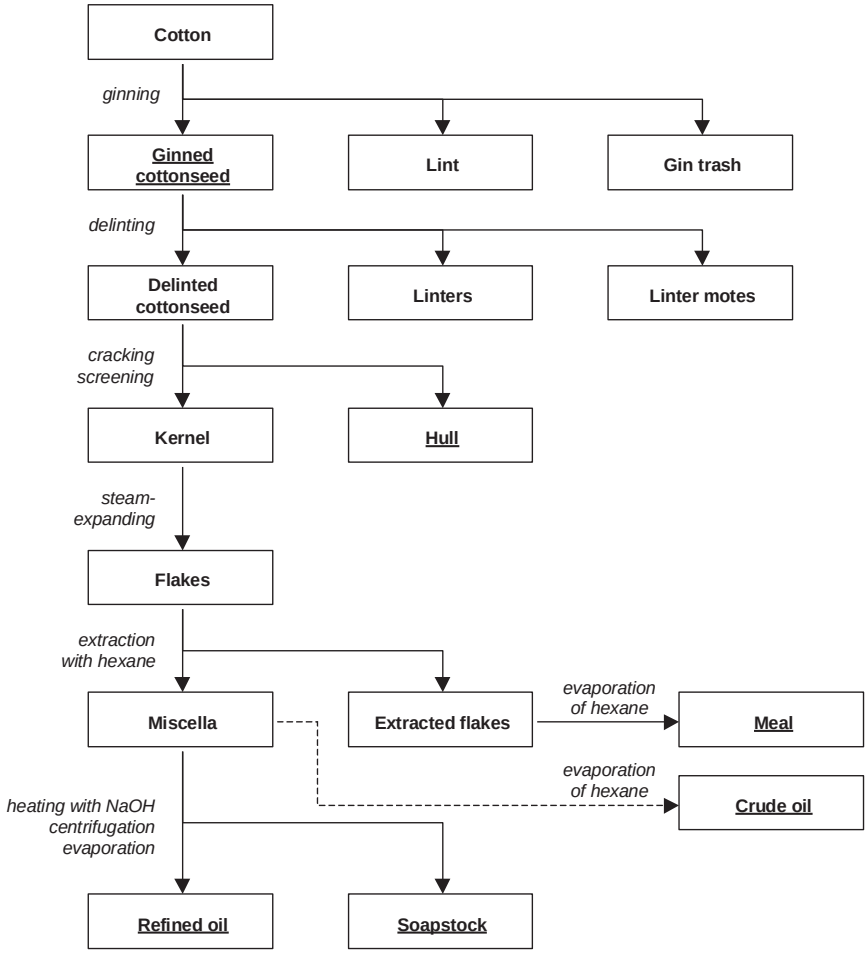

Figure 9 Cotton seed processing

Table 84 Residues of ethephon in cotton seed and processed products (Lee, 1994)

Trial	Commodities	Ethephon, mg/kg	Processing factor
USA (Louisiana) (variety DPL 41)	Cottonseed	5.84, 3.75, 5.30 (mean 4.96)	
	Hulls	0.22, 0.29, 0.55 (mean 0.35)	0.07
	Meal	0.15, 0.07, 0.14 (mean 0.12)	0.02
	Crude oil	< 0.07, < 0.07, < 0.07 (mean < 0.07)	< 0.02
	Soapstock	0.13, 0.15, 0.11 (mean 0.13)	0.03
	Refined oil	< 0.07, < 0.07, < 0.07 (mean < 0.07)	< 0.02
	Refined soapstock	< 0.07, < 0.07, < 0.07 (mean < 0.07)	< 0.02
	Re-refined oil	< 0.07, < 0.07, < 0.07 (mean < 0.07)	< 0.02

Another study was conducted on processing of cotton seed from two field trials in Greece and Spain in 2008 to oil (Billian & Krusell, 2010, 08-3401, [M-367885-01-1]).

The processing included the following steps: conditioning, extraction and refining. Initially pressing was planned, but it was not carried out because the oil content of the cotton seeds was < 25%. Instead, the oil was separated by solvent extraction.

The seeds were defrosted and crushed using a roller mill. After conditioning (adjusting the content of moisture for < 5%), the crushed cotton seeds extracted with n-hexane (2 hours at 60 °C) in a small technical extraction plant. The solvent-oil-mixture (miscella) was pumped into a distillation vessel and the hexane removed by distillation. The hexane was recycled back to the seed for a second hexane extraction step. After distillation, the rest of the solvent was removed from the extracted by rotary evaporation at 50 °C to give solvent extracted oil. The solvent-extracted crushed seed was sampled as meal after storing at room temperature for approximately one day.

The solvent extracted oil was filtered to give pre-clarified crude oil. Refining consisted of hydration, desliming (degumming), neutralization, washing, drying, bleaching, filtration and deodorization

Residues of ethephon were determined using method 00918. The LOQ was 0.05 mg/kg. Mean procedural recoveries at fortification levels of 0.05–15.0 mg/kg were 98% (RSD 6.5%, n=4) in bolls, 88% (RSD 6.4%, n=3) in meal, 91% (RSD 5.5%, n=4) in seed and 94% (RSD 3.2%, n=6) in oil.

The samples were frozen after collection at < –10 °C and stored frozen until extraction and analysis. The maximum period of storage for bolls was 452 days (14.9 months), for seed was 439 days (14.4 months) and for oil and meal was 437 days (14.4 months).

Residues determined in the cottonseed and processed fractions are shown in Table 85. Ethephon concentrations in bolls were 12.7–13.4 mg/kg. Residues in seed were 1.48–2.0 mg/kg. There was no concentration in any of the analysed processed fractions and little transfer of residues into the oil. Residues in all oil fractions were < 0.05 mg/kg and in meal were 0.05–0.14 mg/kg. The mean processing factors are < 0.03 for oil and 0.05 for meal.

Table 85 Residues of ethephon in cotton seed, oil and meal (Billian & Krusell, 2010)

Summary of processing factors

Based on the available processing studies, the processing factors that have been calculated are summarized in Table 86.

Table 86 Summary of processing factors

Commodity	Processed commodities	Processing factor	
		Individual value	Best estimate
Apple	Wet pomace	0.3, 0.4, 0.6, < 0.8, 1.1	0.60

Commodity	Processed commodities	Processing factor	
		Individual value	Best estimate
	Dry pomace	2.0	2.0
	Apple juice	< 0.4, 0.4, 0.5, < 0.8, 1.5	0. 5
	Apple sauce	0.4, 0.5, < 0.8, 1.1	0.5
Grape	Dried grapes	0.79, 0.89, 1.0, 1.4, 3.2, 8.5	1.2
	Grape juice	0.5, 0.7, 0.8, 1.1	0.75
	Wet pomace	0.4, 0.6, 0.9, 1.1	0.75
	Must	0.7, 0.8, 0.8, 0.9, 1.0, 1.0	0.85
	Wine	0.7, 1.0, 1.2, 1.4, 1.5, 2.1,	1.3
Olives	Olive oil (virgin and refined)	< 0.02, < 0.03	< 0.02
	Table olives	< 0.01, < 0.02, < 0.02, < 0.03	< 0.01
Tomato	Wet pomace	< 0.1, < 0.1, < 0.2, 0.52	0.52
	Dry pomace	1.9	1.9
	Tomato juice	< 0.1, 0.1, < 0.2, 0.34	0.22
	Tomato puree	< 0.1, < 0.1, < 0.2, 0.60	0.60
	Tomato paste	0.5, 0.6, 0.75	0.6
	Tomato preserves	< 0.1, < 0.2, 0.2	0.2
Barley	Pearl barley	0.9	0.9
	Barley hulls	1.6	1.6
Wheat	Flour	0.1, 0.2, < 0.3,	0.15
	Wheat germ	2.0	2.0
	Wholemeal flour (germ + shorts)	2.7	2.7
	Wheat bran	1.4, , 3.1, 3.5	3.1
Cotton	Cottonseed refined oil	< 0.02,< 0.03, < 0.03	< 0.02
	Meal	0.02, 0.03, 0.07	0.03

RESIDUES ON ANIMAL PRODUCTS

Livestock feeding studies

Dairy cattle feeding study

As the goat metabolism studies conducted at exaggerated dose rate suggested that residues of ethephon may transfer to edible tissues and mil, a cattle feeding study was conducted (Wells-Knecht, 1996, 96E08334, [M-188195-01-1]). Three groups of three Holstein dairy cows were orally dosed once daily with ethephon in gelatine capsules for 28 consecutive days. One additional cow was maintained as control and received no test compound. One group received an amount of ethephon equivalent to nominally 43 ppm diet (1×, actual mean level = 44 ppm), another was fed 129 ppm diet (3×, actual mean level = 128 ppm), and the last group received 430 ppm diet (10×, actual mean level = 415 ppm).

Milk samples were collected twice daily and, the p.m. milk and the a.m. milk of the following day were combined. Milk samples for each animal were retained for analysis on study days 0, 1, 4, 8, 11, 15, 18, 22, 25 and 27. All cows were sacrificed after 28 days of dosing, within 6 hours after receiving the final dose. Tissues collected were: kidney, liver, fat (composite of omental and peri-renal fat), and muscle (composite of thigh and loin muscle). All samples were frozen at –20 ºC until analysis.

Ethephon was measured in the homogenised tissue samples using analytical method 11-94 (Nygren, 1994, 11-94). The LOQ was 0.01 mg/kg for tissues and 0.002 mg/kg for milk. The concurrent mean recovery in milk was 99±6% (n=17) at fortification levels of 0.002–0.10 mg/kg. The mean recovery in liver was 105±7% (n=3) at fortification levels of 0.01–2.0 mg/kg, in kidney was 94±14% (n=5) at fortification levels of 0.01–12 mg/kg, in fat was 70% (n=2) at fortification levels of 0.01 and 4 mg/kg and in muscle was 98% (n=2) at fortification levels of 0.01 and 0.4 mg/kg.

All milk and tissue samples were analysed within 30 days of sampling, except for the reanalysis of the Day 8 milk samples, which were analysed after 34 days of storage. The results of the reanalysis corresponded with the results of the initial analysis conducted within 30 days of collection. The storage stability study showed that ethephon residues are stable in milk for at least 4 months, and in meat for at least 12 months when stored frozen.

A summary of the residues found in milk is given in in the table below. All milk samples from the control cow did not contain ethephon (ND). Following oral administration to lactating cows for 28 consecutive days, the residues of ethephon in whole milk appeared to plateau after Day 4. At the dose level of 43 ppm diet, residues of ethephon in milk were less than 0.01 mg/kg. Maximum residue concentrations in milk were 0.007 mg/kg at the low dose level, 0.019 mg/kg at the mid dose level and 0.033 mg/kg at the high dose level.

Table 87 Mean residues of ethephon in whole milk during 28 days oral administration to dairy cows

[a] Day 8 milk not included in table because of suspect untreated control

A summary of the residues of ethephon in tissue samples from cows fed 43 ppm, 129 ppm, and 430 ppm in the diet of ethephon for 28 days are summarized in the table below. The results show that residues are very low in tissues except in kidney. The residue levels in kidney are up to 7 times higher than the residue level in liver. Residue levels of ethephon in tissue and milk samples are proportional to dose level.

Table 88 Residues of ethephon in tissues from dairy cattle following dosing with ethephon for 28 days

Tissue	Ethephon in individual cow, mg/kg (Mean ethephon, mg/kg)			
	0 ppm diet	43 ppm diet	129 ppm diet	430 ppm diet
Fat	< 0.01	< 0.01, < 0.01, < 0.01 (< 0.01)	0.016, 0.069, 0.037 (0.04)	0.038, 0.029, 0.13 (0.06)

Poultry feeding study

A poultry feeding study was conducted (Wells-Knecht, 1996, 96E08335, [M-188192-01-1]). Three groups of ten Leg Horn laying hens were orally dosed once daily with ethephon in gelatine capsules for 28 consecutive days. Each group was sub-divided into three subgroups of three or four hens. One additional group of ten hens was maintained as a control and received no test compound. One group received ethephon at a dose level equivalent to nominally 2.3 ppm diet (1×), another was fed 6.9 ppm diet (3×), and the last group received 23 ppm diet (10×).

Eggs were collected twice daily. Egg samples from study days 0, 1, 4, 8, 11, 15, 18, 22, 25 and 27 were pooled by sub-group. All hens were sacrificed after 28 days of dosing, within 4 hours after receiving the final dose. Tissue samples collected were liver, skin with adhering fat, and muscle (breast and leg). All samples were frozen at –20 ºC until analysis.

Ethephon was measured in the homogenised egg and tissue samples using analytical method 11-94. The LOQ was 0.01 mg/kg for tissues and 0.002 mg/kg for eggs. The concurrent mean recovery in egg was 99 ± 4% (n=17) at fortification levels of 0.002–0.10 mg/kg. The mean recovery in liver was 104 ± 10% (n=4) at fortification levels of 0.01–2.0 mg/kg, in skin with fat was 89 ± 3% (n=5) at fortification levels of 0.004–0.20 mg/kg and in muscle was 98 ± 9% (n=5) at fortification levels of 0.04–0.10 mg/kg.

All egg and tissue samples were analysed within 30 days of sampling.

A summary of the residues found in eggs is given in in the table below. Following oral administration to laying hens for 28 consecutive days, the residues of ethephon in whole eggs from the highest dose group were slightly above or below the LOQ of 0.002 mg/kg with the highest concentration of 0.0036 mg/kg in eggs from sub-group C of the high dose group on Day 8 (mean residue on Day 8 was 0.0029 mg/kg). Eggs from the low and mid dose groups were not analysed.

Table 89 Residues of ethephon in whole egg during 28 days oral administration to laying hens

Day sampled	Ethephon in subgroup, mg/kg (Mean ethephon, mg/kg)			
	0 ppm diet	2.3 ppm diet	6.9 ppm diet	23 ppm diet

27	< 0.002	Not analysed	Not analysed	< 0.002, 0.0024, 0.0024 (0.0023)

A summary of the residues of ethephon in tissue samples from hens fed 2.3 ppm, 6.9 ppm, and 23 ppm in the diet of ethephon for 28 days are summarized in the table below. The results show that residues are very low in tissues from the low dose group. The highest residue level was found in liver at 0.033 mg/kg in the low dose level. Residue levels of ethephon in egg and tissue samples increased proportionally with dose level. At the highest dose level, the maximum residue in liver was 0.29 mg/kg.

Table 90 Residues of ethephon in tissues from laying hens following dosing with ethephon for 28 days

Tissue	Ethephon in subgroup, mg/kg (Mean ethephone, mg/kg)			
	0 ppm diet	2.3 ppm diet	6.9 ppm diet	23 ppm diet
Liver	0.01	0.0028, 0.0033 (0.031)	0.059, 0.058, 0.068 (0.062)	0.29, 0.19, 0.20 (0.23)

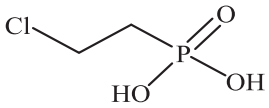
APPRAISAL

Ethephon, 2-chloroethylphosphonic acid, is a systemic plant growth regulator belonging to the phosphonate family. It is readily absorbed by the plant and releases ethylene, a natural plant hormone. Ethylene not only influences directly several physiological processes such as ripening and maturation, but also stimulates the endogenous ethylene production. It has been registered in many countries for a variety of crops, including fruits, vegetables, cereals and oilseed crops.

Ethephon was first evaluated by JMPR in 1977 as a new compound, and then reviewed several times for residues. It was evaluated under the periodic review programme in 1994. The compound was listed in the Priority List by the Forty-sixth Session of CCPR in 2014 for toxicological and residue evaluation by the current Meeting in the CCPR periodic review programme.

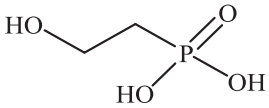
The Meeting received information on identity, metabolism and environmental fate, residue analysis, use pattern, supervised trials (on apples, cherries, grapes, figs, olives, pineapples, tomatoes, cereals, and cotton), processing, and animal feeding studies.

In this Appraisal, the following names were used for referred compounds.



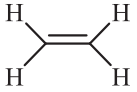
Ethephon

2-Chloroethylphosphonic acid



HEPA

(2-hydroxyethyl)-phosphonic acid



Ethylene

Plant metabolism

The Meeting received information on plant metabolism studies conducted on a variety of plants including information from the published scientific literature. The information dated from 1962 to 2003 and covered peaches, grapes, pineapples, cucumbers, squash, melons, tomatoes, wheat, hazelnuts, walnuts and cotton.

Many studies conducted on various plants indicate the release of ethylene after treatment with ethephon. In several of such studies, methanol, acidified methanol or water was used to extract ethephon from fruits and/or leaves and, where data are available, significant amount of the applied radioactivity (> 60%) or TRR (> 80%) was recovered in the surface wash and solvent extract combined.

The studies involving characterization and identification of other metabolites are described below.

Tomato plants grown outdoor were treated with a foliar spray of uniformly labelled [^{14}C]ethephon at a rate approximating 1.46 kg ai/ha at the "green mature" or "colour break" growth stage and fruits were harvested 0, 5 and 12 days after the treatment (DAT). The majority of the radioactivity was recovered from the methanol surface wash on 0 DAT but 96% (including surface wash) and 98% of the TRR was recovered in methanol extracts of 5 DAT and 12 DAT samples respectively.

The predominant radioactive residue in methanol extract of tomato fruit was ethephon, 70% and 59% of the TRR corresponding to 1.2 mg/kg and 0.68 mg/kg in 5 DAT and 12 DAT was found in fruits, respectively. The concentration of ethephon decreased over the time period in the study from 7.5 mg/kg at 0 DAT to 0.68 mg/kg at 12 DAT. The only significant metabolite found was HEPA accounting for 15% TRR (0.26 mg/kg) on 5 DAT and 13% TRR (0.15 mg/kg) on 12 DAT. No other metabolites exceeded 5% TRR in the methanol extract.

Wheat plants grown outdoor were treated with a foliar spray of [^{14}C]ethephon at a rate of 0.36 kg ai/ha and 3.6 kg ai/ha at the forage stage (BBCH 39) and forage samples were collected on 0 DAT, hay on 14 DAT and grain and straw on 34 DAT. The majority of radioactivity was recovered in methanol extracts of plant parts (hay and straw) on 14 and 34 DAT regardless of the dose used (94% TRR including 1% in surface wash in hay of both doses and 58% and 74% TRR in straw respectively) while radioactivity was similarly distributed in the methanol surface wash and methanol extract (45–46% and 54–55% TRR) of forage on 0 DAT. Unextracted residues were about 5% in 14 DAT for hay and 10% (1×) and 26% (10×) in 34 DAT for straw.

Methanol extraction recovered only 28 and 22% TRR from grain samples after the low and high doses. Acid hydrolysis of the remaining solid released a further 56 and 71% TRR; extraction of the post-hydrolysis solids released a total of 9.9% and 4.3% TRR, respectively. This indicates the presence of significant conjugates in grains. Unextracted residues were 1.8–6.0% TRR.

Most of the TRR was attributed to the sum of ethephon and HEPA. The major radioactive residue in 14 DAT hay was HEPA (72% TRR and 3.7 mg/kg) followed by ethephon (20% TRR and 1.0 mg/kg). In the 34 DAT straw, the major radioactive residue was ethephon (62% TRR and 1.5 mg/kg).

In 34 DAT grain, HEPA was found at a similar level as ethephon after the low dose (HEPA 48% TRR and 0.51 mg/kg and ethephon, 44% and 0.47 mg/kg). After the higher dose, approximately two times larger amount of HEPA was found than ethephon (HEPA, total of 60% TRR and 2.0 mg/kg; and ethephon, total of 32% TRR and 1.1 mg/kg). No other metabolites exceeded 3% of TRR.

Cotton plants grown outdoor were treated with a foliar spray at a rate of 1.4 kg ai/ha seven days before harvest. Plants were harvested at 7 DAT. The majority of radioactivity was recovered in methanol/water (9:1) for gin trash (89% TRR) and in methanol extract for seeds (82% TRR).

The predominant radioactive residue in gin trash was ethephon at 93% TRR and 30 mg/kg; and 78% TRR and 0.64 mg/kg in seeds. HEPA was low, 1.7% TRR and 0.52 mg/kg in gin trash and 9.6% TRR and 0.08 mg/kg in seeds. No other metabolites exceeded 2% of TRR.

In summary, plant metabolism studies conducted on tomatoes, wheat and cotton indicate that the metabolism of ethephon in these plants was qualitatively similar and indicate that radioactivity penetrated into plants after a foliar application and translocated to edible matrices of plants.

After foliar application to plants, ethephon was metabolized to ethylene and phosphates and HEPA which would be either metabolized to carbon dioxide and phosphate or incorporated into biomolecules such as proteins, carbohydrates and lipids after further metabolism.

In tomatoes, cotton, and wheat hay, most radioactivity was recovered from methanol extracts whilst in wheat grains and straw a significant amount of radioactivity was recovered in the acid hydrolysate, suggesting ethephon is present in conjugated forms.

In tomato and cotton, ethephon was the predominant residue with little HEPA present. However, in wheat grains, HEPA and its conjugates were present at a similar concentration as that of ethephon and its conjugates after the 1× dose and approximately two times higher concentration than ethephon after the 10× exaggerated rate in grain. In wheat hay, HEPA was present at 3.5 times higher than ethephon.

Ethephon would be an appropriate marker for plants except cereal grains and straw in which ethephon was significantly metabolised to HEPA and to conjugates of ethephon and HEPA.

Animal metabolism

The Meeting received information on the fate of orally-dosed [^{14}C]ethephon in lactating goats and laying hens.

Metabolism studies on laboratory animals including rats were reviewed in the framework of toxicological evaluation by the current JMPR.

After oral administration of ethephon to rats, absorption was rapid with a Tmax of 1.0–1.3 hours and 1.9–2.5 hours after a single oral dose of 50 or 1000 mg/kg bw, respectively. Six days after a single dose tissue, and carcass contained only 0.08% or less of administered radioactivity. Highest concentrations were found in liver and kidney. Radioactivity was excreted in urine (47–60%), expired air (18–21%, mainly ethylene) and faeces (4–6.5%), indicating that at least 65% of the administered dose was absorbed. Ethephon was mainly metabolized to ethylene and to a small extent to HEPA.

Two lactating goats were orally administered [^{14}C]ethephon twice daily after am and pm milking in capsules for seven consecutive days at 0.37 and 0.46 mg/kg bw/day (approximately 10 ppm in the diet). The goats were sacrificed approximately 16 hours after the last dose.

A significant portion of the administered dose was released as ethylene (29%) and carbon dioxide (2.0%). Radioactivity was also excreted in urine (19%) and faeces (6.7%). In total, milk contained 3.3% of the administered dose, tissues 3.0%, and content of gastro ontestinatl (GI) tract, 0.84%. Amongst tissues, kidney contained the highest radioactivity at 1.2 mg eq/kg followed by liver at 1.0 mg eq/kg. Fat contained 0.50 mg eq/kg, heart 0.16 mg eq/kg and muscle 0.10 mg eq/kg. Over the study period, average TRR in milk increased from 0.081 mg/kg on day 0.5 to a plateau level of 0.42 mg/kg at day 3.5. The fat fraction of milk contained 45% of the TRR in milk; skimmed milk contained 0.15–0.20 mg eq/kg; and milk fat, 3.0–4.2 mg eq/kg.

In order to estimate ethephon, portions of tissues were hydrolyzed by shaking at 40 °C at pH 11 for one hour to transform ethephon to ethylene. Ethylene released by this hydrolysis was 0.4% TRR in kidney corresponding to 0.008 mg/kg ethephon, 0.05% TRR in fat, and 0% TRR in muscle, liver and milk. Radioactivity in the remaining solids were 0.3%, 2.1%, 71% and 35% of the respective TRR in kidney, liver, muscle and fat.

Extraction of a portion of liver with ether released 5.3% TRR, methanol, a further 64% TRR leaving 27% TRR unextracted. Precipitation with trichloroacetic acid resulted in 12% TRR in liver which is associated with proteins. Glycogen was isolated at a concentration of 0.9 mg/kg.

Two studies were provided on metabolism of ethephon in laying hens. In both studies, hens were orally administered either by capsule or gavage [^{14}C]ethephon at a rate equivalent to 53–67 ppm in the diet for five consecutive days. Hens in the first study were sacrificed 22–23 hours after the last dose and those in the second 9–10 hours after the last treatment.

In the first study, the majority of the administered dose (58%) was recovered as expired ethylene while expired carbon dioxide was negligible. In the excreta, 26–30% of the

administered dose was recovered. Liver contained 0.31 mg eq/kg (average), followed by kidney with 0.20 mg eq/kg and fat with 0.15 mg eq/kg. Radioactive residues in the eggs and tissues accounted for less than 1% of the administered dose. Muscle contained 0.023 mg eq/kg showing lower levels than other tissues. Radioactive residues in eggs reached a plateau on Day 4. No identification of metabolites was carried out in this study.

In the second study, approximately one third of the administered dose was recovered in excreta. About 3% of the administered dose was recovered as ethylene but this percentage is not reliable due to the leakage in the experiment. Radioactive residues in the eggs and tissues accounted for less than 1% of the administered dose. Kidneys contained 0.71–1.1 mg eq/kg, liver 0.63–0.90 mg eq/kg, and fat 0.051–0.091 mg eq/kg and muscle, 0.051–0.058 mg eq/kg. Radioactive residues in eggs did not reach a plateau within the study period of 5 days. Higher radioactivity was found in eggs in this study than the first study reaching the level of approximately 0.40 mg eq/kg on Day 5. In eggs, egg yolk contained much higher radioactivity than egg white (1.02 mg eq/kg egg yolk and 0.092 mg eq/kg in egg white).

Ethephon and HEPA were identified in methanol/water extracts of muscle, liver and kidney but not in the hexane/tetrahydrofuran extracts of fat or eggs (both yolk and white). Ethephon was the major residue in kidney accounting for 42% of TRR (0.30 mg/kg) but at a similar level as HEPA in liver (ethephon, 0.11 mg/kg; HEPA, 0.10 mg/kg) and muscle (ethephon, 0.006 mg/kg; HEPA, 0.009 mg/kg). Significant radioactivity was incorporated into amino acids (3–35% of TRR) in these tissues and in fatty acids (around 40% TRR) in fat. Significant amounts of radioactive residues (23 or 40% TRR for liver and 42 or 71% TRR for fat) remain unidentified. In eggs, radioactivity was incorporated into peptides (93% TRR in egg white) and fatty acids/cholesterol/glycerol (77–79% in egg yolk).

In summary, ethephon, when administered orally, was rapidly eliminated either in the excreta or expired as ethylene. Ethephon and HEPA were identified in kidney, liver and muscle in hens. Ethephon was found in kidneys of goats at very low concentrations. Ethephon was metabolized through two routes: metabolized to ethylene and/or to carbon dioxide through HEPA. A similar metabolic pattern was observed in rats, goats and hens. In livestock, radioactivity was found in fatty acids, proteins and glycogen.

Environmental fate

Hydrolysis

Ethephon degrades rapidly at pH 7 and 9 with the half-life of 2.4 and 1.0 day, respectively. At pH 5, it degrades more slowly with a half-life of 73.5 days. Ethylene gas and methylated phosphoric acid were the only degradation products found.

Photochemical degradation

Ethephon showed degradation under continuous irradiation for 360 hours at pH 5 at 25 °C. The half-life was 29 days under irradiation and 51 days without irradiation. Ethephon and ethylene were the only major compounds found. Ethylene was the only degradate of ethephon in the headspace.

Aerobic soil metabolism

The studies on aerobic soil degradation of ethephon in five different soils at 20–25 °C indicate that ethephon applied on soil degraded over time with different rates with the formation of ethylene. DT_{50} values ranged from 2.7–38 days for the five soils tested.

Photolysis on soil surface

Photolysis of ethephon on soil was found to be insignificant. Only ethylene and carbon dioxide were formed.

Field dissipation

Field dissipation studies were conducted at three sites in the USA. In all cases ethephon declined with time. DT_{50} values were 6.8–2 5 days.

Residues in succeeding crops

A confined rotational crop study was conducted to examine the nature and level of residues of ethephon in three succeeding crops (radish, collard and wheat) under outdoor conditions. A single application of radio-labelled ethephon was made on bare plots in plastic containers at a rate of 2.36 kg ai/ha (approximating the highest single application rate for cotton in the USA among approved label rates available to the Meeting). After plant back intervals (PBI) of 30, 120 and 379 days, collard, radish and wheat were planted into the treated soil. Mature radish, collard and wheat were harvested 54–62 days, 68–91 days and 110–158 days after planting. Immature wheat foliage was harvested 47–68 days after planting.

Ethephon declined steadily in soil. Radioactivity in mature plant samples declined in parallel with or faster than the decline in soil. The total extracted radioactive residues were at or lower than 0.07 mg eq/kg in any sample analysed. The solvent extraction recovered 34–37% TRR in 30 day PBI collards, 120 day PBI radish top and 30 day PBI and 120 day PBI wheat forage. As observed in the metabolism study on wheat, only 7.3–24% TRR were extracted by solvents from 30 day PBI and 120 PBI wheat grains and straw.

In the HPLC analysis of plant extracts, where radioactivity was sufficient for characterization, ethephon and HEPA were detected at or below 0.01 mg/kg in the extracts of radish, collard and wheat. No unknown peaks were observed. Sequential treatments of the unextracted radioactive residues for natural components indicated that most of the radioactivity in the plant samples were incorporated into biomolecules, such as starch, proteins, and cellulose fractions.

Overall, ethephon was shown to degrade relatively fast in soil with half-lives around or shorter than the plant back interval of 30 days. The confined succeeding crop study indicated the presence of very low levels of ethephon and HEPA in rotational crops. Therefore, no significant residues of ethephon or HEPA would be expected in rotational crops.

Methods of analysis

Analytical methods for determination of residues of ethephon and its metabolite HEPA were developed for a wide range of matrices of plant and animal origin.

There are three different principles for these analytical methods:

- Ethylene-release by heating in alkaline solution (headspace GC-FID)
- Derivatization to methyl ester using diazomethane (GC-FPD or GC-NPD)
- Extraction: mostly by methanol, acidified methanol or 0.01% formic acid
- LC-MS/MS (m/z 143→ 107 or 145-> 107 and HEPA 125→ 95)
- Extraction: mostly by a mixture of methanol, water and formic acid. Clean-up: mostly with SPE column.

The LC-MS/MS methods were used in the more recent studies.

The methods for plant matrices were validated for ethephon resulting in acceptable mean recoveries and relative standard deviations (RSDs) with the LOQ of 0.01–0.05 mg/kg. They are suitable for determining ethephon in a free form (some methods also for free HEPA).

An LC-MS/MS method was recently developed to determine ethephon and HEPA in both free and conjugated forms in cereal grains, straw and green materials. For the extraction of these compounds, grains and straw were extracted first with methanol and then by a mixture of

concentrated hydrochloric acid and water at 50 °C overnight and the extract and hydrolysate were combined for analysis. For green materials, this acid hydrolysis step was not included. This method was validated for ethephon and HEPA in these matrices resulting in acceptable mean recoveries and RSDs with the LOQ of 0.01 mg/kg for grains and 0.05 mg/kg for straw and green materials.

Methods for animal matrices were validated for ethephon resulting in acceptable mean recoveries and RSDs. The LOQ was 0.002–0.01 mg/kg. They are suitable for determining ethephon in a free form.

A multi-residue method DFG S19 (two variants) was examined for analysis of ethephon in plants for enforcement. However, due to low extraction (30%), this method does not seem appropriate for analysis of ethephon.

Stability of pesticide residues in stored analytical samples

The stability of ethephon was investigated in homogenates of various FROZEN plant and animal matrices at –20–15 °C, at fortification levels 0.2–1.0 mg/kg (plant matrices) or 0.1 mg/kg (animal matrices).

Ethephon was stable when stored frozen for at least 24 months in apples, cherries, grapes, blackberries, pineapples (fruit and forage), melons (36 months), peppers, tomatoes, wheat (grain and straw) and cotton seed (25 months). It was also stable for at least 12 months in apple juice and cotton seed oil.

Ethephon was stable when stored frozen for at least 4 months, the longest period tested, in bovine milk, bovine meat and egg.

Definition of the residue

Plant metabolism studies indicate that ethephon is metabolised in a qualitatively similar pattern in plants. Ethephon penetrates into plants after foliar application and residues of ethephon were found in edible commodities. Ethephon was metabolized to ethylene, which is naturally occurring in plants (but at levels not relevant to MRL setting). Ethephon was metabolized to form HEPA and further metabolized to be incorporated in many biomolecules, such as proteins, carbohydrates and lipids.

In the plants studied, ethephon was the major residue. Except for cereal grains, hay and straw, HEPA was found at much lower concentrations than the parent. In wheat plant fractions, HEPA was present at similar concentrations or higher concentrations than those of ethephon in grain and in hay.

In wheat grains and straw, radioactive residues were recovered at a significant proportion from acid hydrolysate and most of this radioactivity was attributed to ethephon and HEPA. This indicates that ethephon and HEPA were also present in these commodities in the form of conjugates.

The current Meeting considered that HEPA is not a toxicologically relevant metabolite as it does not inhibit cholinesterase activity and the NOAEL for HEPA in a 28-day gavage study in animals is at least two orders of magnitude higher than the NOAEL in humans that formed the basis of the ADI and ARfD.

Residues of ethephon were not expected to occur in significant concentrations in rotational crops.

In summary, the Meeting noted that in cereal grains and straw, presence of ethephon in the form of conjugates is significant. In other plant commodities, the Meeting considered that ethephon would be a good marker for enforcement and for estimation of dietary intake.

One recently developed and validated method, involving methanol extraction and acid hydrolysis/extraction of post methanol-extraction solids is capable of determining total ethephon

in free and conjugated forms in cereal matrices. There are other validated methods suitable for determining ethephon in its free form in plant matrices.

In animal metabolism studies, ethephon was rapidly eliminated either in the excreta or exhaled as ethylene. Ethephon was found at low levels in tissues. No metabolites were significant. The Meeting considered that ethephon is a suitable marker for enforcement and for estimation of dietary intake.

There are validated methods available for the determination of ethephon in its free form in animal matrices.

The log K_{ow} (–1.8 to –0.6 at 20 °C) indicates that ethephon is highly water-soluble. Although radioactive residues were found at higher levels in milk fat and egg yolk than skimmed milk or egg white, they were attributed to radioactivity incorporated into fatty acids. The Meeting concluded that the residue is not fat-soluble.

Based on the above, the Meeting recommended the following residue definitions for plant and animal commodities.

Definition of the residue for plant commodities except cereal grains and straw (for compliance with the MRL and for estimation of dietary intake): *Ethephon.*

Definition of the residue for cereal grains and straw (for compliance with the MRL and for estimation of dietary intake*): Ethephon and its conjugates, expressed as ethephon*.

Definition of the residue for animal commodities (for compliance with the MRL and for estimation of dietary intake): *Ethephon.*

The residue is not fat-soluble.

Results of supervised residue trials on crops

The Meeting received supervised trial data for ethephon on apples, cherries, grapes, figs, olives, pineapples, tomatoes (outdoor and indoor), barley, rye, wheat and cotton using foliar sprays of mostly SL formulations containing various concentrations of ethephon.

As ethephon is reviewed under the periodic review programme, the Meeting decided to withdraw its previous recommendations for blueberries, cantaloupes, peppers, dried chilli peppers, hazelnuts and walnuts due to the lack of data.

Apple

A total of 18 supervised trials were conducted on apples in Europe in 2000, 2002, 2006 and 2007, eight in France, two in Germany, one in the UK, two in Italy, two in Spain, one in Portugal and two in Greece.

Residues of ethephon from 13 trials matching critical GAP for apple in France (0.036 kg ai/hL, one to two applications, and PHI 10 days) were: < 0.05, 0.06, 0.07, 0.08, 0.08, 0.14, 0.15, 0.15, 0.24, 0.26, 0.27, 0.40 and 0.49 mg/kg.

The trials matching GAP in France were appropriate for estimating a maximum residue level. The Meeting estimated a maximum residue level of 0.8 mg/kg for apples to replace the previous recommendation. The Meeting also estimated an STMR of 0.15 mg/kg and an HR of 0.49 mg/kg.

Cherries

A total of 15 supervised trials were conducted on cherries in Europe in 2000, 2002 and 2009, ten in France, one in Italy, one in Spain, one in Greece, one in Belgium and one in the Netherlands.

Residues of ethephon from 13 trials matching GAP in Austria for cherries and in the Netherlands for sour cherries (0.36 kg ai/ha, one application, PHI 7 days) were: 0.28, 0.30, 0.33, 0.37, 0.44, 0.52, 0.65, 0.67, 0.91, 1.4, 2.0, 2.3 and 2.7 mg/kg.

The Meeting estimated a maximum residue level of 5 mg/kg for cherries to replace the previous recommendation and an STMR of 0.65 mg/kg and an HR of 2.7 mg/kg.

Grapes

A total of ten supervised trials were conducted on grapes in France in 1995, 2006 and 2009. The GAP in France for grapes allows one application at a maximum rate of 0.45 kg ai/ha with a PHI of 28 days.

Residues from ten trials matching GAP in France were: 0.05, 0.07, 0.14, 0.18, 0.18, 0.20, 0.21, 0.25, 0.37 and 0.52 mg/kg.

The Meeting estimated a maximum residue level of 0.8 mg/kg for grapes to replace the previous recommendation, an STMR of 0.19 mg/kg and an HR of 0.52 mg/kg.

Fig

Six supervised trials were conducted on figs in Brazil in 2004–2005. GAP in Brazil for figs allows one application of 0.94 kg ai/hL with a PHI of 5 days. Ethephon should be applied directly to fruits using brushes with sponge tips or other equipment for even distribution.

Residues from three trials matching GAP in Brazil were, 0.71, 0.73 and 0.75 mg/kg. The Meeting estimated a maximum residue level of 3 mg/kg, an STMR of 0.73 mg/kg and an HR of 0.75 mg/kg for fig.

Olives

Eight supervised trials were conducted on olives in Spain in 2007–2008. GAP in Italy allows two applications (1st application 18 days before harvest at a rate of 0.45 kg ai/ha and 2nd application 11 days before harvest at 0.60 kg ai/ha) with a PHI of 11 days.

Residues from eight trials matching GAP in Italy were, 0.85, 0.90, 0.98, 1.6, 2.2, 2.5, 2.6 and 4.3 mg/kg.

The Meeting estimated a maximum residue level of 7 mg/kg, an STMR of 1.9 mg/kg and an HR of 4.3 mg/kg for olives.

Pineapple

A total of 15 supervised trials were conducted. Five in Brazil in 1994, 1995 and 2005, two in Costa Rica in 1998, two in Côte d'Ivoire in 1997 and 1998, and six in the USA in 1989.

GAP in Kenya for pineapple allows one application at the maximum rate of 1.92 kg ai/ha with a PHI of 7 days. Residues from trial conducted in Côte d'Ivoire matching this GAP were (n=2): 0.11 and 0.97 mg/kg.

Residues from five trials in Brazil matching GAP in Brazil for pineapple (one application at a maximum rate of 0.94 kg ai/ha with a PHI of 14 days) were: < 0.05, 0.11, 0.15, 0.19 and 0.20 mg/kg.

The trials conducted in the USA involved two applications of ethephon and the rate of the first application was two times higher than GAP in Costa Rica (up to two applications at the maximum rate of 1.2 kg ai/ha with a PHI of 1 day; first one 5–7 months before harvest and second 1–2 weeks before harvest) but it was made six months earlier than the expected harvest time with little impact on the residues at harvest.

In the trial in Costa Rica, pineapple was harvested on 0 DALA but as the decline trials indicated that there was no significant decline from 0 to 1 DALA, the Meeting agreed to use the data from 0 DALA.

Residues from trials conducted in the USA and Costa Rica matching GAP in Costa Rica were (n=4), 0.19, 0.22, 0.42 and 0.72 mg/kg. One trial conducted in Brazil matched GAP in

Costa Rica and residues were (n=1), 0.47 mg/kg. Combined residue dataset was (n=5), 0.19, 0.22, 0.42, 0.47 and 0.72 mg/kg.

As the dataset from five trials matching GAP in Costa Rica would lead to a higher maximum residue level than the dataset from five trials matching GAP in Brazil, the Meeting decided to use the dataset associated with GAP in Costa Rica. The Meeting estimated a maximum residue level of 1.5 mg/kg to replace its previous recommendation.

The Meeting calculated a mean pulp/whole fruit ratio to be 0.29 using residue levels higher than LOQ. Using the mean and highest residue in whole fruit and this ratio, the Meeting estimated an STMR of 0.12 mg/kg and an HR of 0.21 mg/kg for pineapple.

Tomato

A total of 33 supervised trials on tomatoes were conducted. Twenty-one trials were in Europe in 1999, 2000, 2001 and 2004 and 15 in the USA in 1989–1991 and 2005. As the labels provided to the Meeting do not specify outdoor or indoor uses, the Meeting considered both trials conducted outdoor and indoor.

The critical GAP for the European trials was GAP in Italy which allows the maximum rate of 1.92 kg ai/ha which can be divided into two applications with a PHI of 7 days. Residues from 12 outdoor trials in Europe matching GAP in Italy were 0.24, 0.30, 0.40, 0.45, 0.46, 0.5, 0.55, 0.57, 0.62, 0.68, 0.78, and 0.78 mg/kg.

Residues from nine indoor trials matching GAP in Italy were 0.31, 0.36, 0.45, 0.51, 0.52, 0.66, 0.68, 0.69 and 0.79 mg/kg.

Residues from five independent outdoor trials in the USA matching GAP in Canada (one application of 1.54 kg ai/ha, PHI 14–21 days) were 0.05, 0.06, 0.09, 0.67 and 0.69 mg/kg.

As the outdoor and indoor trials conducted in Europe were in compliance with the same GAP of Italy and they were not significantly different according to Mann-Whitney U test, they could be combined to estimate a maximum residue level. Residues in the combined data set were 0.24, 0.30, 0.31, 0.36, 0.40, 0.45, 0.45, 0.46, 0.5, 0.51, 0.52, 0.55, 0.57, 0.62, 0.66, 0.68, 0.68, 0.69, 0.78, 0.78 and 0.79 mg/kg.

The Meeting confirmed the pervious recommendation of 2 mg/kg for tomato and estimated an STMR of 0.52 mg/kg and an HR of 0.79 mg/kg.

Cereal grains

As the residue definition for cereal grains was recommended to be “ethephon and its conjugates, expressed as ethephon”, the Meeting used only those trial data obtained with the recently developed analytical method involving acid hydrolysis to convert ethephon conjugates to free ethephon.

Barley

A total of 53 trials were conducted in Europe in 2000, 2001, 2004, 2007, 2008, 2013 and 2014 on barley.

There are several different groups of GAP in Europe. Critical GAP is either GAP in the UK allowing a maximum single rate of 0.48 kg ai/ha, maximum total rate of 0.48 kg ai/ha, and application timing up to BBCH 49, or GAP in Germany allowing one application at a maximum rate of 0.46 kg ai/ha up to BBCH 49.

Residues from seven trials matching GAP in the UK or Germany were 0.03, 0.07, 0.09, 0.13, 0.23, 0.41, 0.73 mg/kg.

The Meeting estimated, using the dataset matching GAP in the UK or Germany, a maximum residue level of 1.5 mg/kg for barley grains to replace the previous recommendation, and an STMR of 0.13 mg/kg.

Rye

Nine supervised trials were conducted in 2006–2007 in Europe. No data were available on the sum of free and conjugated ethephon in rye grains. (See "Wheat" section below.)

Wheat

A total of 43 supervised trials were conducted on wheat in Europe in 2000, 2001, 2004, 2006, 2007, 2013 and 2014.

There are several different groups of GAP in Europe. Critical GAP is that in Austria and Germany allowing one application at a maximum rate of 0.46 kg ai/ha with application timing up to BBCH 51.

Residues from eight supervised trials matching these GAP were 0.05, 0.06, 0.06, 0.08, 0.11, 0.14, 0.23 and 0.31 mg/kg.

The Meeting estimated, using the dataset from trials matching GAP in Austria and Germany, a maximum residue level of 0.5 mg/kg for wheat grains to replace the previous recommendation, and an STMR of 0.095 mg/kg.

As there are similar GAPs existing for wheat, rye and triticale in countries in Europe, the Meeting decided to extrapolate the maximum residue level and STMR for wheat to rye and triticale.

Cotton seed

A total of ten trials were conducted in Europe in 1993, 1994, 1995 and 2008 on cotton, 41 trials in the USA in 1989, 1993 and 1994, and seven trials in Brazil in 1996 and 2006.

Residues from ten trials conducted in Europe matching GAP in Greece for cotton (one application at a maximum rate of 1.44 kg ai/ha with a PHI of 7 days) were 0.07, < 0.10, < 0.10, < 0.10, 0.10, 0.19, 0.30, 0.35, 0.59 and 1.13 mg/kg.

Residues from six independent trials conducted in Brazil matching GAP in Brazil for cotton (one application at a maximum rate of 1.2 kg ai/ha with a PHI of 7 days) were all below the LOQ: < 0.10 (4) and < 0.20 (2) mg/kg.

Residues from 30 trials matching GAP in the USA for cotton (one application at a maximum rate of 2.24 kg ai/ha with a PHI of 7 days) were 0.06, 0.09, 0.10, 0.11, 0.16, 0.18, 0.23, 0.24, 0.26, 0.26, 0.34, 0.35, 0.36, 0.41, 0.54, 0.55, 0.59, 0.61, 0.65, 0.69, 0.75, 0.86, 1.18, 1.42, 1.50, 2.40, 2.42, 2.73, 2.88 and 4.93 mg/kg.

As the residues from US trials would lead to a higher maximum residue level, the Meeting used the results of the US trials to estimate a maximum residue level. The Meeting estimated a maximum residue level of 6 mg/kg for cotton seed to replace the previous recommendation, and an STMR of 0.545 mg/kg.

Animal feed

Cereal forage

As there is no restriction on feed uses of treated cereal plants, the Meeting used residues in forage samples collected on 0 DALA for cereal forage. Since the determination of ethephon in green materials do not require acid hydrolysis, the Meeting used all available data on barley green material.

Barley forage

Residues in forage collected on 0 DAT from 19 trials matching GAP in the UK or GAP in Germany (a maximum single rate of 0.48 kg ai/ha, maximum total rate of 0.48 kg ai/ha, and application timing up to BBCH 49, or one application at a maximum rate of 0.46 kg ai/ha up to BBCH 49) were 2.6, 3.0, 3.2, 4.2, 4.8, 5.1, 5.7, 6.2, 6.2, 6.2, 6.6, 6.6, 7.7, 7.9, 8.1, 8.4, 9.4, 10 and 11 mg/kg.

Residues from 15 trials matching GAP in France (one application at a maximum application rate of 0.48 kg ai/ha and application timing up to BBCH 39 with a PHI of 56 days) in forage were 3.3, 3.5, 4.2, 4.6, 5.2, 5,6, 5.6, 5.9, 6.0, 6.2, 6.7, 8.1, 8.2, 8.3 and 9.5 mg/kg.

Residues from five trials matching GAP in Poland (one application at a maximum application rate of 0.72 kg ai/ha and application timing up to BBCH 39 were 6.0, 7.1, 8.9, 9.6 and 13 mg/kg.

Residues from seven trials matching another GAP in France (one application at a maximum rate of 0.23 kg ai/ha and application timing up to BBCH 39) were 3.0, 3.7, 4.1, 4.5, 5.2, 5.4, 5.9 and 7.5 mg/kg.

Residues arising from five trials using the application rate of 0.72 kg ai/ha showed higher median and highest residues. Based on this dataset, the Meeting estimated a median residue of 8.9 mg/kg and a highest residue of 13 mg/kg ("as received" basis) for barley forage for animal dietary burden calculation.

Rye forage

Residues in forage collected on 0 DAT from nine trials matching GAP in Germany and Austria (one application at a max rate of 0.73 kg ai/ha, application timing up to BBCH 49) were 4.4, 6.4, 7.2, 7.7, 9.1, 9.2, 9.4, 9.6 and 13 mg/kg.

The Meeting estimated a median and highest residue of 9.1 mg/kg and 13 mg/kg for rye forage on an "as received" basis.

Wheat forage

Residues in forage collected 0 DAT from 17 trials matching GAP in Austria and Germany (one application at a maximum rate of 0.46 kg ai/ha, application timing up to BBCH 51) were 3.1, 3.3, 3.5, 4.0, 4.9, 5.2, 5.9, 6.2, 6.4, 6.5, 7.0, 7.0, 7.1, 7.2, 7.5, 10 and 16 mg/kg.

Residues from 18 trials matching GAP in France (one application at a maximum rate of 0.48 kg ai/ha and application timing up to BBCH 39) were 3.1, 4.5, 4.9, 5.6, 5.7, 6.0, 6.1, 6.9, 7.0, 7.2, 7.4, 7.7, 8.3, 12, 14, 14, 17 and 18 mg/kg

Using the dataset from trials matching GAP in France, the Meeting estimated a median residue of 7.1 mg/kg and a highest residue of 18 mg/kg for wheat forage ("as received" basis).

Cereal straw and fodder, dry

As the residue definition for cereal straw was recommended to be "ethephon and its conjugates, expressed as ethephon", the Meeting used only those trial data obtained using the recently developed analytical method involving acid hydrolysis to convert ethephon conjugates to free ethephon.

Barley straw and fodder, dry

Residues from seven trials matching GAP in the UK or Germany (a maximum single rate of 0.48 kg ai/ha, maximum total rate of 0.48 kg ai/ha, and application timing up to BBCH 49, or one application at a maximum rate of 0.46 kg ai/ha up to BBCH 49) in straw were 0.35, 0.43, 0.51, 0.64, 1.2, 1.5 and 3.6 mg/kg.

Using the data set from the trials matching GAP in the UK or Germany, the Meeting estimated a maximum residue level of 7 mg/kg on a dry weight basis (moisture content of 89%) to replace the previous recommendation. For the purpose of calculation of animal dietary burden, the Meeting estimated a median residue and highest residue of 0.64 mg/kg and 3.6 mg/kg ("as received" basis).

Rye straw and fodder, dry

No data were available on the sum of free and conjugated ethephon in rye straw. (See "Summary of cereal straw and fodder, dry" section below.)

Wheat straw and fodder

Residues from eight trials matching GAP in Austria and Germany (one application at a maximum rate of 0.46 kg ai/ha and application timing up to BBCH 51) in straw were 0.36, 0.44, 0.57, 0.66, 1.2, 1.2, 1.3 and 1.5 mg/kg.

Residues from eight trials matching GAP in France (one application at a maximum rate of 0.48 kg ai/ha and application timing up to BBCH 39 with a PHI of 70 days) in straw were 0.21, 0.29, 0.30, 0.44, 0.84, 0.86, 1.2 and 1.7 mg/kg.

Using the data set from the trials matching GAP in France, the Meeting estimated a median residue of 0.64 mg/kg and a highest residue of 1.7 mg/kg ("as received" basis).

Summary

The Meeting noted that it is not always possible to distinguish straw and fodder of barley, rye, triticale and wheat moving in trade, due to their similarity in appearance. It also noted that there are common or similar GAPs existing for wheat, rye and triticale in countries in Europe. The Meeting decided to extend the maximum residue level recommended for barley straw and fodder at 7 mg/kg on a dry weight basis to straw and fodder of wheat, rye and triticale. The new maximum residue levels for rye and wheat straw and fodder, dry replaces the respective previous recommendations.

The median residue and highest residue estimated for wheat straw and fodder should also apply to rye and triticale straw and fodder, dry.

Cotton gin trash

In 12 US trials, residues in cotton gin trash were analysed and reported. Residues in cotton gin trash from ten trials matching GAP in the USA were: 8.41, 11.1, 13.5, 17.1, 25.1, 28.9, 40.5, 45.5, 54.2 and 55.7 mg/kg. The Meeting estimated a median residue of 27 mg/kg. From the highest residue concentration of individual samples, the Meeting estimated a highest residue of 67 mg/kg.

Fate of residues during processing

High temperature hydrolysis

To simulate the degradation of ethephon during pasteurization, baking, brewing, boiling and sterilisation, the hydrolysis of radio-labelled ethephon was investigated in sterile buffered aqueous solutions.

After incubation at 90 °C (pH 4) for 20 minutes, about 80% of ethephon remained and about 10% was recovered as ethylene. The majority of ethephon was converted to ethylene (76–78%) after incubation at 100 °C (pH 5) for 60 minutes or 120 °C (pH 6) for 20 minutes. Only a minor amount of HEPA was formed.

Processing

The Meeting received information on processing of apple, grapes, olives, tomato, barley, wheat, and cotton seed.

Processing factors calculated for the processed commodities of the above raw agricultural commodities are shown in the table below. STMR-Ps were calculated for processed commodities of apples, grapes, tomatoes, barley, wheat and cotton seed for which maximum residue levels were estimated. Where residues concentrate in processed commodities the Meeting estimated maximum residues levels for these processed commodities using the maximum residue levels for the respective raw agricultural commodities and processing factors.

As no data were available on the processing of fig to dried or dried and candied figs, the Meeting withdrew its previous recommendation on figs, dried and dried and candied.

The processing factor of grape to dried grapes was estimated at 1.2 and therefore a maximum residue level for dried grapes was unnecessary. The Meeting decided to withdraw its previous recommendation on dried grapes.

RAC or Processed commodities	Processing factor		STMR-P	Maximum residue level
	Individual value	Best estimate		
Apple			0.15 (STMR)	0.8
Apple juice	< 0.4, 0.4, 0.5, < 0.8, 1.5	0.5	0.075	–
Apple sauce	0.4, 0.5, < 0.8, 1.1	0.5	0.075	–

Cotton seed			0.55 (STMR)
Meal	0.02, 0.03, 0.07	0.03	0.016

Residues in animal products

Farm animal feeding studies

Lactating cows received oral administration of ethephon at dose rates equivalent to 44, 128 and 415 ppm in the diet once daily for 28 consecutive days. The residues of ethephon in whole milk appeared to reach plateau after Day 4. Ethephon in milk was 0.007 mg/kg at 44 ppm dose, 0.02 mg/kg at 128 ppm dose, and 0.03 mg/kg at the 415 ppm dose. After a 28 day-administration, the highest concentration of ethephon in kidney was 0.58, 3.2 and 7.8 mg/kg respectively after 44, 128 and 415 ppm dose. In liver, it was 0.08, 0.51 and 0.99 mg/kg. In muscle, the ethephon concentration was much lower at 0.01, 0.05 and 0.12 mg/kg for these dose groups. In fat, at the highest dose, ethephon was present at only 0.06 mg/kg.

Laying hens were orally administered with ethephon at rates equivalent to 2.3, 6.9 and 23 ppm in the diet once daily for 28 consecutive days. The residues of ethephon in whole eggs were very low and those from the highest dose group contained at a maximum 0.0036 mg/kg. Therefore, eggs from the 2.3 ppm and 6.9 diets were not analysed. After 28-day administration, liver contained the highest concentration of ethephon, 0.033 mg/kg at the 2.3 ppm dose, 0.068 at the 6.9 ppm dose and 0.29 ppm at the 23 ppm dose. In skin + fat, it was 0.014, 0.032 and 0.117 mg/kg. In muscle, it was 0.060 at 23 ppm diet.

Estimation of dietary burdens

The maximum and mean dietary burdens were calculated using the highest and median residues of ethephon estimated at the current Meeting on a basis of the OECD Animal Feeding Table. In Australia, use of ethephon-treated cereal green materials as feed is not allowed and cereal forage is not in trade. Residues arising from use of ethephon in barley, rye and wheat forages were not used for calculating animal dietary burden for the Australian diets.

Summary of livestock dietary burdens (ppm of dry matter diet)

	US-Canada		EU		Australia		Japan	
	Max	Mean	max	Mean	Max	Mean	Max	mean
Beef cattle	4.19	1.65	18.8	9.14	4.04	0.81	0.13	0.13
Dairy cattle	14.5	6.22	18.9 [a]	9.17 [b]	1.46	0.79	0.059	0.059
Broilers	0.11	0.11	0.10	0.10	0.024	0.024	0.015	0.015
Layers	0.11	0.11	7.33 [c]	3.17 [d]	0.024	0.024	0.012	0.012

[a] Suitable for estimating maximum residue levels for milk, meat, fat and edible offal of cattle

[b] Suitable for estimating STMRs for milk, meat, fat and edible offal of cattle

[c] Suitable for estimating maximum residue levels for eggs, meat, fat and edible offal of poultry

[d] Suitable for estimating STMRs for eggs, meat, fat and edible offal of poultry

Residues in milk and cattle tissues

The maximum and mean dietary burdens in cattle were 18.9 and 9.17 ppm of dry matter diet respectively for estimating a maximum residue level and STMR for milk and edible tissues. The maximum residue levels, STMRs and HRs for relevant commodities of mammal origin were estimated using the residue levels in tissues and milk at 0 and 44 ppm feeding groups.

	Feed level (ppm) for milk residues	Ethephon (mg/kg) in milk	Feed level (ppm) for tissue residues	Ethephon (mg/kg) in			
				Muscle	Liver	Kidney	Fat
Maximum residue level beef or dairy cattle							
Feeding study [a]	0 44	– 0.002	0 44	< 0.01 0.016	0.05 0.095	0.03 0.64	< 0.01 < 0.01
Dietary burden and highest residue	18.9	0.0009	18.8	0.007	0.069	0.29	0.004
STMR beef or dairy cattle							

Feeding study [b]	0 44	– 0.002	0 44	< 0.01 0.01	0.05 0.08	0.03 0.49	< 0.01 < 0.01
Dietary burden and mean residue	9.17	0.0004	8.25	0.002	0.056	0.13	0.002

[a] Highest residues for tissues and mean residue for milk

[b] Mean residues for tissues and mean residue for milk

The level < LOQ at 0 ppm dose is assumed to be 0 mg/kg residue.

The Meeting estimated STMRs of 0.0004, 0.002, 0.056, 0.13 and 0.002 mg/kg, and HRs of 0.0009, 0.007, 0.069, 0.29 and 0.004 mg/kg for milk, meat, liver and kidney respectively.

On a basis of highest residues above, the Meeting estimated maximum residue levels of 0.01*, 0.01*, 0.4 and 0.01* mg/kg for milks mammalian meat, edible offal and fat, respectively.

The previous recommendations for milk of cattle, goats and sheep, meat of cattle, goats, houses, pigs and sheep, and edible offal of cattle, goats, horses, pigs and sheep were withdrawn.

Residues in eggs and chicken tissues

The maximum and mean dietary burdens in poultry were 7.33 and 3.17 ppm of dry matter diet respectively for estimating a maximum residue level and STMR for eggs and edible tissues. The maximum residue levels, STMRs and HRs for relevant commodities of poultry origin were estimated using the residue levels in tissues and eggs at 2.3, 6.9 and 23 ppm feeding groups.

	Feed level (ppm) for egg residues	Ethephon (mg/kg) in			
		Eggs	Muscle	Liver	Fat [a]
Maximum residue level broiler or layer hens					
Feeding study	6.9 23	na 0.0023	0.015 0.060	0.068 0.23	0.032 0.117
Dietary burden and highest residue	7.33	0.00005	0.016	0.072	0.034
STMR broiler or layer hens					
Feeding study	2.3 6.9	na na	< 0.01 0.012	0.031 0.062	0.013 0.024
Dietary burden and mean residue	3.17	0 [b]	0.01	0.037	0.015

[a] From data in fat + skin

[b] At a dose of 23 ppm in the dry matter diet, residues were 0.0036 mg/kg

The Meeting estimated STMR of 0, 0.01, 0.037 and 0.015 mg/kg, and HR of 0.00005, 0.016, 0.072 and 0.034 mg/kg, respectively for poultry eggs, meat, edible offal and fat.

On a basis of HR, the Meeting estimated maximum residue levels of 0.01 *, 0.02, 0.08 and 0.04 mg/kg for eggs, poultry meat, edible offal and fat, respectively. The recommendations for poultry meat and edible offal replace the previous recommendations.

The Meeting withdrew its previous recommendation on chicken eggs.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed in Annex 1 are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of the residue for plant commodities except cereal grains and straw (for compliance with the MRL and for estimation of dietary intake): *Ethephon.*

Definition of the residue for cereal grains and straw (for compliance with the MRL and for estimation of dietary intake): *Ethephon and its conjugates, expressed as ethephon*.

Definition of the residue for animal commodities (for compliance with the MRL and for estimation of dietary intake): *Ethephon.*

The residue is not fat-soluble.

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Dietary Intakes (IEDIs) of ethephon were calculated for the 17 GEMS/Food cluster diets using STMRs and STMRPs estimated by the current Meetings (see Annex 3 to the 2015 Report). The ADI is 0–0.05 mg/kg bw and the calculated IEDIs were 0–6% of the maximum ADI. The Meeting concluded that the long-term intake of residues of ethephon resulting from the uses considered by the current JMPR is unlikely to present a public health concern.

Short-term intake

The International Estimated Short-Term Intakes (IESTI) of ethephon were calculated for commodities using HRs/HR-Ps and STMRs/STMR-Ps estimated by the current Meeting (see Annex 4 to the 2015 Report). The ARfD is 0.05 mg/kg and the calculated IESTIs were 0–100% of the ARfD for the general population and 0–70% of the ARfD for children. The Meeting concluded that the short-term intake of residues of ethephon, when used in ways that have been considered by the JMPR, is unlikely to present a public health concern.

FLONICAMID (282)

The first draft was prepared by Ms Monique Thomas, Pest Management Regulatory Agency, Canada

EXPLANATION

Flonicamid is a new insecticide for control of aphids and other sucking insects. It belongs to a new class of chemistry known as pyridinecarboxamide. Flonicamid has been registered in Canada since 2009. At the 46th Session of the CCPR (2014), flonicamid was scheduled for evaluation as a new compound by 2015 JMPR.

The Meeting received information on the metabolism of flonicamid in peaches, Bell peppers, potatoes, wheat, lactating goats, laying hens and rotational crops, environmental fate, methods of residue analysis, freezer storage stability, GAP, supervised residue trials on various fruits, vegetables, tree nuts, oil seeds, dried hops, mint and tea, processing studies, as well as livestock feeding studies.

IDENTITY

ISO common name: Flonicamid

Chemical name:

IUPAC: *N*-cyanomethyl-4-(trifluoromethyl)nicotinamide

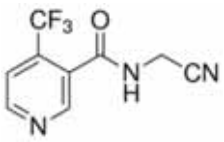
CAS: *N*-(cyanomethyl)-4-(trifluoromethyl)-3-pyridinecarboxamide

CAS Registry. No.: 158062-67-0

CIPAC No.: 763

Trade Name: IKI-220

Structural formula:



Molecular formula: $C_9H_6F_3N_3O$

Molecular weight: 229.16 g/mol

Formulation

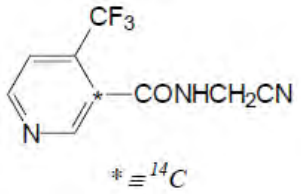
Flonicamid is commercially marketed as a soluble or wettable granule containing 50% flonicamid.

Specification

Flonicamid has not been evaluated by the FAO/WHO Joint Meeting of Pesticide Specifications (JMPS).

METABOLISM AND ENVIRONMENTAL FATE

The metabolism and distribution of flonicamid in plants and animals was investigated using ^{14}C-labelled test material as shown below:



Chemical names, structures and code names of metabolites and degradation products of flonicamid are summarized in the following table. Compounds are referred to primarily by the code name.

Code names, chemical names and structures of flonicamid related substances

Code Name	Structure	Chemical Name	Occurrence
Flonicamid IKI-220		*N*-cyanomethyl-4-(trifluoromethyl)nicotinamide	Goat Hen Peach Peppers Potato Wheat Rotational crop (wheat) Soil
TFNA		4-trifluoromethylnicotinic acid	Goat Hen Peach Peppers Potato Wheat Rotational crop (wheat) Soil
TFNA-AM		4-trifluoromethylnicotinamide	Goat Hen Peach Peppers Potato Wheat Rotational crop (wheat)

Code Name	Structure	Chemical Name	Occurrence
OH-TFNA-AM		6-hydroxy-4-trifluoromethylnicotinamide	Goat Hen
TFNA-OH		6-hydroxy-4-trifluoromethylnicotinic acid	Rotational crop (wheat)
TFNG		*N*-(4-trifluoromethylnicotinoyl)glycine	Peach Peppers Potato Wheat Rotational crop (wheat) Soil
TFNG-AM		*N*-(4-trifluoromethylnicotinoyl)glycinamide	Hen Peach Peppers Wheat Rotational crop (wheat)

Plant metabolism

The Meeting received information on the fate of flonicamid radio-labelled at the 3 position of the pyridine ring following foliar application to peaches, Bell peppers, potatoes and wheat (immature and mature).

Peach

Flonicamid, radio-labelled at the 3 position of the pyridine ring (specific activity: 1.67 MBq/mg), formulated as a wettable granule formulation, was applied to single peach trees (variety: Elberta), grown outdoors in individual 1.4 m^2 plots of clay loam. Each tree received two foliar applications, at a 14-day re-treatment interval, at rates of 100 g ai/ha (low rate) or 500 g ai/ha (high rate) per application, resulting in total seasonal rates of 200 g ai/ha or 1000 g ai/ha. Mature fruits and leaves were harvested 21 days following the second application.

To remove surface residues the fruit was washed with deionised water. Following the removal of pits, the surface-washed fruits were then cut into small pieces and homogenised. The homogenates were then centrifuged to give an aqueous fraction (juice) and a solid fraction (pomace). The juice was decanted, total volume measured and the radioactivity measured. The remaining pomace was weighed and then ground with dry ice in a blender.

Radioactivity was measured by liquid scintillation counting (LSC). Dry-ice-ground peach leaves, pomace and PES were combusted in an oxidizer (Table 1).

Overall total radioactive residues (TRRs) in fruits at the low rate and the high rate were 0.10 mg eq/kg and 0.32 mg eq/kg, respectively, while in the leaves, TRRs were higher than those of fruits, 6.24 mg eq/kg at the low rate and 24.21 mg eq/kg at the high rate.

Table 1 TRRs in peach fruits and leaves

Crop part	TRRs (mg eq/kg)	
	Low rate (200 g ai/ha)	High rate (1000 g ai/ha)
Fruits	0.10	0.32
Leaves	6.24	24.21

Subsamples of both pomace and leaves were extracted twice with acetonitrile:water:phosphoric acid (40:60:0.1, v/v/v). The extracts of each subsample were pooled and the PES were air dried. Quantification and characterization/identification of residues were done by HPLC. To determine the ^{14}C residue profiles, fractions were collected from the HPLC effluent and analysed by LSC. Flonicamid and metabolites were isolated and purified from peach juice and leaf extracts of both treatment groups. The isolated radioactive components were purified by reverse phase HPLC. The identification was supported by other methods such as TLC and LC-MS.

Representative samples of peach fruit fractions (surface wash, pomace and juice) were extracted and analysed immediately after collection and re-analysed after 5 months of storage. Considering the metabolite profiles from the initial and final analyses were very similar, flonicamid and the metabolites were stable during this storage interval.

According to Table 2, the surface wash removed very little radioactivity, 6–15%, demonstrating limited penetration. The majority of the radioactivity in peach fruits was partitioned in the juice fraction, accounting for 64–73% of the TRR while the radioactivity in pomace represented 21% of the TRR.

While juice was not further extracted with organic solvents, extraction of the pulp with acetonitrile:water:phosphoric acid recovered 92% TRR. When treated at the low rate, flonicamid (30.1% of the TRR). and TFNA (49.2% of TRR) were the predominant residues. In peaches treated at the high rate, flonicamid accounted for 60.6% of the TRR while TFNA accounted for 17.4% of the TRR. All other metabolites, TFNG, TFNG-AM and TFNA- AM, were $\leqslant$ 6% of the TRR.

In leaves, (Table 4), flonicamid accounted for 33–65% of the TRR followed by the major metabolites TFNG (8–19% of the TRR) and TFNA (5–16% of the TRR). All other metabolites, TFNG-AM and TFNA-AM, were $\leqslant$ 6% of the TRR.

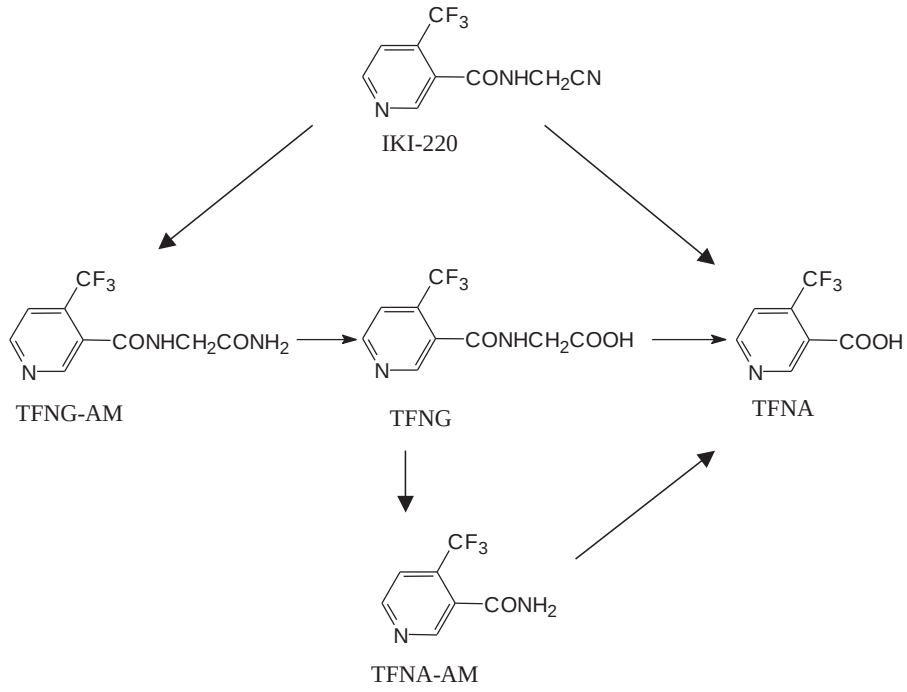

Figure 1 Proposed metabolic pathway in peaches

Bell pepper

Bell pepper plants (variety Wanderbell), grown in individual pots maintained in greenhouses, received a single application of flonicamid, radio-labelled at the 3 position of the pyridine ring (specific activity: 0.182 MBq/mg) and formulated as a 50% wettable granule formulation, at 100 g ai/ha. Bell pepper plants (fruits and leaves) were harvested 7 days and 14 days after application.

Bell pepper fruits and leaves were surface washed with methanol:water (10:90, v/v) prior to being homogenised in a food processor with dry ice. TRRs were determined by combusting triplicate aliquots of the homogenates.

TRRs in leaves decreased from 2.23 mg eq/kg, when harvested 7 days after treatment (DAT) to 1.35 mg eq/kg at 14 DAT. Similarly in fruits, the TRRs decreased insignificantly from 0.17 mg eq/kg (7 DAT) to 0.11 mg eq/kg (14 DAT).

TRRs in each tissue was determined by combusting the samples using an oxidizer. Unextracted residues in post-extraction solids were also determined by combustion.

Table 5 TRRs in bell pepper leaves and fruits

Crop part	TRRs (mg eq/kg)	
	7-DAT	14-DAT
Leaves	2.22	1.35
Fruits	0.17	0.11

Aliquots of fruit and leaf homogenates were extracted twice with methanol:water (50:50) followed by partitioning with hexane and ethyl acetate. The remaining aqueous phase was further separated by open column chromatography. All extracts were analysed by HPLC and TLC.

n.d. = Not detected

Others: consists of multiple peaks, each of which accounted for ≤ 2.0% of the TRR

No information was provided on the duration of storage of the fruit and leaf samples.

While the %TRR in the surface wash decreased with increasing DAT in the leaves and fruit (36% to 17% of the TRR in leaves and 34% to 18% of the TRR in fruits). The extracted TRRs and those in the PES increased with increasing DAT: 61–78% of the TRR and 3–4% of the TRR in leaves, respectively, and 66–81% of the TRR and 0.8–1% of the TRR in fruits, respectively. This trend demonstrates the translocation of the radioactivity from the surface into the leaves and fruits (Table 6).

Analysis of each of the fractions indicated that flonicamid and TFNG were the predominant residues in leaves and fruits at both harvest intervals. In leaves, the parent accounted for 47–74% of the TRR (0.6–1.7 mg/kg) while TFNG accounted for 12–28% of the TRR (0.3–0.4 mg/kg). Similarly in fruits, flonicamid accounted 77–91% of the TRR (0.08–0.16 mg/kg) while TFNG accounted for 3–8% of the TRR (0.005–0.008 mg/kg). All identified metabolites (TFNA, TFNA-AM and TFNG-AM) were either not detected or were ≤ 12% of the TRR.

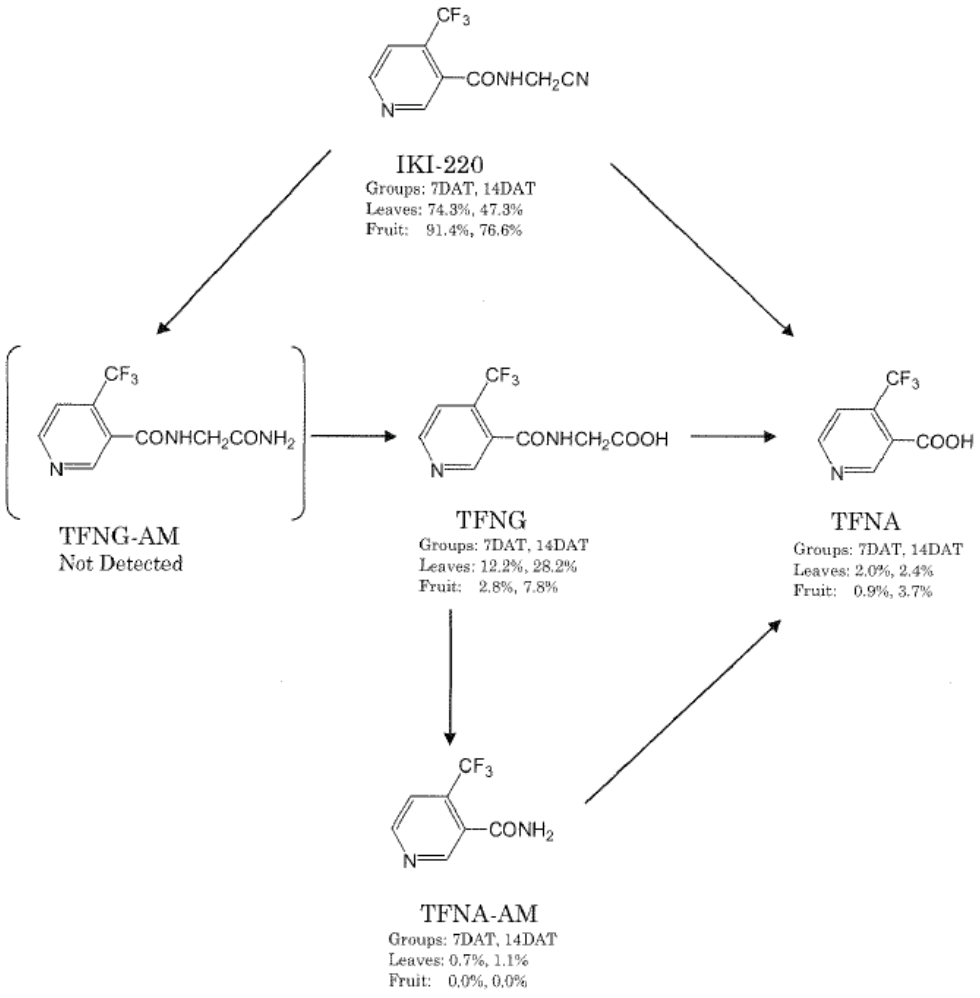

Figure 2 Proposed metabolic pathway in peppers

Potato

Flonicamid, radio-labelled at the 3 position of the pyridine ring (specific activity: 9.08 MBq/mg) and formulated as a 50% wettable powder formulation was applied to potted potato plants (variety Kennebec) maintained outdoors. The plants were treated at either the lower rate of 100 g ai/ha or the higher rate of 500 g ai/ha. Both treatments were repeated after a two-week interval and potato tubers and foliage were harvested 14 days following the second application.

One subsample of potato tubers from each group was washed with ACN:water (80:20, v/v) prior to homogenisation to determine the radioactivity in the surface wash whilst another subsample of potato tubers from each group was homogenised without rinsing the tubers. Potato foliage was processed to isolate the metabolites and to further elucidate the metabolic pathway of flonicamid. Total radioactive residue in each tissue was determined by combusting the samples using an oxidizer. Unextracted residues in PES were also determined by combustion. The radioactivity in the samples was measured by Liquid Scintillation Counting (LSC).

Overall total radioactive residues (TRRs) in unwashed tubers at the low rate and the high rate were 0.11 mg eq/kg and 0.20 mg eq/kg, respectively, whilst those in washed tubers were slightly higher; 0.14 mg eq/kg and 0.53 mg eq/kg. TRRs in mature foliage were higher than those in tubers; 1.53 mg eq/kg at the low rate and 7.67 mg eq/kg at the high rate (Table 9).

Table 9 TRRs in potato tubers and foliage

Crop part	TRRs (mg eq/kg)	
	Low rate (200 g ai/ha)	High rate (1000 g ai/ha)
Unwashed potato tubers	0.11	0.20
Washed potato tubers	0.14	0.53
Foliage	1.53	7.67

Tuber samples were homogenised and consecutively extracted with ACN, ACN:water (80:20, v/v) and twice with ACN:water (50:50, v/v), vortexed, sonicated and centrifuged. The extracts were combined. Foliage samples were homogenised with dry ice and extracted three times with ACN:water:acetic acid (60:40:0.1, v/v/v) and then filtered. The extracts were combined and concentrated.

Metabolites were first identified with HPLC by comparison with reference compounds isolated from repeated HPLC separations of foliage extract of the high treatment group. Most of the isolated metabolites were further purified by normal-phase chromatography. Their identification was supported by other methods such as LC-MS, HPLC on a C8 column and acid hydrolysis (with 3 N HCl).

PM-1a/1b: Acid hydrolyzable conjugates of TFNA

Tuber samples (from the low treatment rate) were analysed 10 days and 397 days after being placed in frozen storage. Extracted and bound residues at the 397-day interval were found to be comparable to those at the 10-day interval. The profiles were also similar between the initial and final analysis.

Considering the applications were made to the foliage of the potato plants, the presence of measurable TRRs in the tubers is evidence of translocation of the radioactivity from the foliage to the tubers. Furthermore, while the TRRs in tubers and foliage increased with increased application rate, the distribution of TRRs was relatively the same irrespective of the treatment rate.

The identity of the radioactive residues in the surface wash of tubers was not further investigated as the TRRs were too low. Analysis of each of the extracted fractions of unwashed and washed potato tubers and foliage from the low and high rate demonstrated that the predominant metabolites, TFNA and TFNG, accounted for a significant portion of the TRRs. Moreover, TFNA accounted for 32–40% of the TRR (0.04–0.21 mg eq/kg) in the unwashed and washed tubers and 12–17% TRR (0.26–0.91 mg eq/kg) in the foliage while TFNG accounted for 25–39% of the TRR in tubers (0.04–0.18 mg eq/kg) and 28–36% of the TRR in foliage (0.6–2.1 mg eq/kg). The parent, flonicamid, was also a major residue in tubers (6–12% of the TRR; 0.01–0.04 mg eq/kg) and foliage (10–25% of the TRR; 0.2–1.9 mg eq/kg), but accounted for less than the major metabolites. All other identified metabolites (TFNA conjugate, TFNG-AM< TFNA-AM, PM-1a, PM-1b and PM-3a) accounted for ≤ 6% of the TRR (0.02 mg eq/kg) in tubers and ≤ 8% of the TRR (0.6 mg eq/kg) in foliage. Overall, the general metabolic profile in foliage was similar to that in tubers.

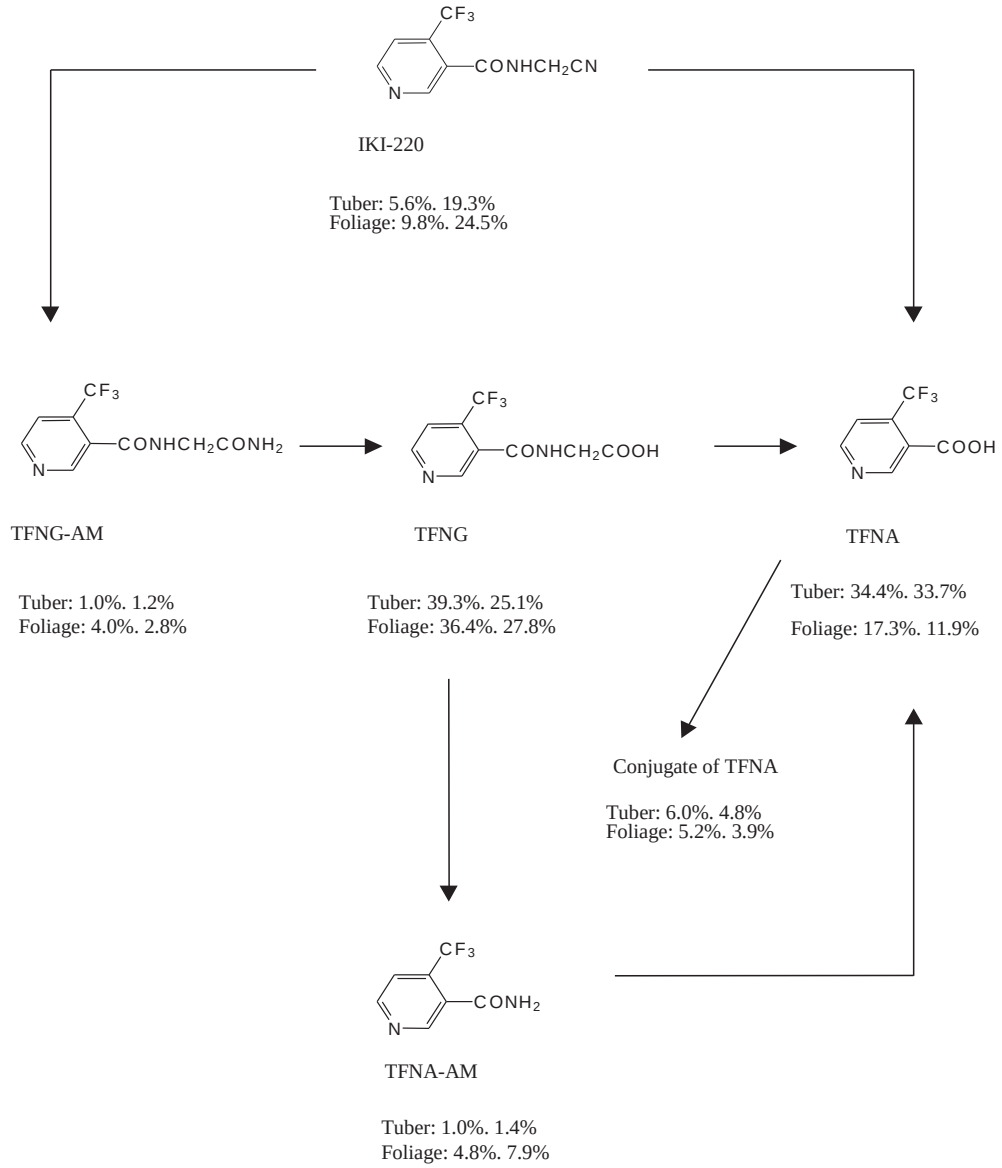

Figure 3 Proposed metabolic pathway in potato

Wheat

Study 1

Spring wheat plants (variety: Kulm) were grown in four separate plots maintained outdoor. Wheat plants grown in Plot I were designated as the control plants. Plants from Plots II and III were treated with flonicamid, radio-labelled at the 3 position of the pyridine ring (specific activity: 9.08 MBq/mg), formulated as a wettable powder, at a single application rate of 100 g ai/ha. Plants in Plot IV were treated twice at 100 g ai/ha/application with a re-treatment interval of 7 days. Forage was harvested 14 days after treatment, from Plot II. Hay was harvested from Plot III, 42 days after treatment. At final harvest, approximately 95 DAT, mature plants from Plot IV were separated into straw, chaff and grain.

The forage, hay, grain, straw and chaff were analysed to determine the total radioactive residue (TRR) levels. The radioactivity was measured with by LSC. Homogenised samples of forage, hay, straw, chaff and grain as well as the PES were combusted in an oxidizer.

Overall residues were lower in the wheat grain sample than the straw or chaff. The TRR levels in the chaff were higher compared to straw potentially because of tissue size differences (higher surface area to weight ratio) assuming a uniform application.

Table 12 Distribution of TRRs in wheat forage, hay, straw, chaff and grain

Plant part	Application rate (g ai/ha)	DAT (days)	TRRs (mg eq/kg)
Forage (Plot II)	100	14	0.648
Hay (Plot III)	100	42	0.951
Straw (Plot IV)	200	95	5.571
Chaff (Plot IV)			6.553
Grain (Plot IV)			2.559

Only samples of forage and hay were analysed to elucidate the nature of the flonicamid residues. These were homogenised in a blender with dry ice, extracted with ACN: water: acetic acid (60:40:0.1, v/v/v), blended with a tissue homogeniser, and then vacuum filtered. The process was repeated twice. The extracts were combined and concentrated by rotary evaporation under vacuum to a small volume. The concentrate was transferred to a vial with appropriate solvent and analysed by HPLC. The radioactivity in the eluate was detected using a radioactivity flow detector.

Table 13 Identification/Characterization of TRRs in wheat forage and hay

Fraction	Forage		Hay	
	mg eq/kg	%TRR	mg eq/kg	%TRR
Extracted	0.58	96.0	0.89	96.0
Flonicamid	0.26	42.8	0.20	21.7
TFNA	0.04	6.5	0.04	3.8
TFNG	0.20	32.7	0.49	52.6

TFNA conjugate	0.004	0.7	n.d.	n.d.
Unknowns	< 0.012	<1.9	0.02	1.6
Polar	n.d.	n.d.	0.02	2.0
Unextracted	0.02	4.0	0.04	4.0
Total	0.60	100.0	0.93	100.0

The extracts were re-analysed by HPLC after storage in the freezer for approximately 2–3 months. Re-analysis confirmed the stability of metabolites in the matrices during storage.

The analysis of forage and hay samples showed that the metabolite profiles were qualitatively similar. Identified residues included flonicamid, TFNA, TFNG, TFNA-AM and TFNG-AM. Differences were observed in the distribution of minor metabolites only. Minor unknown components were observed at less than 0.02 mg eq/kg, $\leqslant$ 2% of the TRR. A trace amount (0.1% of the TRR) of the N-oxide of flonicamid was tentatively identified in forage.

The nature and distribution of metabolites were similar in both wheat forage and hay. The parent compound, flonicamid, accounted for 42.8 and 21.7% of the TRR in forage and hay, respectively. TFNG was the predominant metabolite, accounting for 32.7 and 52.6% of the TRR in forage and hay, respectively. TFNG-AM was present at 11.0–13.1% of the TRR. Metabolites TFNA and TFNA-AM were present at < 7% of the TRR. The unextracted ^{14}C residues in forage and hay represented 0.02–0.04 mg eq/kg (4% of the TRR). Since the samples contained less than 10% of the TRR, the PES were not characterised.

Study 2

Spring wheat plants (variety: Kulm), grown outdoors in metal containers were treated with flonicamid radio-labelled at the 3 position of the pyridine ring (specific activity: 9.08 MBq/mg), formulated as a

wettable granule (WG) and applied on wheat plants as an over-the-top foliar spray at Zadok's stage 86 (soft dough stage), 76 days after sowing. A single application was made at a rate equivalent to 100 g ai/ha. An additional set of wheat plants was treated at a higher rate of 500 g ai/ha. Plants were protected from rain for one week after the spray application. The wheat plants were harvested at maturity, i.e. 21 days after application and separated to straw (leaves and stem), chaff and grain (with hulls attached).

The radioactivity was measured by LSC. Homogenised samples of straw, chaff and grain as well as the PES were combusted in an oxidizer.

The TRRs in wheat straw, chaff and grain samples were 2.03 mg eq/kg, 3.60 mg eq/kg and 0.28 mg eq/kg in the 100 g ai/ha treatment plot (low rate), and 9.28 mg eq/kg, 18.88 mg eq/kg and 1.47 mg eq/kg in the 500 g ai/ha treatment plot (high rate), respectively (Table 14).

Table 14 Distribution of TRRs in wheat straw, chaff and grain

Crop part	TRRs (mg eq/kg)	
	Low rate (100 g ai/ha)	High rate (500 g ai/ha)
Straw	2.03	9.28
Chaff	3.60	18.88
Grain	0.28	1.47

Samples of homogenised straw, grain and chaff were mixed with ACN: water: acetic acid (60:40:0.1, v/v/v), blended with a tissue homogeniser, and then vacuum filtered. This process was repeated twice, following which, the extracts were concentrated and analysed using various HPLC and TLC techniques. The identification of metabolites was supported by other methods such as LC-MS, HPLC on different columns and TLC. The PES were allowed to dry, then combusted to quantitate the unextracted residues. The unextracted residues in the PES obtained by extraction of a second set of subsamples of the normal treatment rate Plot were characterised by acid (1 N HCl) and base hydrolysis (1 N NaOH). For straw and chaff the HCl digestion was followed by treatment with 72% H_2SO_4 to digest the carbohydrate (cellulose) fraction from the matrix leaving behind lignin fraction.

Homogenized straw, chaff and grain, from the low treatment rate experiment, were extracted and analysed immediately after collection and subsequently stored for 480–505 days in a freezer prior to re-analysis. For all three commodities, extracted and bound residues were found to be comparable to those of the initial extraction. The results indicate a similar metabolite profile for straw and chaff between the first and final analysis; however, for grain a decrease in

the concentration of parent and TFNA with a simultaneous increase in TFNG is observed. This does not have any significant impact on the metabolite profile.

Although the TRRs in wheat straw, chaff and grain increased with increased application rates, the distribution of TRRs was relatively the same irrespective of the treatment rate. Considering the timing of application of the test material and the measurable TRRs in grain, chaff and straw at maturity, there appears to have been translocation of the radioactivity from the site of application to the mature plant parts.

The majority of the radioactivity (76–94% of the TRR) in straw, chaff and grain was extracted with organic solvents. Analysis of the organic fractions indicated that flonicamid and TFNG were the predominant residues at both treatment rates. In straw, chaff and grain, the parent accounted for 44–50% of the TRR (1.0–4.1 mg/kg), 41–47% of the TRR (1.5–8.8 mg/kg) and 24–30% of the TRR (0.08–0.4 mg/kg), respectively. The major metabolite TFNG accounted for approximately 20% of the TRR (0.4–2.0 mg eq/kg), 17–19% of the TRR (0.6–3.6 mg eq/kg) and 39–44% of the TRR (0.11–0.65 mg eq/kg) in straw, chaff and grain, respectively. All identified metabolites (TFNA, TFNG-AM, TFNA-AM and N-oxide of TFNA AM) were either not detected or were $\leqslant$ 8% of the TRR.

The unextracted residues amounted to approximately 20, 24 and 11% of the TRR in straw, chaff and grain, respectively, at the low rate and to about 20, 18 and 6% TRR at the high rate. Samples from the low rate treatment were further characterized by:

- Hydrolysis with 1 N HCl at 40 ºC to release covalently bound residues
- Hydrolysis with 1 N HCl followed by digestion with 72% H2SO4 to determine the reincorporated activity in the carbohydrate (cellulose) and lignin fractions of straw and chaff
- Hydrolysis with 1 N HCl followed by 1 N NaOH.

The radioactivity released following hydrolysis with 1 N HCl accounted for 7% of the TRR (straw), 6% of the TRR (chaff) and 3% TRR (grain) and was identified as either parent and metabolites (straw and chaff) or as metabolites of flonicamid only (grain; TFNG, TFNG-AM and TFNA-AM). Each of the identified metabolites was present at $\leqslant$ 2% of the TRR. As a result of sequential digestion with HCl and H_2SO4, ^{14}C incorporation into carbohydrates amounted to 3% of the TRR in straw and 5% of the TRR in chaff. Base digestion with 1 N NaOH released 56, 61 and 59% of the bound radioactivity in straw, chaff and grain, respectively, corresponding to 12, 14 and 5% of the TRR, respectively. Part of this radioactivity may have been due to polar sugars as released by sulphuric acid digestion, with the remainder of ^{14}C attributed to lignin (straw: 10.9% of the TRR, chaff: 13.6% of the TRR).

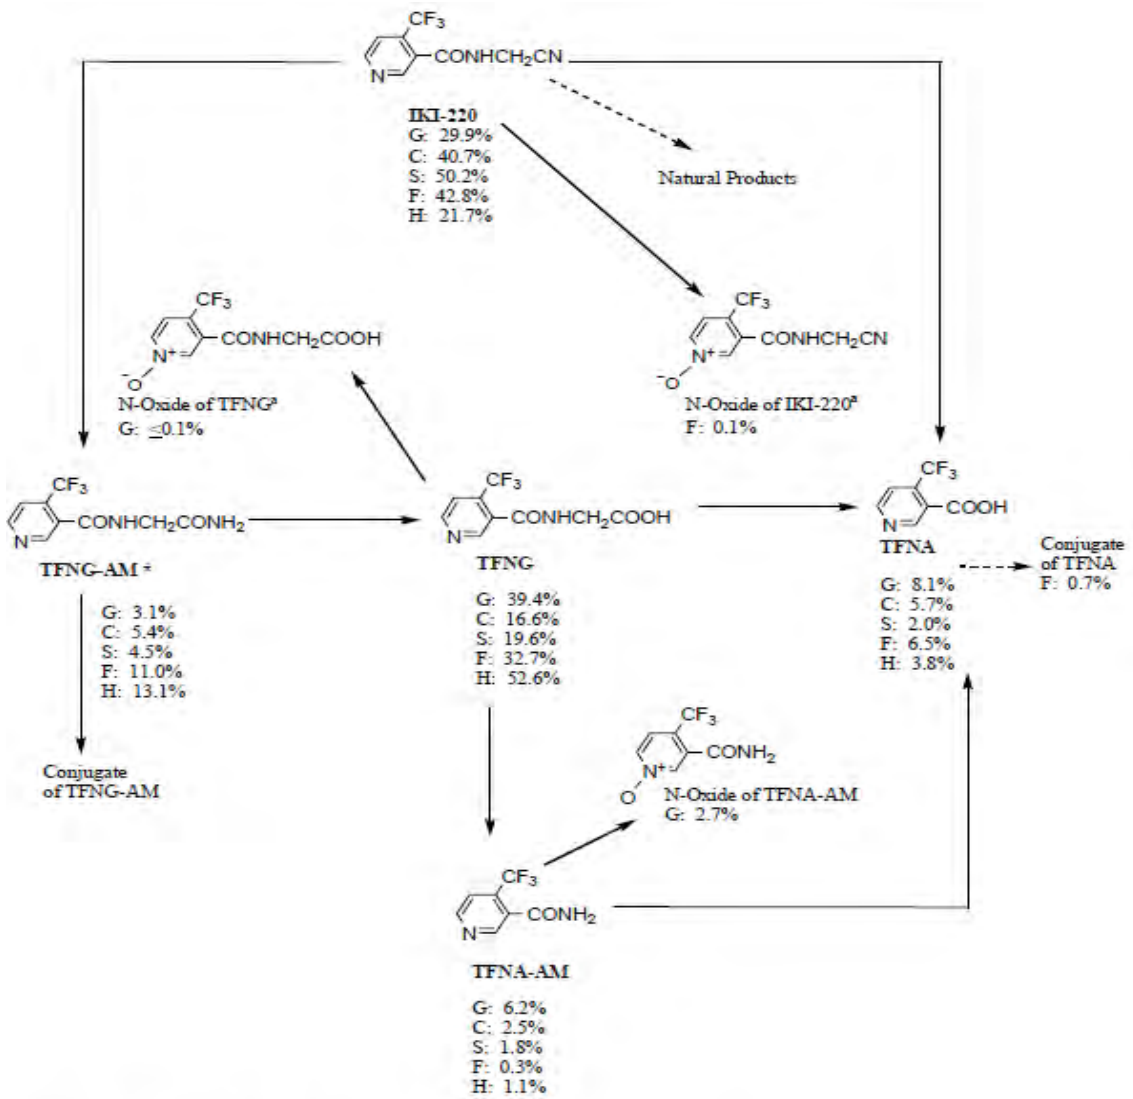

Figure 4 Proposed metabolic pathway in mature wheat

Animal metabolism

The Meeting received information on the fate of 3-pyridine -^{14}C- labelled flonicamid in lactating goats and laying hens. Metabolism in laboratory animals (rat) was summarized and evaluated by the WHO panel of the 2015 JMPR.

Lactating goat

The metabolism of [^{14}C]flonicamid was investigated in two lactating goats (*Capra hircus*), weighing 45–47 kg, dosed orally once daily, using a balling gun, immediately after the morning milking, for 5 consecutive days. The animals were dosed with 3-pyridine-^{14}C-labelled flonicamid (specific activity: 245 µC/mg) at a dose level of 15 mg/day equivalent to 10 ppm in the diet. Milk production ranged from 1.5–1.9 L/day. During the treatment period, milk was collected twice daily, after the morning and evening milking, while urine and faeces were collected once daily. At sacrifice (within 5–8 hours

after the last dose) samples of liver, kidney, muscle (loin and hind leg), fat (omental and peri-renal), heart and GI tract were collected.

Radioactivity in liquid samples (milk, urine, stanchion wash and extracts) was measured LSC. Samples were combusted to verify the total radioactive residues (TRR) prior to extraction. Liver, kidney, muscle, fat, faeces, heart samples and post-extraction solids (PES) were combusted in an oxidizer. The extracted samples were dried before combustion.

The major route of elimination of the radioactivity was via the urine which accounted for 49% of the total administered radioactivity (AD), while faeces accounted for 17–21% of the AD and milk accounted for 1% of the AD. Overall, the tissue burden was low, accounting for < 10% of the AD. The overall recovery of administered radioactivity averaged 95%.

The total radioactive residues (TRRs) were highest in liver (1.2 mg eq/kg), followed by kidney (0.70 mg eq/kg), muscle (0.34–0.39 mg eq/kg) and fat (0.05–0.14 mg eq/kg).

Table 16 Balance of radioactivity in goats following oral administration of [^{14}C]flonicamid for 5 days

Sample	Goat 1		Goat 2	
	%AD	mg eq/kg	%AD	mg eq/kg
Milk	1.18	0.078–0.204	0.97	0.081–0.216
Liver	1.67	1.21	1.71	1.22
Kidney	0.17	0.67	0.15	0.66
Loin muscle	3.80	0.38	3.97	0.39
Hind muscle	3.35	0.34	3.48	0.34
Perirenal fat	0.09	0.14	0.05	0.07
Omental fat	0.07	0.11	0.03	0.05
Heart	0.08	0.22	0.08	0.22
Blood	0.77	0.18	0.88	0.21
Feces	17.06	–	20.59	–
Urine	48.79	–	48.65	–
Cage wash	1.23	–	0.80	–
Subtotal	78.26	–	81.36	–
GI tract	16.62	–	14.09	–
Total Recovery	94.88	–	95.45	–

For collection Days 1–4, evening and morning milk were combined while Day 5 samples consisted of evening milk only. As TRRs were consistently higher in evening milk compared with the morning milk, in the absence of the morning milk on Day 5, ^{14}C-residues were higher than on other collection days.

Table 17 TRRs in goat milk following oral administration of [^{14}C]flonicamid for 5 days

Collection Day	Goat 1		Goat 2	
	mg eq/kg	% AD	mg eq/kg	% AD
Day 1	0.086	0.26	0.081	0.17
Day 2	0.078	0.26	0.090	0.21
Day 3	0.087	0.25	0.090	0.21
Day 4	0.095	0.27	0.096	0.22
Day 5	0.204	0.19	0.216	0.16

Extraction of milk samples with ethanol and ethanol:water (80:20, v/v) and partitioning with hexane released 97–98% of the TRRs. The PES was combusted. The procedure used for the extraction of organs and tissues was relatively similar to that of milk. However, different solvents were used. Kidney and liver samples were extracted with acetonitrile and acetonitrile:water (50:50, v/v) containing 1% acetic acid while muscle samples (loin and rear leg) were extracted with acetonitrile only. The fat samples (omental and peri-renal) were first extracted with hexane and then with acetonitrile. Use of these solvents resulted in extraction efficiencies ranging from 42–57% of the TRRs for organs, 43–52% of the TRRs for muscle and 81–86% of the TRRs for fat.

The unextracted ^{14}C residues in liver, kidney, fat and muscle tissues were sequentially hydrolysed with 1 N HCl and 6 N HCl. The PES from these organs also underwent protease digestion.

Quantification and identification of parent and metabolites were carried out by HPLC (using different solid phases). Purified metabolite isolates were analysed by mass spectrometry.

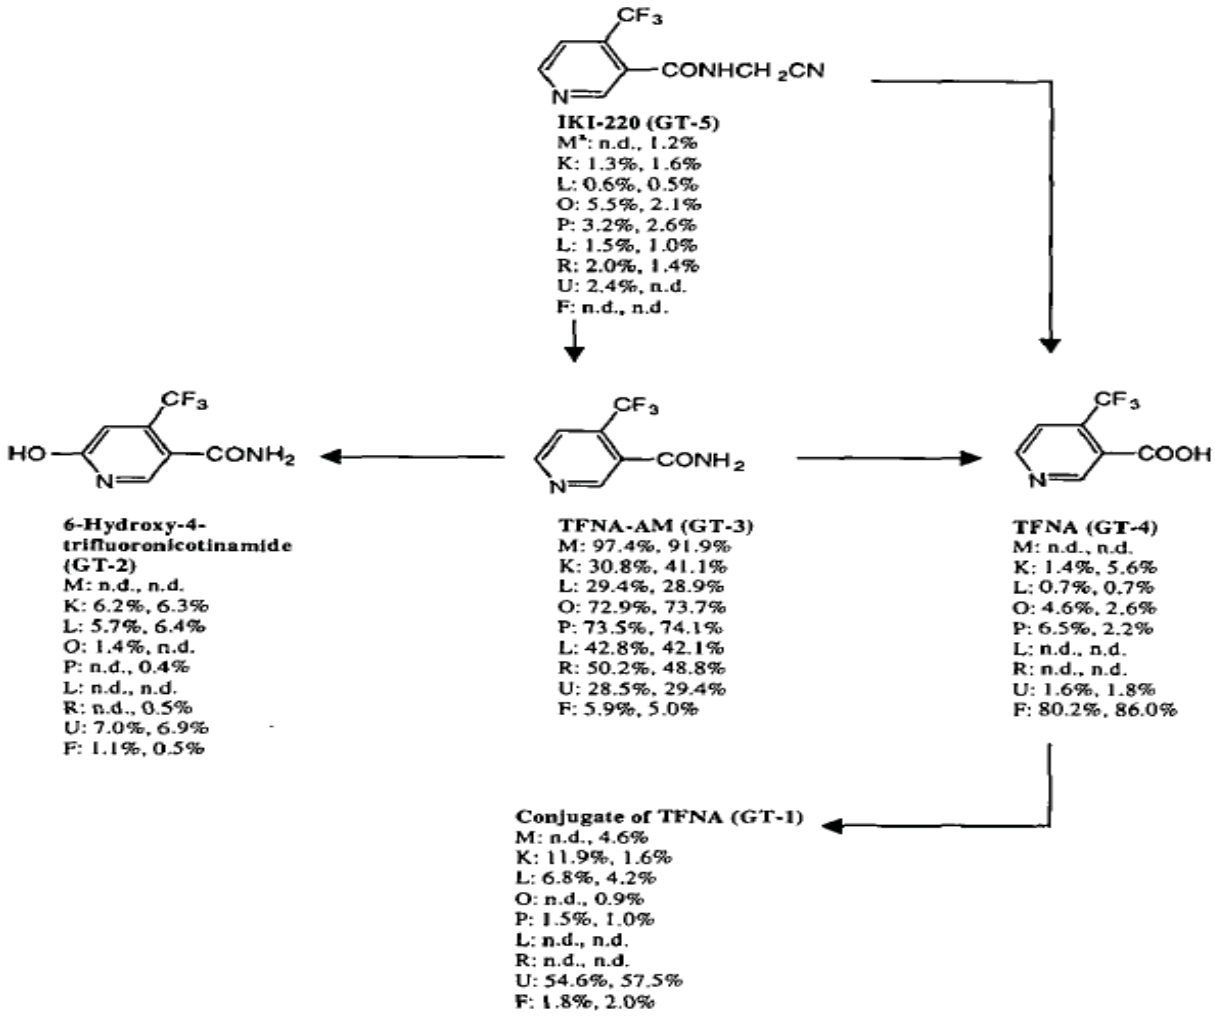
n.a.= Not analysed

All samples of liver, kidney, muscle, fat and Day 3 milk were extracted and analysed within one month of collection, and re-extracted and analysed after 9 months of storage. A comparison of distribution of the TRRs in the initial and final profiles demonstrated minimal changes, indicating stability of the radioactive components under the storage conditions.

Flonicamid was rapidly metabolised in lactating goats, accounting for 0.5–5.5% of the TRRs in tissues and organs. TFNA-AM was the major metabolite in organs (29% of the TRRs in liver, 31–41% of the TRRs in kidney), tissues (74% of the TRRs in fat, 42–50% of the TRRs in muscle) and milk (97% of the TRRs). The metabolite 6-hydroxy TFNA-AM accounted for approximately 3–6% of the TRRs in liver and kidney and less than 1.4% of TRRs in tissue samples and milk.



*M = milk, day 3, K = kidney, L = liver, O = omental fat, P = perirenal fat, L = loin muscle, R = rear leg muscle, U = urine, day 2 and F = feces, day 3.
The values given are % TRR distribution for the samples from goat replicates 1 and 2, respectively.

Laying Hen

Leghorn laying hens (*Gallus domesticus*), weighing 1.37–1.87 kg, were dosed orally once daily for 5 consecutive days with 3-pyridine-^{14}C-labelled flonicamid (specific activity: 1.67 MBq/mg), at 1.3 mg/day, equivalent to 10 mg/kg feed. Eggs were collected twice daily, in the morning before and in the afternoon after administration, while excreta were collected once daily. The average egg production was 95%. The animals were sacrificed approximately 6 h after the last dose and the liver, kidney, thigh muscle, breast muscle, skin and fat were collected and pooled per dose group. Radioactivity in sample solutions was determined by LSC. Solid samples of liver, kidney, muscle, fat, skin, egg and excreta were first combusted in an oxidizer to verify the total radioactive residues (TRR) prior to extraction. Both the dried extracts of tissues and the PES were combusted.

Approximately 91.1% of the administered dose (AD) including 5.7% from the gastrointestinal tract and its contents was recovered. Most of the AD (72.3%) was excreta-related. Total radioactive residues (TRR) in egg white and egg yolk accounted for about 2.4% of AD (1.8% AD in egg white plus 0.6% AD in yolk). The TRR levels in both egg white and egg yolk reached a plateau by Day 3 of dosing. The tissue burden was very low (< 6% of the AD) with highest concentrations found in skin (2.3% of the AD), followed by muscle (evenly

distributed between breast and thigh muscle; each approximately 1.1% of the AD), liver (0.8% of the AD), fat (0.3% of the AD) and kidney (0.2% of the AD). Blood contained 4.7% of the AD.

Extraction of egg yolk and white (Day 3), liver, kidney, breast and thigh muscle with acetonitrile, and acetonitrile:water (80:20, v/v) containing 1% acetic acid released 81–99% of the TRRs. The radioactivity in each extract and in the PES, after combustion, was quantitated. Skin and fat were extracted in the same manner except that an extraction with hexane was done initially, which resulted in an extraction efficiency of 99% of the TRRs.

Each of the PES of liver and kidney was sequentially hydrolysed with 1 N HCl and 6 N HCl. Aliquots of the PES from liver and kidney were additionally hydrolysed using protease. In a separate experiment, digestion of liver PES was carried out with enzyme.

Quantification and identification of parent and metabolites were carried out by HPLC using different columns. For samples containing low levels of radioactivity, fractions of the effluent were collected and analysed by LSC. Analytical methods (HPLC) were validated with authentic standards and shown to achieve the necessary resolution and sensitivity. HPLC column performance and chromatographic resolution were validated with authentic labelled and non-labelled standards.

n.a.= Not analysed

All samples of liver, kidney, muscle, fat and Day 3 egg yolks and egg whites were extracted and analysed approximately 9 months after collection. A comparison of distribution of the TRRs in the initial and final profiles demonstrated minimal changes, indicating stability of the radioactive components under the storage conditions.

Flonicamid was rapidly metabolised and excreted with only a very small percentage of the administered dose found in eggs, tissues and organs. TFNA-AM was the predominant metabolite in egg whites and egg yolks (⩽ 96.0% of the TRR), liver (92.9% of the TRR), kidney (76.4% of the TRR) and tissues (96.8% of the TRR in both breast muscle and thigh muscle, 96.4% of the TRR in skin and 94.7% of the TRR in fat).

Other metabolites identified in organs and tissues were OH-TFNA-AM and TFNG-AM; however, neither of these accounted for greater than 4.8% of TRR. One metabolite found in breast muscle and accounting for 1.1% of the TRR remained unidentified (named HN-1).

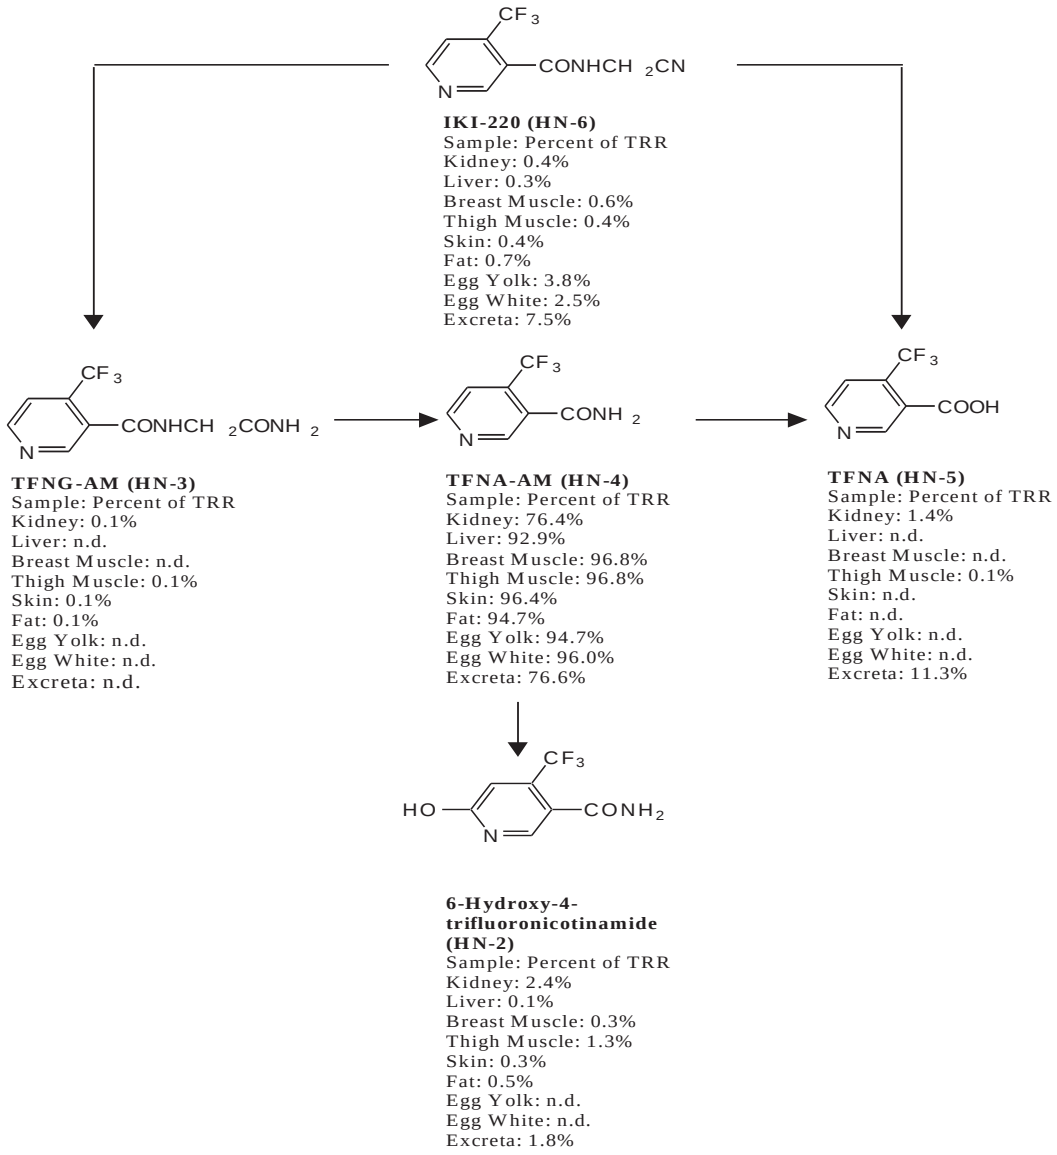

Figure 6 Proposed metabolic pathway in laying hens

Environmental fate in soil

The FAO Manual (FAO, 2009) explained the data requirements for studies of environmental fate. The focus should be on those aspects that are most relevant to MRL setting. For flonicamid, supervised residue trials data were received for foliar spray on permanent crops and on annual crops. Therefore, according to the FAO manual, only studies on aerobic degradation, photolysis and rotational crops (confined, field) were evaluated. For information on hydrolysis and photolysis see also Physical and Chemical Properties.

Aerobic degradation

The route of degradation of [^{14}C]flonicamid (specific activity 8.91 MBq/mg) in soil under aerobic conditions was investigated in a biologically active loamy sand soil collected from Madison, Ohio, USA. A subsample was transferred to a growing pot and stored in a greenhouse. Subsamples of the sieved moist soil were weighed into separate plastic bottles and treated after 43 days of equilibration.

The dosing solution was prepared in water and each subsample was treated to produce a soil concentration of 0.1 µg/g (0.1 ppm). The soil sample was connected to a series of traps to retain any volatiles. Duplicate samples of the treated soil were extracted after treatment on Day 0 and after 0.5, 1, 2, 3, 7, 14 and 30 days of incubation.

The average recovery of applied radioactivity (AR) over the 30-day course of the study was 86.3%. The recovery of radiocarbon was low in the definitive experiment for sampling times days 3, 7, 14 and 30 days due to very rapid extensive metabolism and mineralization which formed $^{14}CO_2$.

A second set of soil samples (mass balance experiment) was dosed and sampled at Days 3, 7, 14 and 30 to correct for mass balance and volatiles. The average recovery of applied radioactivity for the mass balance experiment was 93.3%. Extracted residues decreased from 101.4% AR on Day 0 to 13.7% AR after 30 days incubation. Unextracted soil residues increased steadily from 0.7% on Day 0 to 35.2% on Day 30. Evolution of $^{14}CO_2$ increased throughout the study, reaching a maximum of 47.0% AR after thirty days in this experiment.

Table 27 Distribution of radioactivity in loamy sand soil treated with [^{14}C]flonicamid and incubated at 20 °C and 45% WHC_{max} (values are the average of duplicate analyses)

NA = Not analysed

[a] Values corrected with the data of the mass balance experiment. In the definitive study, the $^{14}CO_2$ was not trapped efficiently.

Flonicamid rapidly declined from 99.3% AR at Day 0 to 2.3% by Day 30. Five metabolites were identified; TFNA, TFNA-OH, TFNG, TFNG-AM and TFNA-AM. TFNA and TFNA-OH were the major metabolites exceeding 10% AR. TFNA peaked at 36.4% AR on Day 3, before declining to 0% by the end of the 30-day interval. Levels of the metabolite TFNA-OH increased steadily, to 20.2% AR through 7 days, then declined to 0.5% AR at Day 30. The metabolite TFNG-AM reached a maximum of 9.6% AR by Day 0.5, but decreased to 0% on Day 7 and 1.8% AR on Day 30. TFNA-AM remained below 7% AR and TFNG below 3% AR over the course of the experiment. TFNA-AM was present in the dose solution at a level of 2.3% AR. Other more polar, minor components were detected on several days, for a combined total of less than 7% AR. The distribution of metabolites in soil treated with [^{14}C]flonicamid is shown in Table 28.

Flonicamid degraded rapidly at 20 °C and 45% WHC_{max} in the loamy sand soil with a DT_{50} of 1 day and a DT_{90} of 3.4 days (r^2 = 0.9960), exhibiting first-order decay kinetics.

Table 29 Degradation of [^{14}C]Flonicamid in soil under aerobic conditions

Soil	DT_{50} [days]	DT_{90} [days]	r^2
loamy sand (Madison, Ohio, USA)	1.0	3.4	0.9960

An effort was made to extract larger quantities of bound residues from the PES and to determine if flonicamid or metabolites were less extracted with time. After acid hydrolysis with 6 N HCl (at ca. 40 °C overnight), the additional radioactivity extracted from the PES represented 37% of the bound residues. Approximately 46% of the released radioactivity was organosoluble. HPLC analysis of the organic phase showed negligible amounts of parent material. The majority of residues released from soil PES were polar in nature. Based on HPLC/LSC of the acid extraction, it was concluded that the unextracted residues remaining after the initial extractions did not contain significant amounts of flonicamid (or its known metabolites).

The major degradates observed exceeding 10% of AR were TFNA and TFNA-OH. TFNG-AM, TFNG and TFNA-AM were detected as minor degradates and were formed as intermediate products. Rapid hydrolysis of the cyano group and the resulting amide group led to the formation of TFNG. Further cleavage of the glycine moiety led to the formation of TFNA. TFNA was apparently rapidly hydroxylated to TFNA-OH by micro-organisms. Mineralisation of the radioactive residues to CO_2 and binding to the soil matrix were the terminal steps in soil metabolism of flonicamid. At the end of the 30-day period, approximately half of the applied dose was mineralized to $^{14}CO_2$ and incorporated into the soil organic matter, primarily into the fulvic acid fraction.

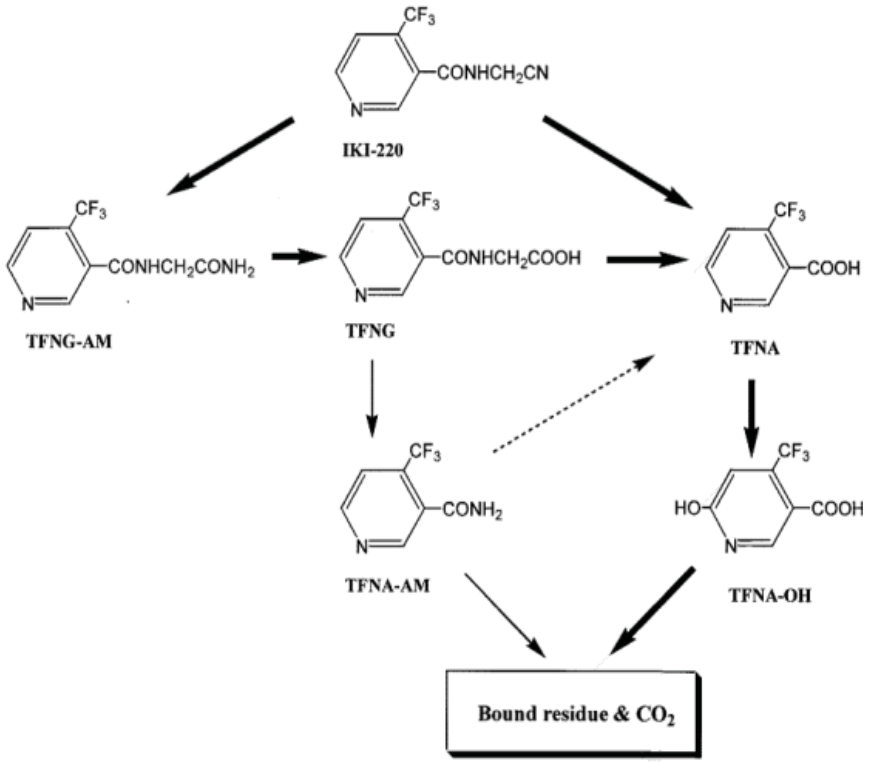

Figure 7 Aerobic degradation pathway in soil

Rate of aerobic degradation in soil

The rate of degradation of [^{14}C]flonicamid, radio-labelled at the 3 position of the pyridine ring (specific activity 9.08 MBq/mg), was investigated in three biologically active soils from the U.K. (Bedfordshire; loamy sand and Birmingham; sandy loam) and one from Germany (LUFA Speyer 2.1; sand) under aerobic conditions at 20 ± 2 °C. In addition, the degradation under aerobic conditions at 10 ± 2 °C was studied in the Bedfordshire soil.

The soil concentration of [^{14}C]flonicamid was 0.1 mg/kg (2 µg/20 g dry soil weight). The moisture content of each subsample was adjusted to approximately 50% of its maximum water holding capacity (MWHC). All three soils were connected to a series of traps to retain any volatiles and maintained in dark environmental chambers at 10 ± 2 °C or 20 ± 2 °C. Soil samples were taken at 0.33, 0.67, 1, 2, 3, 7, 14 and 30 days after treatment.

In UK soils incubated at 20 °C, the total ^{14}C recovery (based on the Day 0 dose) averaged 96% (Table 30). Extracted radioactivity decreased from 98% on Day 0 to 3% after 30 days. For the Bedfordshire soil, unextracted radioactivity reached a maximum of 37.7% by Day 30 and evolution of $^{14}CO_2$ reached 56.6% by Day 30. In Birmingham soil, the PES reached 46.2% by Day 3 and decreased slightly to 43.3% at Day 30 and evolution of $^{14}CO_2$ reached 49.3% by Day 30.

In the German soil, the total ^{14}C recovery (based on the Day 0 dose) averaged 97.2%. Extracted radioactivity decreased from 100.0% on Day 0 to 8.5% at 30 days. The PES reached a maximum of 34.6% by Day 14 and decreased slightly to 29.6% AR by Day 30. Evolution of $^{14}CO_2$ reached 56.2% by Day 30.

In all soils negligible quantities of ^{14}C (< 1%) were detected in the volatile organic compound traps.
