

# Effects of thinning on soil carbon storage in Pinus laricio forest

Muscolo Adele, Settineri G., Mallamaci C., Attinà E., Sidari M.

### INTRODUCTION

Forests act as a natural storage for carbon at the global scale, contributing approximately 80% of terrestrial aboveground, and 40% of terrestrial below-ground carbon storage. The relatively rapid change in the status of forests- from a steady state of CO2

### **OBJECTIVES**

objectives Our were to understand how thinning affects the dynamics of total carbon in forest ecosystems as well as each of its component pools. We estimated carbon stocks in *Pinus laricio* stands, evaluating carbon pool dynamics in forest subject to different thinning intensities (0, 30 and 60%) and clear cut over two contrasting seasons (winter and summer), to verify if the environmental conditions affect in short term soil carbon pool. Our aim was to identify the silvicultural that practice increased carbon storage in pinus forest. Our hypothesis-driven research was that increasing thinning intensities physicochemical, microbiological and biochemical properties of soil related to soil quality and fertility decreased, while improving stand stability, quality, diameter and growth volume of the remaining stand.

### **MAIN RESULTS**

Results showed that soil carbon content and C/N ratio were significantly higher in T60 than in T0, T30 and CC. Under T60, the soils had the highest enzymatic activities, MBC, and colonies of fungi and bacteria (Tables 1, 2). 60% thinning having lower density of trees compared to higher control and ones compared to CC and T30, determined regimes of light, temperature and humidity at soil level that increased the amount and diversity of herbaceous vegetation, promoting an increase in overall soil microbial biomass, and in bacteria responsible for the production of enzymes involved transformation. carbon Humification indices confirmed humification that process prevailed in T60 with consequent carbon storage (Table 3). Additionally, dendro-auxometric parameters evidenced that pinus accretion and wood density changed with the treatments. H/D ratio in 60% thinning was

**Tab. 3** Colonies of fungi and bacteria (CFU g<sup>-1</sup> dry soil) in soil under Pinus laricio plantation differently managed: 0% thinning, T0; 30% thinning, T30; 60% thinning, T60 and clear cut, CC.

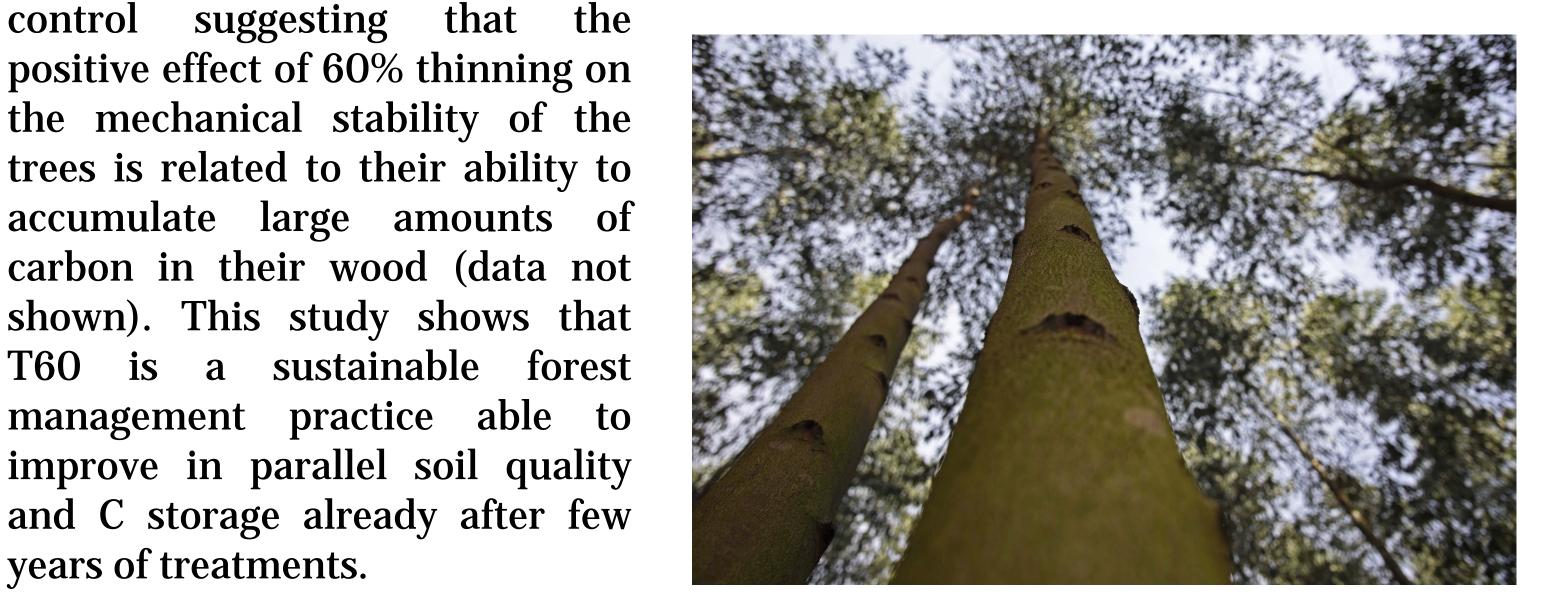

| Season          | Treatment | Fungi                 | Bacteria              | Total count             |  |

#### minimal

emission/sequestration to major CO2 emitter – during this time period may offer a cautionary tale of how quickly the source/sink status of large-scale forest C stocks change. Our can understanding of how forest management influences standing C stocks, however, is limited because many forest C studies have focused on quantifying trends in unmanaged forests. Among silvicultural practices, thinning, reducing tree density and altering microclimate and organic matter budget can affect soil carbon (C) storage and soil ecosystem functioning. In Italy, thinning of pine forests is the effective silvicultural most treatment to enhance the ecological value of these stands; however, changes in soil C, soil microbial biomass and activity after thinning in pine forests are not well elucidated yet.

\*Different letters in the same column indicate, within each season, significant differences (Tukey's test, p ≤0.05)

## **CONCLUSION**

In short we found that 60% thinning was the silvicultural practice to adopt for increasing carbon storage in plant and soil. Our study provides scientific information for predicting the consequences of current management practices for future forest productivity, and understanding how ecological interact with human processes interventions to influence soil carbon storage. The results of our research are for land important managers policymakers, carbon accountants, and scientists working on a variety of forestrelated issues.
