# EVALUATION OF THE WHITE SHRIMP (Penaeus schmitti) STOCK WITHIN THE ORINOCO DELTA AND GULF OF PARIA REGION 

by<br>José J. Alió ${ }^{17}$, Luis A. Marcano ${ }^{18}$, Juan Páez Costa ${ }^{19}$, Douglas E. Altuve ${ }^{20}$, Nelson M. Ehrhardt ${ }^{21}$

## 1. JUSTIFICATION

A common approach for evaluating shrimp resources in areas where information is scant, usually having only data on catch and effort, has been the use of surplus production models (e.g. Fox, 1970). Notwithstanding their valuable contribution to management of marine shrimp fisheries, these types of models make gross assumptions about the dynamics of the population under analysis. Since they treat all individuals in a similar way, they are unsuitable for evaluating, for instance, the variations undergone by different stages within the life cycle of a shrimp species. The information currently available on the shrimp species within the region of the Guyana - Brazil shelf has improved significantly in recent years. In addition to the catch and effort data already available in most countries, processing plants within the region can provide a large amount of information on catch received by month, and how it was converted to catch per size class. Furthermore, there have been numerous studies on the regional species of shrimp covering aspects of growth, reproduction and maturation, morphometry, distribution of life stages, recruitment, natural mortality and stock assessment (see review by Lum Young et al., 1992).

Considering the available, albeit still limited, information the working group on Penaeus schmitti decided to perform a first assessment of this species using virtual population analysis (VPA). It is expected to serve as an introduction of this methodology in the progressive evaluation of other regional shrimp resources, which may become possible in the near future as more information accrues.

## 2. DESCRIPTION OF STOCK AND FISHERIES

The white shrimp, Penaeus schmitti, occurs in shallow waters throughout the Gulf of Paria and the marine border of the Orinoco delta. Its distribution encompasses the Caribbean Sea and the eastern coast of South America, to southern Brazil (Holthuis, 1980). It seems that within the Trinidad - Brazil shelf region, important landings of this species are only made from Venezuelan waters.

Catches of juvenile $P$. schmitti are made by artisanal fishermen in shallow areas within the Gulf of Paria and in the mouths of the rivers throughout the Orinoco delta region (Figure 1). There is an artisanal fishery for this species in the northern coast of the Gulf of Paria (Irapa to Soro), in which fishermen use beach seines in very shallow water (Altuve et al. 1995; Altuve 1997). There is also an artisanal trawl fishery, composed of fishers from Venezuela and Trinidad-Tobago, who operate in the mouths of the rivers of the northern Orinoco delta. Venezuelan fishers operate in the northern sector of Point Bombeador, whereas Trinidad fishers do it in the southern sector, near Cocuina Island. P. schmitti represents most of the landings from the Venezuelan fleet, but only $69 \%$ of the Trinidad landings; the other $31 \%$ in the latter landings are made up of $P$. subtilis (Trinidad and Tobago Fisheries Division, 1996).

Adult $P$. schmitti are trawled in offshore waters close to the mouths of major rivers in the Gulf of Paria and the Orinoco River. The Venezuelan industrial fleet harvests $P$. schmitti in the Gulf of Paria and the Columbus Channel (statistical areas 10621, 10612, 09614, 09613, 09604, 09601, 08594 and 08593; Marcano et al., 1996) while the Trinidad industrial fleet does not make large landings of this species.

[^0]

Figure 1. Distribution of $P$. schmitti in the Gulf of Paria and northern delta of the Orinoco River as indicated by the distribution of fishing effort

Landings of $P$. schmitti by numerous gears in the artisanal fleets can amount to up to 100 t per year (Altuve, 1997), having increased in recent years after the incorporation of the artisanal trawl fleet. The average annual landings of this species in the industrial trawl fleet have been 200 t , with values varying between 160 and 370 t per year during the last 9 years (Figure 2). In spite of the significant increase in effort levels deployed by the industrial fleet in recent years, landings of this species have not followed a similarly increasing trend, probably because the species is not normally targeted by the fleet. P. schmitti represents about $20 \%$ of the total shrimp landings, but its importance relies on its reaching the largest sizes among all shrimp species in the area (Marcano et al., 1997).

For the purpose of this assessment we assumed the existence of a single stock of $P$. schmitti within the area of the Gulf of Paria and the Orinoco delta.

## 3. METHODS

### 3.1 Data on Catch and Size Structure

Total monthly landings of $P$. schmitti for the period July 1996 to February 1997 (Table 1) were obtained from logbook information provided by the Venezuelan industrial fleet and from information gathered by observers on board. This data gathering system was explained in the case study of $P$. subtilis in this volume (Alió et al., 1997). Information pertaining to size structure of $P$. schmitti in the landings was
obtained at industrial processing plants located in Güria and Cumaná. These processing plants provided: 1) data on bulk shrimp that entered the plants from boats landing in the location, and 2) resulting number of boxes by commercial categories (in 5 lb . boxes of tails or 1 kg boxes whole shrimp; Table 2).

Table 1: Total landings of Penaeus schmitti by month, reported by the Venezuelan trawl fleet operating in the Gulf of Paria and the Orinoco River delta

|  | July 96 | Aug. 96 | Sept. 96 | Oct. 96 | Nov. 96 | Dec. 96 | Jan. 97 | Feb. 97 |

| Landings <br> $(\mathrm{kg})$ | 20513 | 13441 | 19166 | 7229 | 11403 | 21503 | 14212 | 20845 |

Table 2: No. of boxes ( 5 lb . tails) of $P$. schmitti per month, reported by processing plants in Cumaná and Güiria during the period July 96 to Feb. 97 . A 5 lb . box of tails would be equivalent to a 7 lb . box whole shrimp (tail weight $+40 \%$ ). The sample size was calculated by the formula: Spl. = No. Boxes tails * 7 lb . * $0.459 \mathrm{~kg} / \mathrm{lb}$. The monthly weighting factor was calculated by dividing the landings by the sample size from Table 1

The parameters for the von Bertalanffy growth equation for $P$. schmitti (both sexes combined) were obtained from Pérez et al. (1980), which were estimated for the population of La Broa Sound, Cuba. These authors provide $L_{\infty}$ values that best approximate the observed maximum sizes observed in the population of $P$. schmitti in the Gulf of Paria. $\mathrm{L}_{\infty}$ values, given by these authors as total length (postorbital notch - sixth abdominal segment, TL'), were converted to total length (rostrum - telson, TLrt) using the conversion equation provided by Giménez et al., (1980):

$$
\text { TLrt }=1.359 \text { * TL' }-0.751
$$

Values of $L_{\infty}$ and $K$ for both sexes combined were obtained by averaging values for females and males: $K=0.35 . \mathrm{mth}^{-1}\left(\mathrm{~K}\right.$ females $=0.31 \mathrm{mth}^{-1} ; \mathrm{K}$ males $\left.=0.39 \mathrm{mth}^{-1}\right)$. Likewise, $\mathrm{L}_{\infty}(\mathrm{TLrt})=253 \mathrm{~mm}\left(\mathrm{~L}_{\infty}\right.$ females $=$ 275 mm ; $\mathrm{L}_{\infty}$ males $=232 \mathrm{~mm}$ ).

The total length (mm) vs. weight (g) relationship for the species (both sexes combined) was obtained from Marcano et al. (1997):

$$
\text { Weight }=1.21^{*} 10^{-6} \mathrm{TL}^{3.3856}
$$

### 3.2 Preparation of Data Sets

The sample size of $P$. schmitti processed in the region every month (St) was estimated as:

$$
\begin{equation*}
\mathrm{St}(\mathrm{~kg})=\Sigma \mathrm{B}_{\mathrm{it}} * 7 * 0.4569 \tag{1}
\end{equation*}
$$

where $\mathrm{B}_{\mathrm{it}}$ is the number of 5-lb tail boxes processed of the commercial category "i" during month " t "; 7 is the weight (lb.) of a box carrying whole shrimp (adding $40 \%$ in weight corresponding to the heads) and 0.4569 is the number of pounds in one kilogram.

The number of $P$. schmitti $\left(\mathrm{N}_{\mathrm{it}}\right)$ in a commercial category " i " every month " t " was estimated as:

$$
\begin{equation*}
N_{i t}=B_{i t} * A_{i} \tag{2}
\end{equation*}
$$

where $A_{i}$ is the number of animals in the commercial category "I".
Finally, the number of animals in a given size class for the monthly samples $\left(\mathrm{C}_{\mathrm{jt}}\right)$ was estimated as:

$$
\begin{equation*}
C_{j t}=\left(\Sigma N_{i t} * P_{j}\right) * L_{t} / S_{t} \tag{3}
\end{equation*}
$$

where $P_{j}$ is the proportion of the size class " $j$ " in the commercial category " $i$ "; $L_{t} / S_{t}$ is a weighting factor which incorporates the total landings in a month and the sample size for that month. The addition is taken over all commercial categories.

The estimated size structure (total number of shrimps per size class) in the monthly catches (Table 5), was used to calculate $Z$ and $F$ values using a linearized catch curve ("Length Converted Catch Curve" procedure, prepared in Excel by Ehrhardt \& Legault, 1996). The mortality rate for every month was assumed constant and equal to 0.2 . The values for $\mathrm{Z}, \mathrm{F}$ and the length interval where the catch curve becomes linear are shown in Table 6. In order to verify the relationship between the changes in $F$ value and the variation of fishing effort by the industrial fleet of trawlers, monthly means and standard errors were plotted for the available period (1992-94; L. Marcano, unpublished results).

The mean number of shrimp at sea by month (Table 7 and Figure 5) were estimated using Length Cohort Analysis (Jones 1984; see also Sparre and Venema, 1995, chapt. 5). In this case, a tuning procedure implemented in Excel and developed by Ehrhardt and Legault (1996) was used. This algorithm permits the tuning of the F-estimates by age (size) class to be performed, based on the estimated F-value and the interval of size classes used in its calculation in the length converted catch curve routine.

Problems in the tuning procedure were encountered in application of VPA in some months (Oct., Dec. 96; Jan., Feb. 97). In these cases the Goal Seek routine of Excel could not converge, forcing a lower weighted $F\left(F_{w}\right)$ value to be used in the calculations of the mean number of animals at sea, instead of the $F$ value calculated from the linearized catch curve ( $F_{1}$ ). Trying to overcome this problem, the size of the interval used in the calculation of $F_{1}$ was restricted and forced towards the largest size classes. The lower $F_{I}$ value thus obtained was used in recalculating the length cohort analysis. If convergence was still not obtained, several $F_{1}$ values were tested, obtained by choosing different size intervals within the linearized catch curve. The one providing the smallest difference between $F_{I}$ and $F_{w}$ values was chosen.

Monthly average biomass in the sea was estimated by multiplying the mean number of shrimp at sea times the mean weight per size class (Table 8 and Figure 6). Biomass of recruits per month was
estimated from data on Table 8, considering that the recruits to the fishery would be animals in the 90100 mm TL length interval (Figure 3). Biomass of parental stock per month (Figure 8) was estimated as the biomass of all animals larger than 160 mm , which was considered a mean size of maturation for female $P$. schmitti (range 128-181 mm TL, Pérez-Farfante, 1969).

| Sep. | 0.74 | 0.54 | $190-220$ |
| Oct. | 0.92 | 0.72 | $200-230$ |
| Nov | 1.03 | 0.83 | $190-220$ |
| Dec. | 1.43 | $1.23(1.13)$ | $180-210$ |
| Jan 97 | 1.78 | 1.58 | $160-190$ |
| Feb | 1.85 | $1.65(1.58)$ | $170-220$ |

## 4. RESULTS

Total mortality (Z), and fishing mortality (F), values showed important variations for the different months for which they were estimated (Table 6, Figure 3). Minimum values, in the range $0.7-0.8$, were observed in July and September, while values larger than 1 were found in August and towards the final and earlier months of the year. A progressive trend in $Z$ values was observed in between these two periods.

The period August - October shows the greatest stability of effort by the industrial fleet of trawlers operating in the region (Figure 4). It is preceded and followed by two months of reduced activity, corresponding to partial closures imposed by the Venezuelan Government to reduce the general

trawlers fishing effort, 15 June - 15 July and 15 December - 15 January. During the Easter period in April there is a self-imposed absolute closure by crewmembers, resulting in an appreciable reduction in the effort level. Effort increases above mean values preceding the partial closure periods in June and November. No significant correlation was found between changes in the fishing mortality and the fishing effort ( $r=0.34, P>0.05$ ).

The estimated number of $P$. schmitti at sea showed wide fluctuations during the year, with a declining trend during the period July to October, changing to an increasing trend towards November - February (Figure 5). A similar trend is observed in the variation of total biomass during the year (Figure 6). The greatest amount of animals at sea, as well as the greatest biomass, occurs during the period July September.

The biomass of recruits shows two periods of greater abundance, July - September, and Dec. - Feb (Figure 7). However, when the proportion of recruits in the population structure is considered, a slow but increasing trend from $14 \%$ in July to a peak $30 \%$ in January is observed (Figure 3). The minimum
biomass of recruits is reached during the month of October. Parental stock biomass is less variable, showing the largest values towards mid year, with a progressive decline until January after which it shows a progressive increase (Figure 8).

There is a strong correlation $(\mathrm{r}=0.83, \mathrm{P}<0.025)$ between the fishing mortality values and the proportion of recruits in the population (Figure 3).

Table 8: Estimated biomass ( t ) of Penaeus schmitti in the study region, by size categories (mean total length), calculated from the N at sea (Table 6) and the common equation Weight ( g ) $=1.21 * 10^{-6}$ *
$\mathrm{TL}(\mathrm{mm})^{3.38}$ (after Marcano et al., 1997, Table 11). Recruits are considered animals smaller than 110 mm TL. Parental stock is assumed formed by animals larger than 150 mm TL

## 5. DISCUSSION

Large fluctuations in monthly total mortality values were observed, amounting to a $200 \%$ variation between the smallest value in September and the largest in February. They could not be correlated to actual variation in fishing effort, but there is a significant positive correlation with the proportion of recruits in the population. It seems that the impact of the fishing gear on the population is greater when there are proportionally more juveniles in the field.

It seems that the recuperation in the shrimp density towards the end of the year is related to a progressive incorporation of recruits to the fishing grounds.

The estimated changes in the biomass of the stock of $P$. schmitti in the region indicate that the period July - October would represent the time of the year where the largest biomass of the parental stock is observed, thus becoming a time of increased potential reproduction. This phenomenon is possibly associated with the fact that 6 months afterwards, towards the beginning of the following year, there is an observable increase in the amount of recruits in the fishing ground. The results of Alió et al. (1990), reporting two periods of greater density of postlarvae of $P$. schmitti in the area (Feb.-March and JulySept.) support this reproductive trend.

The shrimp fisheries in Venezuela have two 1-month closed seasons in the year, as a measure to reduce the trawl effort nation wide. The choosing of the current periods was not necessarily based on biological, but on practical reasons; since the fleet normally stops operating during Christmas time, the setting of a mid year closed season seemed reasonable. Nevertheless, the timing of the seasons could be changed to include periods when the largest amount of recruits is found in the fishing grounds, thus allowing for an increase in the size of the animals and the value of the catch. From the analyses performed herein it appears that the current closed seasons coincide with moments of greater abundance of juveniles in the fishing grounds, so their maintenance is supported. Furthermore, considering that a large number of recruits is still present during February, it is recommended that if the closed season were to be extended, it be done to include February in the current late year season. These recommendations necessarily require a reevaluation when a more complete data base is obtained, which should include information on the exploited population structure during March to June.

Samples of shrimp processed for this study not only did not include the entire year, but sample sizes for some months (July, Sept., and Oct. 96) were very small, so the results obtained for these periods in the present report can only be considered as preliminary. In fact, both the linearized catch curve and length cohort analyses seem to be sensitive to the amount of information on which they are based. It can be observed that abundance of shrimp during the year (Figure 5) shows wider fluctuations during the months when sample sizes are smaller. In spite of these limitations, the working group considered that current limitations could be overcome and it is important to adopt VPA stock assessment algorithms to frame data gathering and more extensive future assessments following similar methods.

As a consequence of the preparation of the information for this workshop, it was found that many industries save the information related to the amount of shrimps processed every month and the resulting number of boxes by commercial category. This valuable information had not been provided to the government, but it is now being requested from the processing plants in order to allow for further population studies of the different penaeid shrimp species in the country.
