# JOINT FAO/WHO FOOD STANDARDS PROGRAMME CODEX COMMITTEE ON PESTICIDE RESIDUES 

$51^{\text {st }}$ Session<br>Macao SAR, P.R. China, 8-13 April 2019<br>ACUTE PROBABILISTIC DIETARY EXPOSURE ASSESSMENT FOR PESTICIDES<br>(Prepared by WHO)

## Introduction

This item should be read in conjunction with Agenda Item 9.

## 1. Background

Some pesticide residues could give rise to acute health effects in relation to short periods of intake and the Joint FAO/WHO Meetings on Pesticide Residues (JMPR) now routinely considers the need to set an acute reference dose (ARfD) for all pesticides it evaluates. In order to characterize the risk for those chemicals for which an ARfD is established, an acute dietary exposure assessment may be performed using deterministic or probabilistic methodologies. At an international level, a deterministic exposure model was developed and implemented by JMPR: The International Estimated Short Term Intake (IESTI). This model, as any model undertaken by international committees, should provide exposure estimates that are conservative and cover all available individual national dietary exposure estimates ${ }^{1}$. Moreover, the risk assessment methodologies should be regularly updated to account for new knowledge and therefore, in 2017, FAO and WHO, following a recommendation of the JMPR, decided to review the IESTI equation. In order to have a realistic reference to compare the various IESTI models, WHO, with the support from Australia, performed a probabilistic exposure assessment based on the best available data for pesticide occurrence and food consumption.
Many countries are regularly monitoring pesticide residues in food. Similarly, national food consumption data recording individual consumptions per day or by eating occasion are available in many countries. WHO collected the 2 kinds of data and hired a consultant to combine them in a probabilistic model. Data description is shown in Annex 1.
The goal of the assessment is to estimates consumer's exposure as well as the probability for exceeding the ARfD established by the JMPR for 47 pesticide active substances in food.
Moreover, the Codex Committee on Pesticide Residues (CCPR) stated that food containing residues at the level of the adopted Codex MRL (CXL) must be safe for the consumers (CX/PR 05/37/4). In other words, the acute exposure resulting of the IESTI equation is implicitly used by risk managers to achieve a level of protection (LoP) for individuals eating a particular commodity with residues at the level of the MRL. According to its definition [European Food Safety Authority - EFSA, 2007] the 'level of protection' of MRL is the percentage of person-days with intakes at or below the Acute Reference Dose when the residue occurs at the level of the MRL. We estimated this LoP for the CXLs established for the 47 pesticides under consideration.

## 2. Methodology

a. Consumer exposure and probability to exceed the ARfDs

A probabilistic model was developed to estimate acute exposures, combining results from national food consumption surveys with reported concentration distribution of pesticide residues from official monitoring programs. The probabilistic model was used each time for 2 scenarios regarding the level of usage (10 and $100 \%$ ) and for 2 populations (children and adults). The potential risk posed by each pesticide was estimated by the proportion of individuals with estimated exposures exceeding the relevant ARfD. We also identified the major contributors to the exposure and the percentage of the ARfD reached by them. The approach was applied to data from 8 countries ${ }^{2}$. Data available for the different countries were prepared and gathered in a database. The nomenclatures of the different datasets per country were mapped to make their combination possible. The methodology is detailed in Annex 2.

[^0]b. Level of protection of MRLs

To assess the LoP we used the same food consumption data than those used to estimate the risk for consumers but combined for each food and each pesticide with the corresponding CXL. We calculated the empirical probability of exceeding the ARfD by the number of individuals with exposure higher than the ARfD divided by the total number of individuals.

## 3. Results

a. Estimation of exposure and probability to exceed the ARfD

The exposure levels expressed in $\mu \mathrm{g} / \mathrm{kg}$ of body weight/day to the different pesticides per country were compared to the respective ARfD. For the majority of pesticides and for both populations and usage scenarios, the exposures between countries were in the same range of values. The exposure to cyfluthrin and beta-cyflythrin, cypermethrin, dichlorvos, imidachloprid, fenpropathrin, phosmet and prothioconazole were higher for the US whatever the studied population and applied usage scenario.
As expected, the scenario using $100 \%$ usage lead to higher exposure than the one using $10 \%$. The difference could be 10 times higher for the mean but less for the other percentiles. Except for USA, the median exposure using 10\% usage scenario equaled zero for all pesticides and for the different population.
For the two usage scenarios and the adult population, the P99 exposure was below $1 \%$ of the ARfD for the majority of pesticides. For the carbofuran, the cyfluthrin and beta cyflythrin, the cypermethrin, the phorate and the prothioconazole, the P99 exposure could reach between 5 and 10\% of the ARfD with the 100\% usage scenario and maximum 4\% of the ARfD with the 10\% usage scenario.
For children population, the P99 exposure to a majority of pesticides was below $5 \%$ of the ARfD with the $100 \%$ usage scenario and $3 \%$ with the $10 \%$ usage scenario. For the carbofuran, the cyfluthrin and beta cyflythrin, the cypermethrin, the fenpropathrin, the phorate and the prothioconazole, the P99 exposure could reach between 20 to $40 \%$ of the ARfD with the $100 \%$ usage scenario and between 12 to $20 \%$ with the $10 \%$ usage scenario.

The food which contributed the most to the exposure to each pesticide regarding the number of runs and \% of exposure were displayed in table 13 for the adults and 14 for the children for both usage scenarios. There is a high variability on main food contributors which are different between pesticides, countries and usage scenarios, except for Italia where cattle milk is prevalent. There is lower difference between the adult and children scenarios, for which similar main food contributors were found.
Whatever the usage scenario applied ( $10 \%$ or $100 \%$ ) and the studied population (adult or children), the probability for dietary exposure to exceed the ARfD was null for the all pesticides and all countries. Results are detailed in Annex 4.

## b. Estimation of the Level of Protection of the MRLs

For 30 pesticides over 47, the LoP is $100 \%$ meaning that assuming that residues in food are at the level of Codex MRL the probability for exceeding the ARfD considering actual consumption is null for all populations in all countries.

For 10 of the remaining pesticides, the probability to exceed the ARfD is lower than $1 \%$ in at least 1 country and for at least 1 population meaning than the LoP is higher than $99 \%$. It should be noted that 9 over these 10 results are related to children in the USA (Annex 5, table 15).

For 5 of the remaining pesticides, the probability to exceed the ARfD if residues in food are at MRL level is up to $10 \%$ in at least one country meaning than the LoP is higher than $90 \%$.

Finally, for 2 pesticides (carbofuran and phosmet) the LoP is below $90 \%$ with a minimum value below $20 \%$ for children in France. It can be noted that for carbofuran more than $90 \%$ of the contribution is related to the MRL in orange. For phosmet the main contributor is the MRL for apple. Results for pesticides MRLs with LoP below 100\% are summarized in Annex 5.

## 4. Conclusions

The IESTI equation is used as a proxy for estimating the acute dietary exposure at international level. According to the principles for international dietary exposure assessment, the international exposure models should be conservative in order to ensure that actual exposure of consumers in each country is lower than the international estimate and therefore that there is no appreciable risk for the population worldwide. The results of the probabilistic assessment do confirm the conservativeness of the model when compared with national assessments based on accurate data and the absence of appreciable risk for the population.

We noted differences on exposure levels between countries and many of them can be explained by differences in data submitted: Higher exposures among countries can be explained by the difference between the number of food items, the inclusion or not of process food. The higher is the number of food items included in the survey, the higher is the exposure. This is the case of US and Canada, which have more than 100 food items considered. In the opposite, for European data, the processing food were not considered at this stage which could lead to lower exposure. For Italy which also has the lowest number of food items, the exposure was often lower than the other and a low variability on the main food contributor was observed. Despite of these differences the results are very consistent across countries.
The risk assessment of pesticide residues in food is one of the key function of the JMPR. The assessments performed for 8 countries are consistent and robust and the overall exercise confirms that the methodology used by the Meeting to assess the acute risk, including the IESTI equation, is an appropriate model for consumer protection.
The establishment of an appropriate Level of Protection for pesticide MRLs is in the remit of the CCPR as a tool for risk management and risk communication. The scenario used to estimate the LoPs (all pesticide residues occurring at MRL level) are not corresponding to actual exposure of the population. Results demonstrate that the CXLs are providing a high Level of Protection for a vast majority of MRLs. However, as no specific Level of Protection is used explicitly by the CCPR to establish MRLs, it is not surprising to observe a significant variability in the LoPs mainly related to certain pesticides and to a lower degree to certain food commodities.

## Annex 1 - Methodology

## 1. Data mapping

The general framework used to match the data available for each country follows the different steps outlined below:

1- Selection of pesticide residue levels from the monitoring programs and food items with a Codex MRL
The first step is to select the residue levels of the 47 pesticides and the 214 food items for which a Codex MRL has been set for these pesticides. For this purpose, the pesticide residue concentrations of monitoring programs for the relevant country were combined with the Codex MRL dataset. They were combined per food item (entire Codex code) and food group (letters of the Codex code) to capture all monitored foods with MRLs.

## 2- Conversion of foods "as eaten" to raw commodity ingredients

The recipe table was used to convert dietary survey records of foods "as eaten" into the corresponding consumed weights of their raw commodity ingredients which could then be matched with pesticide residue levels and food items/groups used in the Codex MRL standard. Each food "as eaten" consumed quantity was multiplied by the proportion of each of the different raw commodity ingredients comprised in the food "as eaten" to determine the consumed amount of each raw commodity ingredient by each individual.

3- Selection of food consumption data for which pesticide residue levels and food items with a Codex MRL exist

To match raw commodity ingredients to Codex MRL food group codes, a nomenclature table was used. If this table was not available or required modifications, it was decided to construct or recode it. For each Codex code with monitoring data, it was determined whether it could be matched with a raw commodity ingredient coming from the consumption survey. As monitoring data are rather limited for processed products ("dried, paste, juiced, puree"), it was decided to also link Codex codes to processed products. For example, the Codex food "tomato" was linked to raw entire "tomato", "tomato baby-food" and "dried, paste, juiced, puree" tomato. Unspecified products, such as "fruit juice", were not considered.
Thereafter, the table with Codex codes per consumed raw commodity ingredient at individual level was combined with the pesticide residue level dataset defined in step 1 using the methodology described in section 3.

4- Combining food consumption and socio-demographic data
The table of consumed raw commodity ingredients with their corresponding Codex codes was combined with the socio-demographic data from each national data set to link individual food consumption records to that individual's gender, age and body weight.

## 2. Probabilistic model

The acute exposure was estimated per geographical area (Canada, USA, Brazil, Australia and Europe) and separately for adults ( $\geq 16$ years old) and children ( $\leq 6$ years old). Pesticide residue monitoring data and results from national food consumption surveys were combined within the same geographical area. Calculations were implemented with the R software ( R Core Team, 2017).

## Usage scenarios

A high source of uncertainty comes from censored data. In case of censored data, the true value of pesticide residue level is unknown and it is not possible to distinguish censored data from true zeros. To account for a part of this uncertainty, two usage scenarios were tested: $100 \%$ and $10 \%$ of usage (i.e. $0 \%$ and $90 \%$ of true zeros). For both scenarios, the censored values were set at the value of the limit of detection (LOD) or quantification (LOQ).

## Acute dietary exposure assessment

A probabilistic approach was used to estimate individual's acute dietary exposure, i.e. the exposure during 24 hours, to the different pesticide residues. For that, one individual and one day of consumption for this individual were randomly selected. The individual daily consumption of a raw commodity ingredient denoted $c_{i, a}$ was then calculated by the sum of all the quantities of commodity a consumed by the individual $i$ during the selected day. For each commodity a treated with the pesticide $p$, the daily consumption $c_{i, a}$ was multiplied by a residue level $q_{p, a}$ randomly selected from the residue monitoring dataset and adjusted by the body weight $w_{i}$ of the consumer $i$. Then, the estimated exposures calculated for each commodity were summed to obtain a total daily exposure in milligrams of the pesticide $p$ per kilogram of body weight of the consumer $i$ per day ( $\mathrm{mg} / \mathrm{kg} \mathrm{bw} / \mathrm{d}$ ).

A sample of 10000 individual daily exposures was thus created to account for consumption and residue level variability. Descriptive statistics of exposures were given for consumers only i.e. the individuals who consumed foods which can contain the pesticide. The relative contribution of each food to total acute dietary exposure for each pesticide residue is estimated for each individual by dividing the exposure per food by the total acute exposure for the residue. This process was repeated several times to account for uncertainty (see next paragraph on modelling uncertainty).

## Hypothesis related to variation in residues

Two sources of variability could exist for contamination in residue: between lot and between sample variability (EFSA, 2012). The between lot variability is due to the fact that contamination between lots may be different and a consumed portion can be derived from several lots. For that, it is proposed by EFSA to multiply a part of the consumed portion by a variability factor of 3 . In this work, the whole consumed quantity was considered to be contaminated at the same value. Indeed, in our case of a high number of censored data the higher probability for the contamination of the second lot is to select a censored value. So considering that the consumed portion is contaminated at the residue level is a conservative assumption.
The between sample variability is due to the fact that the residues data available for use in dietary exposure assessment could be related to composite samples, and not to individual units of commodity. Therefore, the measured values represent the average of a number of units and do not reflect the full range of variation occurring in individual units which are consumed by people. The sample variability is generally accounted for by using a probabilistic approach that selected a concentration level at random from the reported distribution of residue level measurements for that commodity. For US data, these results were compared to the ones based on a selection of US concentration levels in a Lognormal distribution of mean the measured residue level and of variance parametrized such as the P97.5 th value equals to 3 times the mean. No significant impact on exposure and risk was observed and thus no between sample variability was included in the whole analyses.

## Hypothesis related to processing

Following IESTI method used by the JMPR, diet correction factors (DCFs) corresponding to default dilution or concentration factors were used on the residues to avoid under- or overestimation of dietary exposure. As did in the IESTI method, in case the processed food is a fraction of the raw commodity ingredient (e.g. juice, oil, bran, and flour) no DCFs were used. The impact on exposure using DCFs or not was tested on US data and resulted in higher exposure when using DFCs. Thus, DCFs were used in the whole analyses.

## Risk assessment

For each individual, the estimated total dietary acute exposure per pesticide from all foods consumed that could contain the residue was compared to the ARfD established by the JMPR. The potential risk for the population per geographical area was taken to be the proportion of the population of interest with an estimated acute dietary exposure above the ARfD (i.e. number of individuals exposed above the ARfD divided by the total number of individuals (10000). The risk for consumers only was also calculated by dividing the number of individuals with an estimated acute dietary exposure above the ARfD by the number of individuals who reported consuming foods assumed to contain the pesticide.

## Modelling uncertainty due to the limited size of residue and food consumption datasets

In order to produce uncertainty intervals showing the uncertainty related to survey datasets and methodology that have been quantified, a two-dimensional Monte Carlo (2D MC) procedure was used. After testing the stability, 100 runs composed of 10000 individuals were simulated. The multiple output distributions generated by the multiple runs were then used to calculate the estimate and uncertainty intervals of different statistics of the acute dietary exposure. For each run the statistics (mean and percentiles) were calculated. Then the estimate was calculated from the median and the uncertainty intervals from the $2.5^{\text {th }}$ and $97.5^{\text {th }}$ percentiles of the 100 statistics. This procedure also accounts for the uncertainty due to the random sampling of one day of consumption.

Annex 2 - Data description (summary)

Table 1: Description of the national residues survey in food after matching with CXLs

| Country | National residue survey data after matching with CXLs |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Years | Number of pesticides | Number of foods | Number of combinations (pest/food) | Number of measurements | \% total measurements $\geq$ LOD** $^{*}$ | \% total measurements $\geq$ LOQ** $^{*}$ | \% total measurements $\geq$ MRL | \% non-censored measurements $\geq$ MRL |
| Australia | 2011-2017 | 18 | 20* | 78 | 235298 | - | 2.97\% | 0.018\% | 0.6\% |
| Brazil | 2010-2015 | 20 | 23 | 190 | 150154 | 3.08\% | 3.08\% | 0.14\% | 4.54\% |
| Canada | 2008-2017 | 38 | 162 | 1698 | 590550 | 2.79\% | 2.33\% | 0.02\% | 0.66\% |
| Europe 30 countries | 2015 | 39 | 150 | 1503 | 689719 | - | 2.25\% | 0.02\% | 0.94\% |
| USA | 2010-2015 | 34 | 48 | 513 | 430273 | 3.68\% | 3.35\% | 0.03\% | 0.85\% |

*Restrained to grain and fruit products
${ }^{* *}$ The LOQ is always higher than the LOD, thus the proportion of measurements higher than the LOD also contains measurements higher than the LOQ.
