USE OF JMPR REPORTS AND EVALUATIONS BY REGISTRATION AUTHORITIES

Most of the summaries and evaluations contained in this report are based on unpublished proprietary data submitted for use by JMPR in making its assessments. A registration authority should not grant a registration on the basis of an evaluation unless it has first received authorization for such use from the owner of the data submitted for the JMPR review or has received the data on which the summaries are based, either from the owner of the data or from a second party that has obtained permission from the owner of the data for this purpose.

INTRODUCTION

A Joint Meeting of the Food and Agriculture Organization of the United Nations (FAO) Panel of Experts on Pesticide Residues in Food and the Environment and the World Health Organization (WHO) Core Assessment Group on Pesticide Residues (JMPR) was held at FAO Headquarters, Rome (Italy), from 16 to 25 September 2014. The FAO Panel Members met in preparatory sessions on 11–15 September.

The Meeting was opened by Dr Clayton Campanhola, Director, Plant Production and Protection Division, FAO. On behalf of FAO and WHO, Dr Campanhola welcomed and thanked the participants for providing their expertise and for the significant time and effort devoted to such an important activity. He also expressed his sincere gratitude to the respective national authorities, institutes and organizations that have allowed their experts to contribute to the important work of the JMPR.

Dr Campanhola said that as the scientific advisory body for the Codex Committee on Pesticide Residues, the JMPR plays a central role in the establishment of global pesticide residue standards. For more than 50 years, the JMPR has been operating with two main objectives: firstly, risk assessment of pesticide residues and secondly scientific advice on the acceptable levels of pesticide residues in food and feed. Dr Campanhola further acknowledged that the deliberations of the JMPR were recognized as being authoritative, technically sound and provided an invaluable contribution to the collective efforts to provide safe food for consumers and to facilitate international trade. The growing demand for safe food and that agricultural production be sustainable underline now more than ever the continued relevance of the objectives underlying the work of the JMPR.

Given the FAO's goal of eradicating hunger Dr Campanhola observed that this could not be achieved without having safe food in the hands of consumers. And that it was essential that fair practices existed in food trade allowing all producers equitable access to markets. Consequently, the work of JMPR makes an important contribution to the global fight against hunger.

Dr Campanhola also acknowledged that the demand for JMPR evaluations, in support of Codex Maximum Residue Limits, reflected the importance accorded by member countries to the scientific assessments undertaken by the JMPR, and the growth in the international trade in agricultural products. Finally, Dr Campanhola addressed his best wishes to the Meeting on behalf of the two parent organizations.

During the meeting, the FAO Panel of Experts was responsible for reviewing residue and analytical aspects of the pesticides under consideration, including data on their metabolism, fate in the environment and use patterns, and for estimating the maximum levels of residues that might occur as a result of use of the pesticides according to good agricultural practice (GAP). Maximum residue levels and supervised trials median residue (STMR) values were estimated for commodities of animal origin. The WHO Core Assessment Group was responsible for reviewing toxicological and related data in order to establish acceptable daily intakes (ADIs) and acute reference doses (ARfDs), where necessary.

The Meeting evaluated 33 pesticides, including eight new compounds and three compounds that were re-evaluated within the periodic review programme of the Codex Committee on Pesticide Residues (CCPR), for toxicity or residues, or both.

The Meeting allocated ADIs and ARfDs, estimated maximum residue levels and recommended them for use by CCPR, and estimated STMR and highest residue (HR) levels as a basis for estimating dietary intake.

The Meeting also estimated the dietary intakes (both short-term and long-term) of the pesticides reviewed and, on this basis, performed dietary risk assessments in relation to their ADIs or ARfDs. Cases in which ADIs or ARfDs may be exceeded were clearly indicated in order to facilitate the decision-making process of CCPR. The rationale for methodologies for long- and short-term dietary risk assessment are described in detail in the FAO manual on the submission and evaluation of pesticide residue data for the estimation of maximum residue levels in food and feed (2009).

The Meeting considered a number of current issues related to the risk assessment of chemicals, the evaluation of pesticide residues and the procedures used to recommend maximum residue levels.

AMINOCYCLOPYRACHLOR (272)

The first draft was prepared by Dr Dugald MacLachlan Australian Government Department of Agriculture, Fisheries and Forestry, Australia

EXPLANATION

Aminocyclopyrachlor is a new pyrimidine carboxylic acid herbicide used for the control of broadleaf weeds and woody vegetation. Aminocyclopyrachlor mimics the naturally occurring phytohormone indole acetic acid (auxin) disrupting plant growth. At the 45th Session of the CCPR (2013), it was scheduled for the evaluation as a new compound by 2014 JMPR.

The Meeting received information on the metabolism of aminocyclopyrachlor and also its methyl ester (aminocyclopyrachlor-methyl DPX-KJM44) in lactating goats and grass, methods of residue analysis, freezer storage stability, GAP information, supervised residue trials, and a cattle feeding study.

IDENTITY

Common name	Aminocyclopyrachlor
Chemical name	
IUPAC:	6-amino-5-chloro-2-cyclopropylpyrimidine-4-carboxylic acid
CAS:	6-Amino-5-chloro-2-cyclopropyl-4-pyrimidinecarboxylic acid
Manufacturer's code numbers:	DPX-MAT28
CAS number:	858956-08-8
CIPAC Code:	
Molecular formula:	C ₈ H ₈ ClN ₃ O ₂
Molecular mass:	213.62 g/mole
Structural formula:	

Formulations	Active ingredient content
SG	50% aminocyclopyrachlor
WG	39.5% aminocyclopyrachlor, 12.6% metsulfuron methyl
WG	35.3% aminocyclopyrachlor, 17.6% metsulfuron methyl

PHYSICAL AND CHEMICAL PROPERTIES*Specifications*

Specifications for aminocyclopyrachlor have not been developed by FAO.

Physical and chemical properties (pure aminocyclopyrachlor 99.7%)

Property	Results (method)	Reference
Appearance	Pure aminocyclopyrachlor is a white solid with a mild fruity odour	Shalini 2007 23196
Melting point	140.5 ± 0.1 °C	Shalini 2007 23196

Hydrolysis	Stable at pH 4, 7 and 9 and at 25 °C	Manjunatha 2008 22116
Photolysis	Half-life: 7.3 days at pH 4, 25 °C and 1.3 days in sterile natural spring water	Lowrie 2008 22117 rev 1
Quantum yield	Φ = 2.5521 × 10 ⁻⁴ molecules degraded/photon	Lowrie 2008 22117 rev. 1
Dissociation constant	pK _a 4.65 ± 0.04 at 20 ± 1 °C	Anand 2011a 22555 rev 1
Stability	Aminocyclopyrachlor was tested for stability at normal (ambient) and elevated (54 ± 2 °C) temperatures and in the presence of metal and metal ions for a period of 14 days. The results of the test show that the aminocyclopyrachlor is stable to normal and elevated temperatures and metal and metal ions	Yogeesha 2011 22539 rev 1

Technical grade material (aminocyclopyrachlor 92.2%)

Property	Results (method)	Reference
Melting point	138.9 ± 0.1 °C	Anand 2011b 22551 rev 1
Density at 20 °C	1.3476 ± 0.0813 g/mL	Anand 2011b 22551 rev 1

METABOLISM AND ENVIRONMENTAL FATE

Metabolites are given various abbreviations and code numbers in the studies. Structures and abbreviations and codes are shown below.

Degradation compounds from metabolism of aminocyclopyrachlor in plants, animals, soil, or water

Compound Name	Structure	Found in:
Aminocyclopyrachlor 6-Amino-5-chloro-2-cyclopropyl-4-pyrimidinecarboxylic acid CAS Number: 858956-08-8 DPX-MAT28 MW 213.62		grass, goat, rotational crops, soil

Compound Name	Structure	Found in:
Aminocyclopyrachlor-methyl Methyl 6-amino-5-chloro-2-cyclopropyl-4-pyrimidinecarboxylate CAS Number: 858954-83-3 DPX-KJM44, DPX-MAT28 methyl ester MW 227.65		
5-Chloro-2-cyclopropyl-pyrimidin-4-ylamine IN-LXT69 MW 169.61		Grass, goat, photolysis, rotational crops, soil
5-Cyano-2-cyclopropyl-3H-imidazole-4-carboxylic acid methyl ester IN-QGC48 MW 191.19		grass
5-Cyano-2-cyclopropyl-3H-imidazole-4-carboxylic acid IN-QFH57 MW 177.16		Photolysis, grass Structural formulae changed
Cyclopropane carbamidine IN-YY905		Photolysis
Cyclopropane carboxylic acid CAS NO.: 1759-53-1 IN-V0977		Photolysis, grass
Cyclopropane carboxamide CAS No.: 6228-73-5 IN-Q3007		Photolysis, grass

Animal metabolism

The Meeting received studies on the metabolism of DPX-KJM44 (aminocyclopyrachlor-methyl) in rats and lactating goats. The metabolism of aminocyclopyrachlor in animals was investigated using [^{14}C]-DPX-KJM44 while in plants studies were available for metabolism of [^{14}C]aminocyclopyrachlor and [^{14}C]-DPX-KJM44. The structural formula and the positions of the ^{14}C label are shown below. The studies on rats were evaluated by the WHO Core Assessment Group.

[pyrimidine-2- ^{14}C]aminocyclopyrachlor

[pyrimidine-2- ^{14}C]DPX-KJM44

Figure 1 Label positions of aminocyclopyrachlor and DPX-KJM44: marked as *

The identification of residue components in the animal and plant metabolism studies was achieved using authentic standards of the compounds involved.

Laboratory animal (rat) studies

Metabolism of aminocyclopyrachlor-methyl (DPX-KJM44) in rats was evaluated by the WHO Core Assessment Group of the 2014 JMPR. The metabolic conversion of DPX-KJM44 to aminocyclopyrachlor by plasma esterases is rapid (*in vitro* plasma $t_{1/2}$ approximately 5 minutes). As a result, administration of DPX-KJM44 to animal models will result in systemic exposures to primarily aminocyclopyrachlor. Both aminocyclopyrachlor and DPX-KJM44 have comparable pharmacokinetic profiles. Each is rapidly absorbed, and rapidly and essentially completely eliminated. For both substances the terminal compound in laboratory animals is aminocyclopyrachlor.

Lactating goat

Melville and Vance (2009 22837) studied the metabolism of DPX-KMJ44 in a lactating goat (British Saanen $\times$, 51.3 kg bw; 2.0 kg milk/d) that was dosed orally via gelatin capsule twice daily with ring labelled [^{14}C] DPX-KMJ44 for 5 consecutive days at the equivalent of 97 ppm in the feed (feed consumption 1.45–1.73 kg DM/d). Doses were administered following milking (ca. 8:00 and 20:00 hours). Milk was collected twice daily and urine and faeces were collected daily. The goat was sacrificed approximately 6 h after the administration of the final dose and tissues taken post-mortem for quantification and analysis of radioactivity.

Composite liver, kidney, muscle, and fat samples were ground to a powder in dry ice and initially extracted with buffered acetonitrile:water (9:1, v/v). The extracted liver and kidney samples were digested with pepsin and protease to liberate additional ^{14}C -residues. Milk samples were initially partitioned with hexane and subsequently extracted with acetone. Aliquots of the extracts were analysed using liquid scintillation counting (LSC) while the post-extraction solids were dried under nitrogen, and triplicate portions were analysed using combustion and LSC.

Radioactive residues in the various extracts from each matrix were analysed by HPLC, using a C_{18} column with a mobile phase gradient of 10 mM ammonium formate and methanol. Radioactive residues were quantified by LSC analysis of the collected HPLC fractions. Radiolabelled components identified by HPLC and/or TLC co-chromatography with authentic unlabelled reference standards were later confirmed in selected samples using mass spectrometry.

All samples were extracted and analysed within 8 months of frozen storage. Reanalysis of liver and kidney extracts, stored for 11 months, showed no significant changes in the metabolite profile indicating metabolites in the extracts were stable to frozen storage.

The total recovery of dosed radioactivity was 85% with the majority of the radioactivity excreted in urine (54%) and faeces (20%). Approximately 8% remained in the contents of the gastrointestinal tract and a further 3.1% was found in the cage wash.

TRR in milk samples increased during the dosing period and reached a maximum of 0.031 mg equiv/kg in the milk collected at Day 5 of the study. Acetone extractions recovered ca. 80.5% of the total milk [^{14}C] residues. Aminocyclopyrachlor accounted for 15.9% TRR (0.004 mg equiv/kg). Other milk components accounting for 0.002 to 0.007 mg equiv/kg were not identified. Composite sample of milk from days 1 to 5 was separated into skim milk and cream with the majority of ^{14}C located in the cream fraction (0.016 mg equiv/kg skim milk, 0.12 mg equiv/kg cream). Residues in skim milk and cream were too low for identification.

Radioactive residues in tissues ranged from 0.01 mg equiv/kg in the omental fat to 1.67 mg equiv/kg in the kidneys. Good extractability was achieved for the milk and tissue samples with greater than 80% TRR recovered in solvent extracts (except omental fat = 47.4%). Residues remaining after solvent extraction of liver and kidney were subject to sequential treatment with pepsin and protease enzymes liberating an additional 1 to 11.6% of the TRR.

The identified metabolites in the tissue and milk samples are summarised in Table 1.

Table 1 Identification of radioactivity in tissue and milk of goats dosed orally with DPX-KJM44

Matrix	Milk ^a	Liver	Kidney	Muscle	Renal Fat	Omental fat	SC fat
TRR (mg equiv/kg)	0.023	0.30	1.67	0.042	0.016	0.010	0.026
			%TRR				
Solvent extracted	80.5	86.7	98.3	87.5	83.8	47.4	80.7
Aminocyclopyrachlor	15.9	55.6 ^b	55.3 ^c	43.3	83.8	47.4	80.7
unknowns	64.6 ^d	ND	ND	32.7 ^e	ND	–	–
Pepsin/protease digest	NC	11.6	1.0	NC	NC	NC	NC
Aminocyclopyrachlor		10.1	NA				
Unextracted	19.5	1.7	0.7	12.5	16.2	52.6	19.3
Losses during processing	–	29.3 ^f	43.0 ^f	11.5	–	–	–

^a composite day 1–5 d sample

^b Total characterised as aminocyclopyrachlor by TLC (concentrated extract prior to SPE clean-up) was 87.5% TRR (0.26 mg equiv/kg); confirming aminocyclopyrachlor as the only component present

^c Total characterised as aminocyclopyrachlor by TLC (concentrated extract prior to SPE clean-up) was 93.2% TRR (1.56 mg equiv/kg); confirming aminocyclopyrachlor as the only component present

^d Three components ranging from 0.002–0.007 mg equiv/kg

^e Two components ranging from 0.006–0.008 mg equiv/kg

^f Concentrated muscle and liver solvent extracts required SPE clean-up prior to HPLC analysis; efforts to improve low recoveries following SPE clean-up were unsuccessful.

ND = Not detected

NC = Not conducted

NA = Not analysed

Solvent extraction of liver recovered 86.7% TRR (0.259 mg equiv/kg). The concentrated solvent extract was subjected to SPE clean-up which resulted in losses such that the concentrated cleaned extract accounted for 57.4% TRR. Pepsin and protease digestion of the liver PES liberated a further 11.6% TRR (0.034 mg equiv/kg). Unextracted liver residues were 1.7%TRR (0.006 mg equiv/kg).

Aminocyclopyrachlor was the major extractable component in liver accounting for 55.6% TRR (0.167 mg equiv/kg) in the SPE cleaned solvent extract by HPLC. Aminocyclopyrachlor was the only component observed by TLC analysis of the concentrated extract prior to SPE clean-up accounting for 87.5% TRR (0.262 mg equiv/kg). A single radiolabelled component was detected in the pepsin digest which co-chromatographed with aminocyclopyrachlor and accounted for 10.1% TRR (0.030 mg equiv/kg).

Total liver residues characterised as aminocyclopyrachlor by a combination of TLC (concentrated extract prior to SPE clean-up) and HPLC of the pepsin digest was 97.6% TRR (0.292 mg equiv/kg).

Solvent extraction of kidney recovered 98.3% TRR (1.64 mg equiv/kg). The concentrated solvent extract was subjected to SPE clean-up which resulted in losses such that the concentrated cleaned extract accounted for 55.3% TRR. Pepsin and protease digestion of the kidney PES only liberated an additional 1.0% TRR (0.017 mg equiv/kg) and were not analysed further. Unextracted kidney residues were 0.7% TRR (0.011 mg equiv/kg). Aminocyclopyrachlor was the major extractable component in kidney accounting for 55.3% TRR (0.925 mg equiv/kg) in the SPE cleaned solvent extract by HPLC. Aminocyclopyrachlor was the only component observed by TLC analysis of the concentrated extract prior to SPE clean-up accounting for 93.2% TRR (1.560 mg equiv/kg). Total kidney residues characterised as aminocyclopyrachlor by TLC (concentrated extract prior to SPE clean-up) was 93.2% TRR (1.56 mg equiv/kg).

Solvent extraction of muscle recovered 87.5% TRR (0.037 mg equiv/kg). The HPLC profile of the concentrated muscle extract showed that aminocyclopyrachlor was the major component accounting for 43.3% TRR (0.018 mg equiv/kg). Two minor components accounted for 14.4% TRR (0.006 mg equiv/kg) and 18.3% TRR (0.008 mg equiv/kg) were not identified. Unextracted muscle residues were 12.5% TRR (0.005 mg equiv/kg).

Solvent extraction of the three fat samples ranged from 47.4–83.8% TRR with lower extractability in omental fat. The HPLC profile of the renal, omental, and subcutaneous fat extracts showed that aminocyclopyrachlor was the major extractable component accounting for 83.8% TRR (0.013 mg equiv/kg), 47.4% TRR (0.005 mg equiv/kg), and 80.7% TRR (0.021 mg equiv/kg), respectively. Unextracted fat residues were ≤ 0.005 mg equiv/kg.

In summary, DPX-KJM44 was rapidly metabolised and eliminated as aminocyclopyrachlor, primarily in the excreta (74% of the administered total dose). Identified residues in tissues were exclusively aminocyclopyrachlor. A proposed metabolic pathway for DPX-KJM44 in the lactating goat is presented in Figure 2.

Figure 2 Metabolism of DPX-KJM44 and aminocyclopyrachlor (DPX-MAT28) in lactating goats

Plant metabolism

The Meeting received plant metabolism studies with DPX-KJM44 on grass, aminocyclopyrachlor on grass and DPX-KJM44 and aminocyclopyrachlor on a variety of weeds. When applied to plants, the methyl esters of aminocyclopyrachlor (DPX-KJM44) is quickly broken down to release free acid which is readily translocated throughout the plants.

Grass

Lowrie (2009, 22393) studied the metabolism of [^{14}C]-DPX-KJM44 in grass (Amenity mix: 30% Disco perennial ryegrass, 30% Franklin strong creeping red fescue, and 40% Vienna perennial ryegrass) grown under field conditions. A single application at a nominal rate of 373 g DPX-KJM44/ha (spray volume 1000 L/ha) of a WP formulation was made to a 1 m² plot of grass growing in a sandy loam soil (67.6% sand, 15.1% silt, 17.4% clay; pH 6.5; 5.8% organic matter; 17.5 cmol/kg CEC). At the time of application the grass was approximately 30 cm in height. The grass plot was enclosed during the experiment. Grass samples were collected at 0, 3, 7, 14, 30 and 60 days after application and were separately homogenised and radioactivity determined by combustion/LSC. The identity of DPX-KJM44, aminocyclopyrachlor, and the various grass metabolites were investigated by chromatographic (HPLC) comparison of the extracted residues with authentic reference standards of DPX-KJM44, aminocyclopyrachlor, IN YY905, IN V0977, IN Q3007, IN LXT69, IN QFH57, and IN QGC48. All samples were stored frozen (ca. -20°C). Analyses of ^{14}C residues were completed within 4 months.

The grass foliage collected at each sampling point was gently washed with acetonitrile to remove the surface residues. The rinsed tissues were homogenised and portions of plant tissue were extracted twice with acetonitrile:0.2% formic acid in water (80:20, v/v; ca 150 mL) then twice with acetonitrile:0.2% formic acid in water (1:1, v/v; ca 150 mL). Levels of radioactivity in the wash and extract samples were determined by liquid scintillation counting (LSC). The unextracted radioactivity in the post extraction solids (PES) was determined by combustion analysis followed by LSC. Total

radioactive residues in each sample were determined by summing radioactivity in the surface wash, extracts and post extraction solids.

Unextracted ^{14}C residues in PES of tissues harvested 0, 7, and 60 DAT were subject to enzymatic and chemical hydrolysis. Post-extraction solids were incubated twice with a 2% solution of α -amylase in 0.2 M sodium phosphate buffer (pH 7 at 50 °C for 72 hours). After the second incubation with α -amylase, the remaining pellet was incubated with a mixture of 0.5% amyloglucosidase and 2% cellulase in 0.2 M sodium acetate buffer (pH 5 at 50 °C for 48 hours). Following each incubation the solution was separated from the pellet by centrifugation followed by decantation. The pellet remaining following enzyme hydrolysis was sequentially incubated with sodium hydroxide (0.1 N, 60 °C, 6 hours) and hydrochloric acid (1 M, 60 °C, 6 hours). The hydrolysates were separated from the remaining solids on each occasion by centrifugation and decanting.

Surface wash, solvent extracts, enzyme digests and hydrolysates were analysed using reversed phase HPLC. Radioactivity in collected fractions was quantified by LSC. LC-MS was conducted to confirm the presence of DPX-KMJ44, aminocyclopyrachlor and related metabolites.

Table 2 Characterisation of ^{14}C residues in grass following application of DPX-KJM44

				%TRR		
Days after application	TRR (mg equiv DPX-KJM44/kg)	Surface wash and extracted				Unextracted
		Surface wash	Extract 1	Extract 2	Total

Figure 3 Plot of DPX-KJM44, aminocyclopyrachlor and IN-LTX69 residues in grass following foliar application of DPX-KJM44

Total surface wash and tissue extracted residues in grass ranged from 15.3 to 1.18 mg equiv/kg (98.2 to 48.3% TRR) at 0 DAT to 60 DAT, respectively. The unextracted residue accounted for 0.28 and 1.27 mg equiv/kg (1.8 and 51.7% TRR, respectively) at 0 DAT and 60 DAT, respectively. Only a very small amount of the TRR was released from PES by enzyme and chemical hydrolysis (1.2%) at 0 days after application; 28.5% of the TRR was released from PES by enzyme and chemical hydrolysis at 60 days after application.

TRR in grass harvested immediately following application was 15.6 mg equiv/kg. Acetonitrile surface washes removed 13.0% TRR (2.0 mg equiv/kg). Solvent extracted residues accounted for 85.2% TRR (13.3 mg equiv/kg). Unextracted residues were further investigated by enzyme 1 (amylase), enzyme 2 (a mixture of amyloglucosidase and cellulose), base and acid hydrolysis, resulting in the liberation of 0.7% TRR (0.11 mg equiv/kg), 0.3% TRR (0.041 mg equiv/kg), 0.1% TRR (0.016 mg equiv/kg), and 0.1% TRR (0.013 mg equiv/kg), respectively. Unextracted residues remaining following enzyme/chemical hydrolysis of PES accounted for 0.6% TRR (0.102 mg equiv/kg).

The identification of extracted residues was confirmed by LC-MS including several minor components including IN Q3007, IN V0977, IN QFH57, IN LXT69, and IN QGC48. Aminocyclopyrachlor (32.9 to 64.2%TRR) was the principal extracted residue in the grass samples with DPX-KJM44 (5.9 to 24.7%TRR) present at lower levels. IN-LXT69, IN V0977, IN Q3007, IN QFH57, and IN QGC48 were identified as minor grass components that individually accounted for no greater than 6.1% TRR (0.14 to 0.77 mg equiv/kg; Table 3).

Lewis *et al.* (2013) studied the absorption and translocation of ^{14}C -aminocyclopyrachlor in tall fescue (*Lolium arundinaceum* (Schreb.) SJ Darbyshire, cv. Confederate) following application to a tiller leaf. Plants were grown to the 5 to 7 leaf stage (single tiller) and the third leaf from the crown was covered with aluminium foil and the plants sprayed with commercially formulated aminocyclopyrachlor at 79 g ai/ha with the addition of 0.25% non-ionic surfactant (NIS). The foil was removed and five 1 μL droplets of ^{14}C -aminocyclopyrachlor and 0.25% NIS were applied to the previously covered leaf. Plants were harvested 3, 12, 24, 48, 96 and 192 hours after application and separated into ^{14}C -treated leaf, remaining above ground foliage, crown and roots. The treated leaf was washed with 50% v/v methanol:water to remove surface residues. Similarly, roots were washed with methanol:water to remove root exudates.

Absorption of ^{14}C - aminocyclopyrachlor was high accounting for 63% (100%-leaf wash %) of the applied ^{14}C by 24 hours after application (Table 4). Translocation of absorbed ^{14}C was observed as evidenced by ^{14}C accumulation in the untreated foliage and in the roots. Accumulation of ^{14}C -radioactivity in other foliage ranged from 25 to 41% of the absorbed ^{14}C and for roots from 22 to 27% at 24 to 72 hours after treatment. Metabolism was not observed with 100% of ^{14}C in solvent extracts present as aminocyclopyrachlor at 192 hours after application.

Table 4 Distribution of ^{14}C following foliar application of ^{14}C -aminocyclopyrachlor to tall fescue

Hours after application	Leaf wash	^{14}C -treated leaf	Other foliage	%applied ^{14}C Crown	Roots	Root exudates	Total recovery
3	49	25	5	4	0	3	86
12	38	35	11	4	0	1	89
24	37	41	14	3	0	0	95
48	32	35	21	2	1	8	99
96	29	30	34	2	1	1	97
192	26	26	25	1	2	3	83

Following application to grass, DPX-KMJ44 was rapidly metabolised (demethylated) to form aminocyclopyrachlor. Aminocyclopyrachlor was the principal radiolabelled component found in grass samples collected immediately after treatment and up to 60 days after treatment. Aminocyclopyrachlor was decarboxylated to a lesser extent to IN-LXT69. Other minor routes of metabolism included photo-induced simultaneous elimination of hydrogen chloride and pyrimidine ring contraction yielding the imidazole-nitriles, IN-QGC48 and IN-QFH57 (from DPX-KJM44 and aminocyclopyrachlor, respectively), and pyrimidine ring opening with subsequent oxidation providing the amide IN-Q3007. Formation of the carboxylate, IN V0977 could occur through photolysis and is a minor pathway or it could be an artefact of the extraction process as hydrolysis experiments on IN-Q3007 under alkaline and acidic conditions showed that IN V0977 is produced under conditions comparable to exhaustive extraction procedures employed in the grass metabolism study (Brown 2011 31316).

The proposed metabolic pathway for DPX-KMJ44 and aminocyclopyrachlor in grass is provided in Figure 4.

Figure 4 Metabolic pathway of DPX-KJM44 and aminocyclopyrachlor following foliar application to grass

Studies on weeds

A number of literature studies have investigated the absorption, translocation and metabolism of aminocyclopyrachlor and DPX-KJM44 in various weed species.

Bukun *et al.* (2010) studied absorption and translocation of both aminocyclopyrachlor and DPX-KJM44 in Canada thistle (*Cirsium arvense*). Plants at the five- to six-rossette stage were selected and the youngest fully expanded leaf on each plant was covered with aluminium foil. The plants were sprayed with formulations containing aminocyclopyrachlor or DPX-KJM44 at the equivalent of 0.14 kg ai/ha together with 1% v/v methylated seed oil (MSO). Following spray application the protected leaves were exposed and treated with formulations containing ^{14}C -herbicide. Plants were harvested at 24, 48, 96 and 192 hours after application and separated into ^{14}C -treated leaf, and above and below ground tissue. In studies on metabolism, plants were harvested at 0, 2, 6 and 24 hours after application with residues analysed by HPLC.

Metabolism of ^{14}C - DPX-KJM44 was exclusively to the free acid (aminocyclopyrachlor). By 2 hours after application, 65% of the ^{14}C in plant extracts was aminocyclopyrachlor and by 6 hours after treatment 82% of the absorbed DPX-KJM44 had been metabolised to aminocyclopyrachlor.

The effect of adjuvants on absorption was studied in a separate experiment where [^{14}C]aminocyclopyrachlor or [^{14}C]DPX-KJM44 were formulated in treatment solutions containing methylated seed oil (MSO), crop oil concentrate (COC), non-ionic surfactant (NIS), NIS plus ammonium sulphate (AMS) or NIS plus urea ammonium nitrate (UAN). Solutions were 1% MSO (v/v), 1% COC (v/v), 0.25% NIS (v/v), 0.25% NIS (v/v) plus 0.2% AMS (w/v) and 0.25% NIS (v/v) plus 1% UAN (v/v) combined with formulated product to provide a concentration when applied to leaves that was equivalent to application at 0.14 kg ai/ha. Leaves were harvested 96 hours after application and surface residues measured by washing the leaves with 90% water, 10% methanol and 0.25% NIS. Quantitation of radioactivity was by liquid scintillation spectroscopy. The fraction absorbed was determined as the difference between applied radioactivity and radioactivity in the surface wash divided by applied radioactivity.

Absorption of both DPX-KJM44 and aminocyclopyrachlor was maximised in formulations containing methylated seed oil (MSO). While absorption of DPX-KJM44 by leaves was greater than for aminocyclopyrachlor, once absorbed DPX-KJM44 is rapidly metabolised to aminocyclopyrachlor and translocation from the application site to other parts of the plant was almost identical for the two formulations.

A aminocyclopyrachlor

B DPX-KJM44

Figure 5 Effect of adjuvants on absorption of A aminocyclopyrachlor and B DPX-KJM44. MSO = methylated seed oil, COC = crop oil concentrate, NIS = non-ionic surfactant, NIS+AMS = NIS + ammonium sulphate, NIS+UAN = NIS + urea ammonium nitrate

Lindenmayer (2012) studied the absorption, translocation and metabolism of aminocyclopyrachlor in field bindweed (*Convolvulus arvensis*). Field bindweed plants were grown from seed, pruned to maintain a single shoot and prevent flowering. When plants reached 12–15 leaf

stage, and vined to a height of 30 cm on a wooden stake, a single leaf midway up the stem was covered by aluminium foil and the plant sprayed with aminocyclopyrachlor (with 1% v/v MSO) at the equivalent of 0.14 kg ai/ha and a spray volume equivalent to 187 L/ha. Following the spray application, the aluminium foil was removed and the protected leaves were treated with a solution of [^{14}C]aminocyclopyrachlor plus 1% MSO v/v. Plants were harvested at 0, 6, 12, 24, 48, 96 and 192 hours after application and separated into ^{14}C -treated leaves, above-ground tissues, below ground tissue.

To determine absorption, treated leaves were washed with 90% water, 10% methanol and 0.25% NIS and the wash solution analysed by liquid scintillation spectroscopy. Radioactivity in distant plant parts was extracted by homogenising with 90% methanol, centrifuging and decanting the extract for LSC. Samples of the extracts were also subject to HPLC to determine metabolites.

Absorption of ^{14}C was rapid, reaching a maximum of 48% of the applied radioactivity by 48 hours after application. Translocation to above and below ground plant parts increased with time after application and reached 14% of the applied radioactivity by 192 hours after application. No soluble metabolites of aminocyclopyrachlor were detected in the plant extracts suggesting limited or no metabolism of aminocyclopyrachlor within 192 hours of application.

The results for Canada thistle and field bindweed described above are similar to those reported by Bell *et al.* (2011) who studied the absorption, translocation and metabolism of DPX-KJM44 and aminocyclopyrachlor on yellow star thistle (*Centaurea solstitialis* L.), rush skeleton weed (*Chondrilla juncea* L.) and prickly lettuce (*Lactuca serriola* L.). Following application of DPX-KJM44 there was rapid formation of the free acid (aminocyclopyrachlor) with a half-life of 3.5 hours and no subsequent metabolism in yellow starthistle, rush skeleton weed and prickly lettuce. Proportional herbicide movement between species was similar, with the majority translocating to developing shoots. However, in rush skeleton weed, early translocation was directed to root tissue. Highly sensitive species such as prickly lettuce absorb and translocate less material than relatively less sensitive species such as rush skeleton weed. De-esterification of DPX-KJM44 appeared to delay translocation of the resulting aminocyclopyrachlor in yellow star thistle and rush skeleton weed.

Vargas *et al.* (2014) studied the absorption, translocation, and metabolism of ^{14}C -DPX-KJM44 in large crabgrass (*Digitaria sanguinalis* (L.) Scop) and black nightshade (*Solanum nigrum* L) applied with and without diflufenzopyr (35 g ai/ha). Diflufenzopyr had minimal effects on translocation of radioactivity in either species. Accumulation of radioactivity in above ground parts of black nightshade was greater than, or equal to, that in large crabgrass by 72 h after treatment. In both species, metabolism of ^{14}C -DPX-KJM44 was rapid such that 60 to 78% of the extracted radioactivity was present as aminocyclopyrachlor at 8 hours after application.

Lym (2014) studied the absorption and translocation of aminocyclopyrachlor in leafy spurge (*Euphorbia esula*) and yellow toadflax (*Linaria vulgaris*). Application of [^{14}C]aminocyclopyrachlor was made approximately 8 weeks after planting and when plants were 10–12 cm tall. The application was to a single leaf midway on the stem of each plant. Samples were collected at 24, 48, 96 and 192 hours after application with plants separated into treated leaf, leaves above and leaves below the treated leaf as well as roots. In both weed species absorption was rapid averaging 63 and 71% of the applied ^{14}C in yellow toadflax and leafy spurge respectively at 24 hours after application. By 96 hours after application, 28 and 16.5% of the applied ^{14}C for yellow toadflax and leafy spurge respectively had translocated to other above ground plant parts. Relatively low levels of ^{14}C translocated to the roots of both weeds (< 12% applied ^{14}C).

In summary, DPX-KJM44 and aminocyclopyrachlor are rapidly absorbed and translocated by plants. Absorption is improved by the addition of spray adjuvants such as MSO or NIS. Following administration of DPX-KJM44 to plants, DPX-KJM44 is rapidly metabolised to aminocyclopyrachlor which is the major component of the residue. Following administration of aminocyclopyrachlor to plants, aminocyclopyrachlor is the major component of the residue.

ENVIRONMENTAL FATE

The FAO Manual on the Submission and Evaluation of Pesticide Residues Data for the Estimation of Maximum Residue Levels in Food and Feed (2009) explains the data requirements for studies of environmental fate. The focus should be on those aspects that are most relevant to MRL setting. For aminocyclopyrachlor, supervised residue trials data are available for grass. Aerobic degradation in soil is relevant, as well as the normal requirements for hydrolysis, photolysis and rotational crop studies.

The Meeting received information on soil aerobic metabolism and soil photolysis properties of aminocyclopyrachlor and DPX-KJM44. Studies were also received on the behaviour of [^{14}C]-DPX-KJM44 in a confined rotational crop situation.

Aminocyclopyrachlor residues are persistent in soils. Aminocyclopyrachlor residues in soils resulting from recommended uses could contribute to the residues in succeeding crops.

Aerobic degradation in soil

The rate and route of degradation of [^{14}C]-DPX-KJM44 was investigated in a sandy loam soil (Sassafras, Maryland USA, pH 5.4, 2.1% OM) under aerobic conditions by Hirata *et al.* (2011, 22435). [^{14}C]-DPX-KJM44 was applied at a nominal rate equivalent to a single application of 0.336 kg ai/ha. The soil samples were incubated under aerobic conditions in the laboratory and maintained under moist, dark conditions at $20 \pm 2^\circ\text{C}$ for up to 360 days. Samples were extracted twice with 0.2% formic acid in water:acetonitrile (20:80 v:v). For samples from day 40 onwards, an additional extraction was conducted using 0.15M ammonium acetate:acetonitrile (30:70 v:v). This extraction step was repeated to demonstrate exhaustive extraction.

The mean total recoveries of radioactivity for the 0 to 360 DAT soil samples were between 91.8 and 93.7% of applied radioactivity (AR). By 360 days, 20.4 to 25.8% of the AR was mineralised to $^{14}\text{CO}_2$ with 46.4–46.6% AR extracted with the solvent systems used and 21.4 to 25.0% remaining unextracted.

DPX-KJM44 was rapidly degraded, accounting for less than 1% AR by Day 3 as it was converted to aminocyclopyrachlor which accounted for 91.0–91.4% AR. By day 360, aminocyclopyrachlor accounted for 42.8–43.1% AR. The only other product observed was IN-LXT69 which reached a maximum between days seven and 122 accounting for 2.8–3.1% AR and declining to 2.2–2.4% AR by day 360.

The rate of degradation was estimated using single first-order (SFO) kinetics. The DT_{50} and DT_{90} values obtained are presented in Table 5.

Table 5 Summary of DT_{50} for DPX-KJM44 and aminocyclopyrachlor in Sassafras sandy loam (20°C in the dark)

Soil: Sassafras sandy loam	DT_{50} (days)	DT_{90} (days)	r^2
DPX-KJM44	0.1	0.2	0.9999
aminocyclopyrachlor	275	912	0.9492

The proposed degradation pathway of DPX-KJM44 in soil is presented in Figure 6 and involves the rapid de-methylation of DPX-KJM44 to form aminocyclopyrachlor which then undergoes de-carboxylation to form IN-LXT69. Both $^{14}\text{CO}_2$ and bound residue are significant degradation products of DPX-KJM44 in soil.

Figure 6 Proposed degradation pathway for DPX-KJM44 in soil under aerobic conditions

Manjunatha (2010, 22119) studied the degradation of aminocyclopyrachlor in three soils maintained under aerobic conditions in the dark at a nominal temperature of $20 \pm 2^\circ\text{C}$ for 120 days. The moisture content of the soils was adjusted to between 40 and 60% maximum water holding capacity and as close as possible to 75% water holding capacity at 1.033 MPa. Relevant properties of the soils used are presented in Table 6.

Table 6 Properties of soils used to study aerobic degradation of aminocyclopyrachlor

Soil Name	Texture	Origin	pH Water	0.01 M CaCl_2	% Organic Matter Walkley-Black	Soil initial	biomass $\mu\text{g/g}$ final
Nambsheim	Sandy Loam	Europe	8.09	7.48	2.2	1394	4796
Tama	Silty Clay	USA	6.45	6.13	4.6	650	4234
Drummer	Clay Loam	USA	6.40	5.79	6.5	284	4181

[Pyrimidine-2- ^{14}C] aminocyclopyrachlor was applied at a nominal rate of 0.448 mg/kg dry soil. Samples were analysed after 0, 7, 15, 30, 60, 90 and 120 days incubation. Residues in samples, other than day 0, were sequentially extracted using: (1) phosphate buffer (pH 7.4); (2) and (3) acetonitrile: pH 7.4 phosphate buffer 70:30 v/v; 4 acetonitrile: The extraction for the day 0 Drummer soil sample omitted the acetonitrile:ammonium acetate extraction. The extraction for the day 0 Nambsheim and Tama samples utilised: 1 $2\times$ acetonitrile: 0.2% (v/v) formic acid 80:20 v/v; 2 acetonitrile: 0.15 M ammonium acetate 70:30 v/v; 3 acetonitrile: pH 7.4 phosphate buffer 70:30 v/v followed by: 4 acetonitrile. Analysis of residues was by LSC and LC-MS/MS.

Extracted radioactivity recovered from samples ranged from *ca* 98 to 110% AR at day 0 decreasing to *ca* 49–81% AR after 120 days. Unextracted residues accounted for *ca* 0.6–6.9% AR at Day 0, increasing to a maximums *ca* 13–43% AR after 120 days while radioactivity associated with volatile traps reached 0.1–0.6% AR at Day 120. Following extraction, the organic matter from the Tama and Drummer soils of day 120 were fractionated into humin, fulvic acid, and humic acid. The mean radioactivity in the unextracted residue associated with humin, fulvic acid and humic acid were 13–20%, 11% and 0.3% AR, respectively.

The overall material balance ranged between *ca* 90 and 111% AR.

The amount of aminocyclopyrachlor in the solvent extracts declined from 105, 93 and 94% AR at zero time to 76, 42 and 45% AR after 120 days in the Nambenheim, Tama and Drummer soils, respectively. IN-LXT69 accounted for 4.0–6.4% AR at Day 0 declining thereafter to 0.2–0.4% AR at Day 120.

The dissipation half-lives were calculated using nonlinear first-order regression and are summarised in Table 7.

Table 7 DT₅₀ and DT₉₀ times for aminocyclopyrachlor in three soils (SFO kinetics)

Soil	<i>k</i> (day ⁻¹)	DT ₅₀ (days)	DT ₉₀ (days)	r ²
Nambenheim sandy loam	0.0016	433	1439	0.448
Tama silty clay	0.0058	120	397	0.964
Drummer clay loam	0.0055	126	419	0.938

Conklin and Lym (2013) studied the effect of temperature and moisture on the soil half-life of aminocyclopyrachlor on four soils from the Northern Great Plains. Relevant properties of the soils used are presented in the table below.

Table 8 Properties of Northern Great Plains soils used to study the degradation of aminocyclopyrachlor

Location	Soil	Sand	Silt	% by weight Clay	Organic Matter	FCWC ^a	pH
Fargo	Fargo	5	45	50	7.0	55	7.2
Jamestown	Svea-Barnes	37	42	21	6.4	51	5.7
Medora	Glendive-Havre	5	35	60	1.2	38	8.1
Walcott	Lamoure	86	9	5	2.6	49	7.8

^a Field capacity gravimetric water content

Ten mL of a 36 µg/kg aminocyclopyrachlor solution was mixed thoroughly with 500 g air-dry soil. The treated soil was maintained in the dark at different soil moisture contents and temperatures for 8 weeks. At the end of this period, the soil was frozen to reduce or eliminate microbial activity until soybean bioassay for aminocyclopyrachlor residues. DT₅₀ values for the decline of aminocyclopyrachlor were calculated based on the soybean bioassay results (Table 9).

The rate of aminocyclopyrachlor dissipation generally increased as soil moisture content or temperature increased however, there were also effects that may be due to organic matter and clay content. The DT₅₀ times for aminocyclopyrachlor are not easily predicted by a single soil characteristic.

Table 9 Effect of moisture content and temperature on DT₅₀ values (days) for four soils after treatment with aminocyclopyrachlor at 39 µg/kg.

Moisture content (FCWC ^a)	Temperature (°C)	Fargo	Glendive-Havre	Lamoure	Svea-Barnes

45%	24	11	51	13	13

^a Field capacity gravimetric water content

The soil dissipation of aminocyclopyrachlor occurs at a slow rate. Aminocyclopyrachlor is persistent in the environment.

Field dissipation

In a series of studies, the degradation of DPX-KJM44 was studied following a single application of a wettable powder formulation to bare soil (Shepard 2009 22528, 2010a 22527) or to turf grass (Shepard 2012 22529, 2010b 22526). Treated plot areas ranged from 279 to 372 m². In each experiment, five replicate soil core samples at each sampling time were collected from each of three treated plots. Soil samples were collected at various intervals after depending on the site and up to 540 days after treatment. Samples were collected from depths of 0–5, 5–15, 15–30, 30–50, 50–70, and 70–90 cm. Where available, grass samples were taken from a 30 × 30 cm area by cutting the grass as close as possible to the soil surface. Soil and grass samples were extracted and analysed for residues of DPX-KJM44 and its degradation products aminocyclopyrachlor and IN-LXT69 by LC-MS/MS. The LOQ and LOD for DPX-KJM44 aminocyclopyrachlor and IN-LXT69 were 0.001 mg/kg and 0.0003 mg/kg respectively. Table 10 contains a summary of the experimental conditions.

Table 10 Experimental conditions for soil field dissipation studies on DPX-KJM44

	Location	Application rate g as/ha (g ai/ha)	Spray volume (L/ha)	Soil type	Soil pH ^a	Soil OC% ^b
Bare soil	Ontario	336 (315)	980	Brant silt loam	6.0–8.4	0.23–1.0
	California	336 (315)	890	Tagus silt loam	8.4–8.7	0.1–0.4
Turf	Georgia	168 (158)	944	Tifton sandy loam	6.3–6.4	0.7–0.9

^a Range of soil pH measured in water for soil fraction collected from 0–90 cm depth

^b Range of soil organic carbon measured in soil fraction collected from 0–90 cm depth

Analysis of the total residue (DPX-KJM44 + aminocyclopyrachlor + IN-LXT69) in soil indicated that DPX-KJM44 was rapidly hydrolysed to aminocyclopyrachlor and quickly declined to soil concentrations that were below the limit of detection. Within 14 days after application, aminocyclopyrachlor was the major residue present. The degradation product IN-LXT69 generally showed concentrations < LOD throughout the study. Figure 7 summarises visually the degradation of DPX-KJM44 and aminocyclopyrachlor. Total residues, calculated as the sum of DPX-KJM44, aminocyclopyrachlor and IN-LXT69, are almost entirely due to aminocyclopyrachlor.

Air sampling did not recover significant quantities of DPX-KJM44 or aminocyclopyrachlor in volatile traps suggesting loss through volatilisation is not a significant dissipation mechanism.

The DPX-KJM44 concentrations in soil in units of % mass of applied parent equivalents were used to calculate the DT₅₀ and DT₉₀ values tabulated below. DPX-KJM44 is rapidly degraded to aminocyclopyrachlor with DT₅₀ values of 0.7 to 1.6 days for the four sites studied. In contrast the DT₅₀ values for aminocyclopyrachlor are much longer ranging from 55 to 163.6 days. Meaningful kinetic information could not be generated for IN-LXT69.

The dissipation of DPX-KJM44 in established grass foliage was investigated at two sites with DT₅₀ values for DPX-KJM44 of 0.4 days while the DT₅₀ values for aminocyclopyrachlor were 4.8 to 8.9 days (Figure 8, Table 11).

The modelling results are summarized in Table 11.

Table 11 DT₅₀ and DT₉₀ values for DPX KJM44 and aminocyclopyrachlor in four soils

Soil photolysis

Wardrope (2007 22118) studied the soil photolysis of aminocyclopyrachlor. [Pyrimidine- ^{14}C]aminocyclopyrachlor was applied by pipette to thinly-layered soil (*ca* 2 mm thick) to achieve a nominal concentration of 448 $\mu\text{g ae/kg}$ soil (448 ppm), equivalent to a field use rate of 336 g ai/ha soil, and irradiated under artificial irradiation (Xenon light) equipped with filters to eliminate wavelengths of < 290 nm. $^{14}\text{CO}_2$ and ^{14}C non-specific organic volatiles were collected. Samples were taken for analysis at 0, 1, 3, 5, 7, 11, and 15 days of irradiation. The soil samples were extracted twice with acetonitrile: 0.2% formic acid (8:2 v/v) followed by an extraction with acetonitrile: 0.15 M ammonium acetate (7:3 v/v). Identification of the transformation products was performed by HPLC and LC-MS analysis using authentic reference standards.

The material balance ranged from 96 to 102% and 95 to 102% of the applied radioactivity (AR) in the irradiated and dark (non-irradiated) samples, respectively. The total extracted radioactivity for irradiated samples decreased during the irradiation period, from a mean of 97% AR at Day 0 to a mean of 83% AR after 15 days. Unextracted ^{14}C -residues increased from $< 4\%$ to a maximum mean value of 17% AR after 15 days. Throughout the experimental phase, evolved $^{14}\text{CO}_2$ and ^{14}C -organic volatile radioactivity were below the limit of quantification. In the non-irradiated (dark control) samples the total extracted radioactivity remained relatively constant at all time points, with means of 97% AR at Day 1 and 92% AR at Day 15. Unextracted ^{14}C -residues increased from *ca* 2 to 5.1% AR after 15 days. Throughout the experimental phase, evolved $^{14}\text{CO}_2$ and ^{14}C -organic volatile radioactivity were below the limit of quantification.

In the irradiated samples, aminocyclopyrachlor decreased from a mean value of 94% AR at day 0, to a mean of 74% AR after 15 days. The only significant transformation product was identified as IN-LXT69, with a maximum mean concentration of 4.9% AR observed at Day 7. Multiple (a total of fourteen but up to six for any one sample) minor transformation products were detected, accounting for a combined mean maximum value of 8.7% AR at Day 11. No individual unidentified component accounted for greater than 5% AR at any time point. In the non-irradiated samples, the parent compound decreased from a mean of 94% AR at day 1 to 87% AR after 15 days. One major transformation product was identified as IN-LXT69, with a mean maximum value of 5.2% AR observed at Day 11. Eight minor transformation products were detected, none of which accounted for greater than 5% AR with a majority less than 1% AR at any time point.

To calculate the rate of degradation of aminocyclopyrachlor due to photolysis only, the first-order rate of degradation constant in the non-irradiated samples was subtracted from the first-order rate of degradation constant in the irradiated samples. The resulting corrected DT_{50} and DT_{90} values

were 61 and 204 days, respectively. These estimated DT_{50} and DT_{90} values are extrapolated beyond the limits of the observed data, 15 days.

Soil photolysis is expected to be a significant route of aminocyclopyrachlor degradation when compared to aerobic soil degradation.

Hydrolysis

Manjunatha (2008, 22116) studied the hydrolytic stability of aminocyclopyrachlor at 50 ± 0.5 °C for 5 days in dark, sterile, aqueous buffered solutions at pH 4, pH 7 and pH 9. Aqueous solutions of aminocyclopyrachlor showed less than 10% degradation at the end of the 5 day study period. Aminocyclopyrachlor is considered stable to hydrolysis at pH 4, 7 and 9 ($t_{1/2}$ at 25 °C > 1 year).

Hydrolysis of aminocyclopyrachlor is not expected to be a significant process under environmental conditions.

Aqueous Photolysis

Lowrie (2008, 22117) studied the photolysis of aminocyclopyrachlor in sterile natural water. Solutions containing 2 µg [^{14}C]aminocyclopyrachlor/mL were continuously irradiated using light from a xenon arc lamp filtered to give a spectral distribution close to that of natural sunlight. The samples were maintained at 20 °C and were irradiated for periods up to 360 h.

The mass balance (mean across all samples) was 99% of the AR. In the pH 4 buffer system, aminocyclopyrachlor was relatively rapidly degraded accounting for 28.1% AR after 360 hours of continuous irradiation. A number of photo-degradates were formed; IN-QFH57 (13.8% AR) and IN-LXT69 (16.1% AR), IN-YY905 (8.0% AR), IN-Q3007 (6.8% AR) and IN-V0977 (12.4% AR) together with several minor components that individually accounted for < 10% AR. No significant degradation was apparent in the dark controls indicating that the degradation in irradiated samples was the result of photodegradation only.

Degradation was also rapid in the irradiated natural water test system. Aminocyclopyrachlor accounted for 5.6% AR after 144 hours of continuous irradiation and was not detected at subsequent sampling times. IN-QFH57 was the major degradation product accounting for 29.7% AR at 360 hours with other significant degradates IN-YY905, IN-Q3007 and IN-V0977 accounting for 11.7, 24.4 and 14.6% AR at 360 hours. Two other components that each accounted for more than 10% AR could not be identified though from their properties are thought to be small aliphatic molecules. Other components individually accounted for less than 10% AR.

Figure 9 Proposed photodegradation pathway for aminocyclopyrachlor in pH 4 buffer and natural water.

Calculated degradation rate constants (half-lives) for aminocyclopyrachlor under constant irradiation are 7.3 days and 24.2 days for the DT_{50} and DT_{90} values in pH 4 buffer and 1.3 and 4.5 days for the DT_{50} and DT_{90} values in natural water.

Aminocyclopyrachlor is rapidly degraded by photolysis in both pH 4 sterile buffer and natural water solutions. Aminocyclopyrachlor is photodegraded through at least three separate pathways: decarboxylation to form IN-LXT69, photo-induced simultaneous elimination of hydrogen chloride and pyrimidine ring contraction to form the imidazole-nitrile IN-QFH57 and pyrimidine ring destruction to form the cyclopropyl amidine, IN-YY905 with subsequent hydrolysis to IN-Q3007 and IN-V0977. Unidentified products are likely to be other low molecular weight compounds.

Photolysis of aminocyclopyrachlor could potentially be a significant route of degradation under environmental conditions.

Confined rotational crop studies

A confined rotational crop study was conducted on a sandy loam soil (65.9% sand, 18.7% silt, 15.4% clay; pH 6.3; 3.2% organic carbon; 15.4 meq/100 g CEC) treated with [^{14}C]-DPX-KJM44 at either 75 or 369 g ai/ha (MacDonald and Hall 2009 22559). The lower application rate was used for rotations of 15, 30, 60, 120, and 300 days while the high application rate was used with a 300 day rotation only. Seeds of cabbage and turnip were sown into the soil at 30, 60, 120 and 300 (both treatment rates) days after application (DAA). Seeds of maize (field corn) were sown into the soil at 15, 120 and 300 (both treatment rates) DAA. The trials were conducted under greenhouse conditions. The growth stages for harvest of immature crop fractions were maize forage (whole aerial portion, collected at late dough/early dent, BBCH 85), ca 50% expected mature head size (BBCH 45) for cabbage and ca 50% expected tuber diameter (BBCH 45) for turnip. Tissues were homogenised and, if necessary, extracted sequentially with acetonitrile:water (9:1, v/v) and acetonitrile:water (7:3 v/v, twice). For select samples, the post extraction solids (PES) were further extracted sequentially with enzymes (α -amylase, amyloglucosidase/cellulase combination), alkali (0.1 N NaOH at 60 °C) and acid (1 N HCl at 60 °C). The total radioactive residues (TRR) were expressed as mg equiv DPX-KJM44/kg.

Radioactive residues detected in immature and mature cabbage ranged from 0.005 to 0.027 mg equiv/kg (at both treatment rates). The majority of the ^{14}C was recovered in solvent extracts with unextracted residues amounting to no more than 0.005 mg equiv/kg. Aminocyclopyrachlor accounted for 60–61%TRR (0.008–0.014 mg equiv/kg) in mature cabbage from plots treated 30 and

60 days before sowing (low application rate) and for 83% TRR (0.010 mg equiv/kg) from plots treated 300 days before sowing (high application rate). DPX-KJM44 was only observed at trace levels (0.001 mg/kg) in mature cabbage. Unidentified residues accounted for ≤ 0.004 mg equiv/kg.

TRR in immature turnip tops at the 75 g ai/ha soil treatment rate were ≤ 0.029 mg equiv/kg while TRRs in immature turnip tubers were ≤ 0.010 mg equiv/kg. The TRR in immature turnip tops at the 369 g ai/ha soil treatment rate were 0.085 mg equiv/kg with no residues detected in the immature tubers. TRR in turnips grown from seeds sown 30, 60, 120 and 300 DAA at the lower treatment rate were ≤ 0.011 mg equiv/kg in mature turnip tops and ≤ 0.003 mg equiv/kg in the tubers. TRR in mature turnip tops and tubers from the high rate were each 0.004 mg equiv/kg.

Aminocyclopyrachlor accounted for 40 to 59% TRR (0.004–0.007 mg equiv/kg) of the ^{14}C present in mature turnip tops from crops sown 60 and 120 DAA. DPX-KJM44 (17% TRR, 0.002 mg equiv/kg) was only detected in the mature tops from the 60 DAA planting interval. Unidentified components were individually present at < 0.01 mg equiv/kg.

TRR in immature maize (forage) from seeds sown at 15, 120, 300 (75 g ai/ha) and 300 (369 g ai/ha) DAA were 0.091, 0.011, 0.028 and 0.246 mg equiv/kg, respectively; the corresponding values for stover were 0.149, 0.023, 0.058 and 0.262 mg equiv/kg, for cobs were 0.024, 0.003, ND and 0.012 mg equiv/kg, and for grain were 0.067, 0.012, 0.018 and 0.085 mg equiv/kg. The majority of the radioactivity from all maize tissues was able to be extracted with the solvent systems used (61–99% TRR). TRR in post-extraction solids did not exceed 0.009 mg equiv/kg.

Aminocyclopyrachlor was the principal component (63–70% TRR) in forage from the 15 and 120 DAA plots. DPX-KJM44 was only observed in the 15 DAA forage (10% TRR; 0.009 mg/kg) and not in forage of crops sown at later intervals after soil application. Unidentified components were also present accounting for ≤ 0.01 mg equiv/kg in total.

Aminocyclopyrachlor was also the major ^{14}C component in forage from the 300 DAA plots (low and high treatments groups) comprising 68–71% TRR. A trace amount of DPX-KJM44 (0.7% TRR; 0.002 mg/kg) was detected in forage from the high soil treatment rate. A component with similar chromatographic properties to IN LXT69 was detected at ≤ 0.01 mg equiv/kg at both soil treatment rates. Multiple (5–26) unidentified and apolar components totalling 5–21% TRR (≤ 0.05 mg equiv/kg) with individual components ≤ 0.01 mg equiv/kg were also observed in the various forage samples at both soil treatment rates. Chromatographic analysis of enzyme digests of the post extraction solids from the high soil treatment rate demonstrated the presence of aminocyclopyrachlor (11% TRR, 0.026 mg equiv/kg).

Aminocyclopyrachlor was the major component detected in all stover samples ranging from 0.014 to 0.151 mg equiv/kg. DPX-KJM44 accounted for 0.013 mg/kg in the stover sample from the 15 DAA plot, and ≤ 0.002 mg/kg in all other stover samples. A late eluting apolar unknown accounted for 2–7% TRR (≤ 0.018 mg equiv/kg) whereas a component with similar chromatographic properties to IN-LXT69 was detected at ≤ 0.001 mg equiv/kg. Multiple (12 to 27) unidentified components totalled 6–25% TRR (0.001–0.064 mg equiv/kg), with individual components ≤ 0.012 mg equiv/kg, were also observed in the various stover samples.

In grain, aminocyclopyrachlor accounted for 71–72% TRR (0.01–0.05 mg equiv/kg) in samples from the 15 and 120 DAA plots. DPX KJM44 was observed at a trace level (< 0.01 mg/kg) in the 15 DAA plot grain. Aminocyclopyrachlor accounted for 72–76% TRR in the grain from maize sown at 300 DAA at the low and high treatment rates. DPX-KJM44 (2.5% TRR) was detected in the low treatment rate sample only. Unidentified components totalled 2.2–4.2% TRR with no single component comprising greater than 0.001 mg equiv/kg were also detected.

ACP = aminocyclopyrachlor

The proposed metabolic pathway for DPX-KJM44 in confined rotational crops is provided in Figure 10. The pathway involves de-esterification of DPX-KJM44 to form aminocyclopyrachlor. Aminocyclopyrachlor undergoes decarboxylation (to a much lesser extent) to form IN LXT69.

Figure 10 Proposed metabolic pathway for [¹⁴C]DPX-KJM44 in confined rotational crops

Field crop rotational studies

No field crop rotational studies were made available to the meeting. From the confined rotational crop study, low levels of residues are expected in rotational crops.

METHODS OF RESIDUE ANALYSIS*Analytical methods*

The Meeting received descriptions and validation data for analytical methods for residues of aminocyclopyrachlor in animal and plant matrices. The methods are suitable for analysis of DPX-KJM44, aminocyclopyrachlor and metabolites in plant matrices as well as for DPX-KJM44, aminocyclopyrachlor and IN-LXT69 in animal commodities.

A brief description of the methods used in the residue trials is given in Table 13.

Table 13 Summary of major analytical methods used for the determination of aminocyclopyrachlor and metabolites in various matrices

Method/ reference	Matrix	Extraction	Clean-up	Detection, LOQ
22582	Plant commodities	0.15 M ammonium acetate/acetonitrile. Combined extracts are diluted with 0.1 N HCl and water	aminocyclopyrachlor , DPX-KJM44, IN-LXT69, IN-QGC48: Extract aliquots concentrated under a stream of N ₂ at 40 °C, diluted with 0.5% formic acid, passed through SAX SPE columns and loaded onto an Oasis® MCX SPE cartridge, eluted with 75 mM ammonium hydroxide in methanol into tubes containing 0.2% formic acid. Eluates are concentrated under stream of N ₂ at 40 °C, diluted with 0.01% formic acid and filtered through 0.45 µm PTFE filter ready for analysis IN-QFH57: Extract aliquots concentrated under a stream of N ₂ at 40 °C, diluted with 0.01% formic acid, loaded onto an SAX SPE cartridge, eluted with 1% formic acid in methanol into tubes containing 0.2% formic acid. *Plant materials**Residue Analytical Method 22582 (Penz and Nanita 2008 22582)*

After grinding the samples in dry ice to a powder, the samples should be returned to the freezer until ready for analysis. The analytes were extracted sequentially from a 10 g sample by (1) soaking in 35 mL of 0.15 M ammonium acetate (aq), addition of 80 mL of acetonitrile and homogenization; and

(2) homogenization in 100-120 mL of acetonitrile/0.15 M ammonium acetate (aq) 70/30. Extracts were combined and diluted with 0.1 N HCl and water.

For analysis of DPX-KJM44, aminocyclopyrachlor, IN-LXT69, and IN-QGC48, 1–2 mL of extract aliquots were concentrated to 0.5 mL (stream of N₂, 40 °C) and diluted with 0.5% formic acid (aq). The extracts were filtered using SAX SPE cartridges and loaded onto Oasis® MCX SPE cartridges. The analytes were eluted with 15–20 mL of 75 mM ammonium hydroxide in methanol into tubes containing 1 mL of 0.2% formic acid (aq). The eluates were concentrated to a volume of 1–2 mL (stream of N₂, 40 °C), diluted with 0.01% formic acid (aq), filtered through a 0.45 µm PTFE filter and analysed by LC-MS/MS.

For analysis of IN-QFH57, 1 mL of extract aliquots were concentrated to a volume of 0.5 mL (stream of N₂, 40 °C), diluted with 0.01% formic acid (aq) and loaded onto SAX SPE cartridges. IN-QFH57 was eluted with 1% formic acid in methanol into tubes containing 0.5 mL of 0.2% formic acid (aq). The eluates were concentrated to a volume of 0.5 mL (stream of N₂, 40 °C), diluted with 0.01% formic acid (aq), filtered through a 0.2 µm PTFE filter and analysed by LC-MS/MS.

Transitions monitored for quantitation were m/z 214 → 68 for aminocyclopyrachlor (confirmation m/z 214 → 101), 228 → 68 for DPX-KJM44 (confirmation m/z 228 → 101), 170 → 76 for IN-LXT69 (confirmation m/z 170 → 103), 192 → 178 for IN-QGC48 (confirmation 192 → 132) and 176 → 132 for IN-QFH57 (confirmation 176 → 105).

Good linearity was observed for the calibration curves of DPX-KJM44, aminocyclopyrachlor, IN-LXT69, IN-QGC8 and IN-QFH57 solvent standards at 0.02–2.0 ng/mL, i.e. each had correlation coefficient, r , ≥ 0.99 . Inferences were not observed for DPX-KJM44, aminocyclopyrachlor, IN-LXT69, IN-QFH57, and IN-QGC48 at their respective chromatographic retention times in the samples tested.

The LOQ determined in this method for all analytes was 0.01 mg/kg for all matrices tested. In addition, at this fortification level, the analyte peak consistently represents a signal-to-noise ratio of approximately 5–20 to 1 for the least responsive analyte.

Rodgers (2010 30574) conducted an independent laboratory validation of the method. Two slightly different versions were studied: one, following purification, based on strong anion exchange (SAX) filtration and the other using SAX and mixed cation exchange (MCX) solid phase extraction (SPE). Additionally, the effect of replacing the 0.5% formic acid flushing solvent for the SAX cartridge with 0.1 N HCl was investigated. The simple SAX filtration method (no MCX step) combined with 0.1 N HCl flushing solvent gave satisfactory performance (Table 15).

Boughton (2011 31151) conducted an independent laboratory validation of method 22582 in grass and representative oily (corn), watery (lettuce) and acidic (oranges) crops. Acceptable recoveries were obtained for all analytes in all matrices except for IN-QFH57 in oranges.

Nanita *et al.* (2013) reported the results of an inter-laboratory study comprising five participating laboratories in the USA that was used to evaluate the method reproducibility and ruggedness. Method validation sets for the matrix white pine were analysed at the five laboratories. One laboratory also analysed grass forage and hay samples. The results are shown in Table 16.

Table 16 Summary of aminocyclopyrachlor recoveries during method validation and concurrent fortifications for routine sample analysis at five laboratories in the USA

Laboratory	Matrix	N	%Recovery (mean ± SD) ^a
A	White pine	6	111 ± 10
B	Conifers (Norway spruce 16, white pine 7, white spruce 4)	27	100 ± 15
C	White pine	6	101 ± 7
D	White pine	10	88 ± 14
E	White pine	9	102 ± 13
A	Grass forage	10	103 ± 13
A	Grass hay	10	107 ± 5

^a Fortification levels for aminocyclopyrachlor included 0.01, 0.1 and 1 mg/kg.

It was reported that acceptable analyte calibration curves were routinely obtained at each laboratory ($r > 0.99$, RSD response factors $< 20\%$) and when combined with the satisfactory mean recoveries and standard deviations it is concluded the method is suitably validated for use as a single analyte method in regulatory laboratories.

RESIDUES IN FOOD OF ANIMAL ORIGIN

Residue Analytical Method 25836

The extraction procedure for milk involves extraction twice using acetonitrile/0.1% aqueous formic acid (90:10, v/v). The extracts are combined and an aliquot diluted with 0.01% aqueous formic acid prior to analysis. For tissue samples, after grinding the samples in dry ice to a powder, the samples should be returned to the freezer until ready for analysis. Muscle, liver, kidney and fat are extracted sequentially with acetonitrile/0.1% aqueous formic acid 90:10, 70:30 then 50:50 v/v (liver, kidney and muscle are extracted on ice). An aliquot of the extract of fat, liver or kidney is analysed following a dilution step with 0.01% aqueous formic acid. An aliquot from the extract of muscle is analysed following a clean-up step using mixed mode cation exchange solid phase extraction.

Aminocyclopyrachlor, DPX-KJM44, and IN-LXT69 are quantified by liquid chromatography with tandem mass spectrometry employing turbo ion spray ionisation in positive mode. Transitions monitored for quantitation were m/z 214 → 68 for aminocyclopyrachlor (confirmation m/z 214 →

101), 228 → 68 for DPX-KJM44 (confirmation m/z 228 → 101) and 170 → 76 for IN-LXT69 (confirmation m/z 170 → 103). The method LOQs were 0.01 mg/kg for each analyte.

Good linearity was observed for the calibration curves of DPX-KJM44, aminocyclopyrachlor and IN-LXT69 solvent standards at 0.02–2.0 ng/mL, i.e. each had correlation coefficient, r , ≥ 0.99 . Inferences were not observed for DPX-KJM44, aminocyclopyrachlor and IN-LXT69 at their respective chromatographic retention times in the samples tested.

As the solvent extraction procedure is close to that used in the metabolism study for which greater than 80% of the TRR were recovered from tissues and milk, the extraction procedure is considered suitable.

Recovery data reported by Pentz and Nanita (2009 25836) and also by Ward and Spence (2010 27162 rev 1) are shown in Table 17.

In a study describing the independent laboratory validation of the method (Sheehan 2010 28151), acceptable recoveries were obtained with fortified samples though it is noted that analysis of DPX-KJM44 requires special care to ensure the compound does not hydrolyse during the analytical procedure. Initially DPX-KJM44 was hydrolysed during analysis of liver samples fortified with a mixture of DPX-KJM44, aminocyclopyrachlor and IN-LXT69 leading to low recoveries for DPX-KJM44 and high recoveries for aminocyclopyrachlor. Subsequent minor modifications such as smaller sample sizes lead to satisfactory recoveries being obtained (liver 2). Special care should be taken to keep liver and kidney samples chilled on ice where practical during the extraction procedure.

Aminocyclopyrachlor is not suitable for inclusion in QuEChERS and US FDA pesticide multi-residue methods (Nanita *et al.* 2013).

STABILITY OF RESIDUES IN STORED ANALYTICAL SAMPLES

The freezer storage stability of aminocyclopyrachlor in homogenised plant, animal tissues, milk and egg samples fortified with DPX KJM44, aminocyclopyrachlor or metabolites was studied. Except for liver and kidney, residues were stable for the duration of the storage studies.

Stability of residues in plant products

Vogl (2009b 24605) studied the freezer storage stability of DPX-KJM44, aminocyclopyrachlor and IN-LXT69 in samples of grass forage and hay spiked separately with the compounds at a nominal rate of 0.5 mg/kg. Samples were analysed using procedures based on method 22582. The data indicate residues of DPX-KJM44, aminocyclopyrachlor and IN-LXT69 are stable at approximately -20 °C for at least 500 days in grass forage and grass hay.

Table 19 Storage stability results for samples spiked with aminocyclopyrachlor, DPX-KJM44 and IN-LXT69

In another study, separate grass forage and grass hay control sample replicates were individually fortified with IN-QFH57 or IN-QGC48 (Vogl 2010 27890). Grass samples were fortified with the respective analyte at 0.30 mg/kg for forage and hay, and stored at approximately -20 °C.

The data indicate residues of IN-QFH57 and IN-QGC48 are stable at approximately -20 °C for at least 400 days in grass forage and grass hay.

Animal matrices

Aliquots of homogenized bovine muscle, liver, kidney, fat, milk and hens eggs were fortified with DPX-KJM44, aminocyclopyrachlor or IN-LXT69 at 0.2 mg/kg (Roberts and Ward 2010 26273). All samples were stored at approximately -20 °C prior to analysis after approximate intervals of 1 week, 2 weeks, 1, 2, 3 and 5 months, with the exception of kidney which was not analysed at 5 months. In addition, extracts of liver and kidney were stored at approximately -20 °C for ca. 7 and 14 days.

The freezer stability of DPX-KJM44, aminocyclopyrachlor and IN-LXT69 was demonstrated in milk, muscle, fat and hens eggs for at least 133 days. Aminocyclopyrachlor and IN-LXT69 were

stable in liver and kidney for at least 147 and 88 days, respectively. DPX-KJM44 was not stable in liver and kidney, being converted to aminocyclopyrachlor either during storage or subsequent analysis. However, DPX-KJM44 was stable in liver and kidney extracts stored at *ca.* -20 °C for at least 14 days.

Table 21 Storage stability results for egg, milk and tissue samples spiked with DPX-KJM44, aminocyclopyrachlor or IN-LXT69

^a DPX-KJM44 muscle 138 d also contained 0.012 and 0.01 mg/kg aminocyclopyrachlor. No evidence of significant hydrolysis. Possible incorrect fortification. In addition, the procedural recoveries for DPX-KJM44 and IN-LXT69 were very low indicating an issue with the fortification of the muscle samples. Data for muscle day 138 should be discarded.

^b DPX-KJM44 kidney 8 d, also contained 0.068 and 0.074 mg/kg aminocyclopyrachlor indicating significant hydrolysis of DPX-KJM44 either during storage or during sample analysis

^c DPX-KJM44 kidney 14 d, also contained 0.070 and 0.060 mg/kg aminocyclopyrachlor indicating significant hydrolysis of DPX-KJM44 either during storage or during sample analysis

^d DPX-KJM44 kidney 26 d, also contained 0.088 and 0.086 mg/kg aminocyclopyrachlor indicating significant hydrolysis of DPX-KJM44 either during storage or during sample analysis

^e DPX-KJM44 egg 133 d, also contained 0.026 and 0.02 mg/kg aminocyclopyrachlor indicating significant hydrolysis of DPX-KJM44 either during storage or during sample analysis

^f storage intervals are for aminocyclopyrachlor and IN-LXT69. Storage intervals for DPX-KJM44 were 0, 6, 13, 40, 54, 89 and 141 days.

USE PATTERNS

Aminocyclopyrachlor is a broad-spectrum herbicide that is rapidly absorbed by leaves and roots and translocated to the meristematic regions of the plant, where it is thought to act as an auxin mimic. Aminocyclopyrachlor is active on most broadleaf weeds and brush species with selectivity to most grasses and is used for the control of a range of broadleaf weeds in pasture, rangeland and industrial non-crop situations.

Table 22 Selected registered uses of aminocyclopyrachlor

Crop	Country	Formulation a		Application				PHI (days)
		g ai/L or g ai/kg	type	Method	Rate g ai/ha	Water L/ha	No	
Pasture, rangeland, industrial non-crop, industrial grassed	Canada	50%	WG	Broadcast	70 (max 70/season)	200 grd 30–50 air	1	0 b, c
Rangeland, non-crop	Canada	39.5% + 12.6% metsulfuron-methyl	WG	Broadcast	264 (max 264/season)	≤ 2000 grd 30–50 air	1	0 b, c
Pasture, rangeland, industrial non-crop	Canada	35.3% + 17.6% metsulfuron-methyl	WG	Broadcast	60	200 grd 30–50 air	1	0 b, c

^a Product labels require the use of adjuvants: non-ionic surfactant (NIS) at 0.25% v/v or Merge Adjuvant at 1% v/v or crop oil concentrate at 1% v/v.

^b There are no grazing or haying restrictions for non-lactating or lactating animals (including cattle, horses, sheep and goats). Grazing animals do not have to be moved off pasture or rangeland before, during or after applying aminocyclopyrachlor.

^c If range or pasture or non-crop sites treated with aminocyclopyrachlor are to be converted to a food, feed, or fibre agricultural crop, or to a horticultural crop, a field bioassay should be completed before planting the desired crop.

grd = For application using ground based equipment

air = For application using aircraft

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

Aminocyclopyrachlor is a non-selective herbicide that is highly active against growing weeds. The Meeting received information on supervised field trials for aminocyclopyrachlor on the following crops or crop groups:

Commodity	Table No.
Grass forage	Tables 24, 25
Grass hay	Tables 26, 27

Trials were generally well documented with laboratory and field reports. Laboratory reports included method validation with procedural recoveries from spiking at residue levels similar to those occurring in samples from the supervised trials. Dates of analyses or duration of residue sample storage were also provided. Although trials included control plots, no control data are recorded in the tables except where residues in control samples exceeded the LOQ. Control samples are indicated in the summary tables with a "c". Unless stated otherwise, residue data are recorded unadjusted for recovery.

The application rates for DPX-KJM44 and aminocyclopyrachlor are expressed in terms of acid equivalents (i.e., aminocyclopyrachlor).

Residues and application rates have generally been rounded to two significant figures or, for residues near the LOQ, to one significant figure. Residue values from the trials conducted according to maximum GAP have been used for the estimation of maximum residue levels. Those results included in the evaluation are underlined.

Conditions of the supervised residue trials were generally well reported in detailed field reports. Trial designs used non-replicated plots. Field reports provided data on the sprayers used, plot size, field sample size and sampling date.

Table 23 Summary of sprayers, plot sizes and field sample sizes in the supervised trials (Shepard 2010c 24323)

Location	Year	Sprayer	Plot size	Sample size	Sample to analysis interval (days)

Where duplicate field samples from an un-replicated plot were taken at each sampling time and were analysed separately, the mean of the two analytical results was taken as the best estimate of the residues in the plot and only the means are recorded in the tables. Similarly where samples were collected from replicate plots the mean result is reported (see general consideration JMPR 2010).

Animal feeds**Grass**

Twenty-two supervised residue trials with aminocyclopyrachlor or DPX-KJM44 on grass pastures were conducted in Canada and the USA in 2008 and 2009 (Shepard 2010c 24323). In these trials aminocyclopyrachlor (SL formulation) or DPX-KJM44 (WG formulations) were applied once at rates of 303–335 g ai/ha to pasture. All applications included an adjuvant at the recommended rate. Two replicate samples were collected from each treated plot. Samples of grass and hay were stored for a maximum of 401 days. Residues of aminocyclopyrachlor, DPX-KJM44, IN-LXT69, IN-QFH57 and IN-QGC48 samples were determined using method 22528. Mean concurrent recoveries for the analytes in samples fortified at 0.01 to 120 mg/kg ranged from $83 \pm 11\%$ to $95 \pm 9\%$ per analyte/matrix combination ($n = 32$ to 39).

Table 24 Application of DPX-KJM44 to grass: Residues of DPX-KJM44, aminocyclopyrachlor and IN-LXT69 (mg/kg, mean of two replicate samples) in grass forage (rates expressed in terms of aminocyclopyrachlor equivalents)

No residues of IN-QGC48 were detected while only occasional trace (< LOQ) residues of IN-QFH57 were detected.

PRIMARY FEED COMMODITIES OF PLANT ORIGIN

Livestock feeding studies

Dairy cow feeding study

The transfer of aminocyclopyrachlor-methyl (DPX-KJM44) residues from feed to tissues and milk of dairy cows was studied by Roberts and Ward (2010, 26273).

DPX KJM44 was administered orally to four groups of three Holstein/Friesian cattle (4–9 yrs old; 504–704 kg bw) by gelatine capsule (with one control cow fed capsules only) for 28 days. Mean daily feed consumption during the exposure period was 14.3–16.4 kg DM (hay, *ad libitum* and 8 kg/day protein concentrate). Mean daily milk yield during the exposure period was 8.1 to 29 kg/cow/day. Based on mean daily feed consumption, the exposure was equivalent to 73, 160, 454 and 1594 ppm in the feed (1.9, 3.8, 11.4, and 37.9 mg/kg bw/day). Milk was collected twice daily (pm sampling pooled with am sampling the next day) at 11 intervals through the 28 days of dosing. Selected samples were analysed for residues of DPX-KJM44 and aminocyclopyrachlor and a metabolite, IN-LXT69. Cream and skim milk were produced from selected milk samples taken at two intervals after milk residue plateau and these samples were analysed for DPX-KJM44, aminocyclopyrachlor and IN-LXT69. Muscle, liver, kidney and fat samples were collected at sacrifice 22–24 hours after the last dose; 14–16 days in the case of the depuration animals. Due to potential instability of DPX-KJM44 in frozen storage, liver and kidney samples were extracted shortly after sacrifice. Milk, skim milk and cream samples were all analysed within approximately 2 months of collection. The maximum frozen storage intervals were 65 days for milk, 30 days for skim milk and 59 days for cream. The maximum storage intervals for tissues were 44 and 36 days for muscle and fat, respectively. Liver and kidney samples were extracted on the day of collection with the exception of selected repeat samples.

Table 28 Concurrent recovery results for DPX-KJM44, aminocyclopyrachlor and IN-LXT69 for the dairy cow feeding study

Matrix	Fort level (mg/kg)	N	DPX-KJM44		aminocyclopyrachlor		IN-LXT69

	0.10	4	97–102	99 $\pm$ 2	86–100	93 $\pm$ 6	81–105	95 $\pm$ 10

^a Outliers (recovery values > 160%) omitted from calculations

^b Note: There were 2 additional aminocyclopyrachlor kidney and fat fortifications, each, at 2 mg/kg (96 and 99% and 97 and 104% recoveries for kidney and fat, respectively).

Average aminocyclopyrachlor milk residues at each sampling interval are presented below for the two dose rates that routinely had milk residues above the LOQ.

Table 29 Daily average residues of aminocyclopyrachlor in milk of cows dosed with DPX-KJM44.

DPX-KJM44 dose	Average residue (mg/kg) in milk at various sampling intervals (days)									
	1	3	5	7	10	14	17	21	24	28
454 ppm	0.014	0.017	0.021	0.024	0.019	0.018	0.020	0.021	0.022	0.022
1594 ppm	0.038	0.050	0.055	0.053	0.050	0.053	0.061	0.059	0.071	0.077

These data suggest that residues of aminocyclopyrachlor detected in whole milk reached a plateau by 5 to 7 days of dosing.

The maximum individual milk residue for all groups at each dose level over the 28 days of dosing is summarized below (Table 30).

Table 30 Maximum residues of aminocyclopyrachlor in milk of individual cows dosed with DPX-KJM44

Analyte	Maximum individual cow daily residue in milk in mg/kg			
	73 ppm	160 ppm	454 ppm	1594 ppm

ND = Not detected.

Aminocyclopyrachlor was the only analyte with residues greater than the LOQ (0.01 mg/kg). In tissue samples obtained within approximately 24 hrs of dose completion, quantifiable aminocyclopyrachlor residues levels were highest in kidney followed by fat, liver and muscle. Where quantifiable, residue levels in fat, liver and kidney were dose dependent.

Following cessation of dosing and where present, residues in milk and tissues rapidly declined. The average residues of DPX-KJM44, aminocyclopyrachlor and IN-LXT69 in milk obtained 1 day post last dose were < 0.01, 0.013 mg/kg and not detected, respectively. These residues declined to non-detectable in milk obtained 7 days post last dose.

Three days after withdrawal of dosing, residues of DPX-KJM44, aminocyclopyrachlor and IN-LXT69 declined to not detected, < 0.01 mg/kg and not detected in cream and not detected, < 0.01 mg/kg and not detected in skim milk, respectively. All residues were not detected 10 days post last dose.

Following a 15 day withdrawal period, all residues of DPX-KJM44 in tissues were not detected with the exception of kidney (< 0.01 mg/kg). Residues of aminocyclopyrachlor were < 0.01, 0.056, < 0.01 and 0.019 mg/kg in kidney, fat, liver and muscle, respectively. No residues of IN-LXT69 were detected.

Following a 17 day withdrawal period, all residues were not detected with the exception of aminocyclopyrachlor in kidney (< 0.01 mg/kg) and fat (0.03 mg/kg)

NATIONAL RESIDUE DEFINITIONS

Canada: aminocyclopyrachlor

APPRAISAL

Aminocyclopyrachlor is a new pyrimidine carboxylic acid herbicide used for the control of broadleaf weeds and woody vegetation. Aminocyclopyrachlor mimics the naturally occurring phytohormone indole acetic acid (auxin) disrupting plant growth. At the Forty-fifth Session of the CCPR (2013), it was scheduled for evaluation as a new compound by the 2014 JMPR.

The Meeting received information on the metabolism of aminocyclopyrachlor and also its methyl ester (aminocyclopyrachlor-methyl, DPX-KJM44) in lactating goats and grass, methods of residue analysis, freezer storage stability, GAP information, supervised residue trials, and a cattle feeding study.

Aminocyclopyrachlor is 6-amino-5-chloro-2-cyclopropyl-4-pyrimidinecarboxylic acid (IUPAC).

Metabolites referred to in the appraisal were addressed by their codes:

DPX-KJM44	(methyl 6-amino-5-chloro-2-cyclopropyl-4-pyrimidinecarboxylic acid)	
IN-LXT69	(5-chloro-2-cyclopropyl-pyrimidin-4-ylamine)	
IN-QGC48	(5-cyano-2-cyclopropyl-3H-imidazole-4-carboxylic acid methyl ester)	
IN-QFH57	(5-cyano-2-cyclopropyl-3H-imidazole-4-carboxylic acid)	
IN-Q3007	(cyclopropane carboxamide)	

The methyl ester of aminocyclopyrachlor (DPX-KJM44) was initially explored as a potential herbicide before finally settling on aminocyclopyrachlor (free acid) as the compound to be commercialised. As DPX-KJM44 is rapidly converted to aminocyclopyrachlor in both animals and plants, studies on DPX-KJM44 were submitted to the Meeting to support the evaluation of aminocyclopyrachlor.

Animal metabolism

The current meeting evaluated laboratory animal (rat) metabolism studies of orally administered aminocyclopyrachlor-methyl (DPX-KJM44) and reported that the ester is rapidly converted to the free acid (aminocyclopyrachlor). Therefore, studies with DPX-KJM44 also serve to demonstrate the metabolism of aminocyclopyrachlor.

A lactating goat was orally dosed twice daily for five consecutive days with [pyrimidine-2-¹⁴C]DPX-KJM44 at a dose equivalent to 97 ppm in the feed. Approximately 85% of the administered dose was recovered in the excreta (20% faeces, 54% urine) or gastrointestinal tract (8%). The radioactivity in the tissues ranged from 0.01 mg DPX-KJM44 equivalents/kg in fat to 1.67 mg DPX-KJM44 equivalents/kg in kidney. TRR values in milk reached 0.031 mg DPX-KJM44 equivalents/kg after five days of dosing.

With the exception of one fat sample, greater than 80% of the TRR was extracted with the solvent systems used (acetone for milk and acetonitrile/water for tissues).

No intact DPX-KJM44 was detected in tissues or milk. The major component of the ^{14}C residues were aminocyclopyrachlor (kidney 55% TRR, liver 66% TRR, muscle 43% TRR, fat 47–84% TRR, milk 16% TRR). A number of minor metabolites were unable to be identified but were generally only present at low levels (< 0.01 mg DPX-KJM44 equivalents/kg).

In summary, the metabolism of DPX-KJM44 and aminocyclopyrachlor in goats is similar to metabolism in laboratory animals in the respect that the ester is de-esterified with little further breakdown of the acid (aminocyclopyrachlor).

Plant metabolism

A study on the metabolic fate of DPX-KJM44 in grass was made available to the meeting and a number of studies were located in the literature where aminocyclopyrachlor or DPX-KJM44 were sprayed onto grass and also a variety of weed species. While the literature studies were not conducted according to the protocols developed for submission of data to regulatory authorities, they were used to contribute to the weight of evidence regarding metabolism of aminocyclopyrachlor in plants. As with animal systems, following treatment with DPX-KJM44, rapid degradation occurs with the formation of aminocyclopyrachlor, thus studies with DPX-KJM44 also provide evidence on the metabolism of aminocyclopyrachlor in plants.

Grass

The metabolic fate of [pyrimidine-2- ^{14}C]DPX-KJM44 in mixed grass (30 cm high) was examined following a single foliar application at 373 g ai/ha. Absorption following spraying was rapid with only 13% of the TRR in leaves recovered in surface washes from samples collected on the day of application. DPX-KJM44 was rapidly degraded, representing 25% TRR on the day of application, 14% TRR after three days and less than 9% TRR thereafter. Aminocyclopyrachlor was the major component of the ^{14}C residue comprising 64% TRR at day 0, declining to 33% TRR at 60 days after application. Minor metabolites were IN-LXT69 (4–6% TRR), IN-QGC48 (0–4% TRR), IN-QFH57 (0–2% TRR) and IN-Q3007 (0–1% TRR). Combined, the minor metabolites accounted for no more than 6.1% TRR in individual grass samples.

In a study of [^{14}C]-aminocyclopyrachlor metabolism in tall fescue grass sprayed once at 79 g ai/ha with aminocyclopyrachlor with the addition of 0.25% non-ionic surfactant, absorption from a single leaf treated with [^{14}C]-aminocyclopyrachlor was rapid with only 37% TRR recovered in surface washes 1 day after application. At eight days after application, aminocyclopyrachlor was the only compound detected in solvent extracts of plant material.

The metabolism of DPX-KJM44 and aminocyclopyrachlor was also studied in a range of weeds (black nightshade, Canada thistle, field bindweed, large crabgrass, prickly lettuce, rush skeleton weed, yellow star thistle). In those cases where DPX-KJM44 was applied, there was rapid hydrolysis to form aminocyclopyrachlor which was translocated in the plant. There was no further transformation of aminocyclopyrachlor within the three to eight day duration of the studies.

The metabolism of aminocyclopyrachlor by plants is well understood. Following application to grass (and weeds) the major residue component consists of parent aminocyclopyrachlor.

Environmental fate

The Meeting received information on the soil aerobic metabolism, soil photolysis, aqueous hydrolysis and aqueous photolysis properties of [^{14}C]-aminocyclopyrachlor and [^{14}C]-DPX-KJM44. Studies were also received on the behaviour of [^{14}C]-DPX-KJM44 in a rotational crop situation.

In soil incubation studies under aerobic conditions in the dark at 20 °C, ^{14}C -DPX-KJM44 degraded to form aminocyclopyrachlor with a DT_{50} of 0.1 days. Subsequently aminocyclopyrachlor degraded with a DT_{50} of 275 days. In studies following the aerobic degradation of ^{14}C -aminocyclopyrachlor applied to soil, the DT_{50} for degradation ranged from 120–433 days the sandy loam, clay loam and silty clay soils studied. IN-LXT69 accounted for 4.0–6.4% of the applied radioactivity (AR) at day 0 declining to 0.2–0.4% AR by day 120 of the study. Further analysis of the

unextracted portion of ^{14}C demonstrated incorporation into humin (13–20% AR), fulvic acid (11% AR) and humic acid (0.3% AR) fractions present in the soil.

In four field dissipation studies where DPX-KJM44 was applied to bare soil at two sites and to grass plots at two sites, the soil DT_{50} values were 0.4–1.6 days for DPX-KJM44 and 55 to 163 days for aminocyclopyrachlor. The DT_{50} values for grass foliage were 0.4 days for DPX-KJM44 and 4.8–8.9 days for aminocyclopyrachlor.

In a soil photolysis study with application of ^{14}C -aminocyclopyrachlor on the surface of a silt loam soil the estimated DT_{50} was 61 days suggesting photolysis will contribute to soil degradation.

Aminocyclopyrachlor was stable to hydrolysis in aqueous solutions at pH 4, 7 and 9 suggesting hydrolysis plays a negligible role in its degradation. A study on the aqueous photolysis of aminocyclopyrachlor showed it is degraded on irradiation. Aminocyclopyrachlor accounted for 28% AR after 360 hours continuous irradiation. Photodegradates formed at levels above 5% AR were IN-QFH57 (14% AR), IN-LXT69 (16% AR), IN-YY905 (8% AR), IN-Q3007 (7% AR) and IN-V0977 (12% AR).

In a confined rotational crop study with cabbage, turnip and maize, a plot of sandy loam soil was treated with [^{14}C]-DPX-KJM44 at the equivalent of 75 g ai/ha with some plots treated at 369 g ai/ha and crops sown 30, 60, 120 and 300 days after soil application for cabbage and turnip and 15, 120 and 300 days after application for maize. TRR in cabbage ranged from < LOD to 0.023 mg eq./kg with 60 to 83% of the ^{14}C accounted for by aminocyclopyrachlor. For turnips, negligible ^{14}C residues were detected in roots (maximum 0.004 mg eq./kg) while ^{14}C residues in tops ranged from 0.003 to 0.011 mg eq./kg. In the two samples with sufficient residues for identification, the major components of the ^{14}C residue in tops were aminocyclopyrachlor (41–59% TRR) and DPX-KJM44 (0–17% TRR). Radioactive residues in maize ranged from 0.011 to 0.246 mg equiv/kg for forage, 0.023–0.262 mg eq./kg for stover and 0.012–0.085 mg eq./kg for maize grain. In all cases aminocyclopyrachlor was the major component of the ^{14}C residue (46–71% TRR) with DPX-KJM44 present at $\leq 10\%$ TRR together with small amounts of IN-LXT69 (< 2% TRR). Residues of aminocyclopyrachlor present in soil are able to be taken up the rotational crops.

In summary, aminocyclopyrachlor residues in soil may contribute to residues observed in rotational crops. A field crop rotation study is desirable.

Methods of Analysis

The Meeting received description and validation data for analytical methods suitable for residue analysis of DPX-KJM4, aminocyclopyrachlor and related metabolites IN-LXT69, IN-QFH57 and IN-QGC48 in grass and DPX-KJM4, aminocyclopyrachlor and IN-LXT69 in animal commodities.

Grass samples are homogenised with 0.15 M ammonium acetate (aq) and acetonitrile, extracted with acetonitrile/0.15 M ammonium acetate (aq) 70/30 and the extracts acidified with dilute HCL. Extracts are cleaned up using SPE cartridges before analysis by LC-MS/MS. The LOQs for all analytes are 0.01 mg/kg.

Animal commodities are analysed using a different procedure. Milk samples are extracted using acetonitrile/0.1% aqueous formic acid (90:10, v/v) with analysis by LC-MS/MS. Tissue samples are homogenised and extracted with acetonitrile/0.1% aqueous formic acid with analysis by LC-MS/MS. In the case of muscle the samples are analysed following a clean-up step using solid phase extraction. The LOQs for all analytes are 0.01 mg/kg.

QuEChERS and the US FDA pesticide multiresidue methods are not suitable for analysis of aminocyclopyrachlor.

In conclusion, suitably validated methods are available for the analysis of aminocyclopyrachlor and selected metabolites in animal and plant matrices although currently there are no multi-residue methods available for aminocyclopyrachlor.

Stability of pesticide residues in stored analytical samples

The Meeting received information on the stability of DPX-KJM-44, aminocyclopyrachlor, IN-LXT69, IN-QFH57 and IN-QGC48 in grass and hay stored frozen. The compounds were all stable in grass and hay for the duration of the stability studies; 500 days for DPX-KJM-44, aminocyclopyrachlor, IN-LXT69 and 400 days for IN-QFH57 and IN-QGC48.

In animal matrices fortified separately with DPX-KJM44, aminocyclopyrachlor and IN-LXT69, residues were stable in milk, muscle, fat and hens eggs for at least 133 days. Aminocyclopyrachlor and IN LXT69 were stable in liver and kidney for at least 147 and 88 days, respectively. DPX-KJM44 was not stable in liver and kidney, being converted to aminocyclopyrachlor either during storage or subsequent analysis.

The periods of demonstrated stability cover the frozen storage intervals used in the residue studies.

Definition of the residue

Livestock may be exposed to residues present in feeds. In a lactating goat metabolism study with DPX-KJM44, the ester was rapidly converted to aminocyclopyrachlor which was the major component of the residue in all tissues and milk (kidney 55% TRR, liver 66% TRR, muscle 43% TRR, fat 47–84% TRR, milk 16% TRR) with no individual metabolite of aminocyclopyrachlor was identified as present at levels above 0.01 mg/kg.

Residues of aminocyclopyrachlor were higher in muscle than fat in the metabolism study while in the livestock feeding study they were much higher in fat compared to muscle (2.4 to 9.0×). Levels of aminocyclopyrachlor were higher in skim milk compared to cream. The log K_{ow} for aminocyclopyrachlor is -2.48 (pH 7) suggesting the compound is not fat soluble. Taken as a whole, the Meeting considered that residues of aminocyclopyrachlor are not fat soluble.

Following foliar application of aminocyclopyrachlor (and also DPX-KJM44) to grass, the major component of the residue is aminocyclopyrachlor (33–68% TRR). All components formed from aminocyclopyrachlor were minor (<6.1% TRR).

Based on the above the Meeting decided the residue definition for compliance with MRLs and estimation of dietary intake should be as follows:

Definition of the residue for compliance with MRL and estimation of dietary intake (for animal and plant commodities): *aminocyclopyrachlor*.

The residue is not fat soluble.

Results of supervised residue trials on crops***Grass***

The Meeting received supervised residue trial data for aminocyclopyrachlor on grass (including hay). GAP in the Canada is one application at up to 264 g ai/ha with a PHI of 0 days. In trials approximating critical GAP in Canada residues in grass forage were (n=6): 13, 18, 18, 22, 25, 39 mg/kg (on an as received basis) and 58, 60, 72, 77, 79 and 81 mg/kg when corrected for reported moisture contents.

The Meeting estimated a highest and median residue of 81 and 74.5 mg/kg for grass (dry weight basis).

Residues in grass hay from field trials performed in Canada and the USA approximating GAP in Canada were (n=6): 30, 35, 40, 46, 46, 48 mg/kg (on an as received basis) and 40, 45, 46, 49, 60 and 60 mg/kg when corrected for reported moisture contents.

The Meeting estimated a maximum residue limit and median and high residues of 150, 47.5 and 60 mg/kg for grass hay.

Rotational crop residues

Soil residues of aminocyclopyrachlor are moderately persistent. The use-pattern (Canadian GAP) does not specify plant-back intervals for follow-crops. In the confined rotational crop study, where DPX-KJM44 was applied to soil at the equivalent of 70 to 346 g aminocyclopyrachlor/ha, residues of aminocyclopyrachlor in cabbage and turnip from crops planted 300 days after application to soil were below practical LOQs of 0.01 mg/kg. Residues of aminocyclopyrachlor were above 0.01 mg/kg in maize commodities (forage, stover, grain). The Meeting considered the available information on residues in rotational crops to be inadequate for the purposes of estimating maximum residue levels and STMR values to cover potential residues in such crops. The Meeting also noted that the livestock dietary burden is dominated by residues in grass and hay (100% of the diet for Australia) and that any contribution from potential residues in feeds in follow crops is minor. To enable completion of the risk assessment, the Meeting noted that residues in follow crops are unlikely to average more than 0.01 mg/kg and agreed that a value of 0.01 mg/kg could be used in estimates of consumer exposure for commodities from non-permanent crops.

Residues in animal commodities

Farm animal feeding studies

The Meeting received information on the residue levels in tissues and milk of dairy cows dosed with DPX-KJM44 at the equivalent of 73, 160, 454 and 1594 ppm in the feed for 28 consecutive days.

Residues of DPX-KJM44 and IN-LXT69 in tissues and milk and aminocyclopyrachlor in muscle were < 0.01 mg/kg at all sampling intervals and doses.

Aminocyclopyrachlor residues in milk were < 0.01 mg/kg for the 73 ppm dose group and most of the samples for the 160 ppm dose group. The maximum daily mean residues were 0.024 mg/kg for the 454 ppm dose group and 0.077 mg/kg for the 1594 ppm dose group.

In kidney mean aminocyclopyrachlor residues were 0.12, 0.31, 0.34 and 0.98 mg/kg for the 73, 160, 454 and 1594 ppm dose groups respectively. Mean residues liver residues were 0.039, 0.042, 0.049 and 0.096 mg/kg and mean fat residues were < 0.01, 0.015, 0.062 and 0.46 mg/kg for the 73, 160, 454 and 1594 ppm dose groups respectively.

Animal commodity maximum residue levels

Dietary burden calculations for beef cattle and dairy cattle and poultry are provided below. The dietary burdens were estimated using the OECD diets listed in Appendix IX of the 2009 edition of the FAO Manual.

Potential cattle feed items include: grass and grass hay.

Summary of livestock dietary burden (ppm of dry matter diet)

	US-Canada		EU		Australia		Japan	
	max	mean	Max	mean	Max	Mean	Max	Mean
Beef cattle	9	7.2	41.5	37.2	81	74.5	21.2	20.4
Dairy cattle	36.4	33.5	48.6	44.7	81 ^a	74.5 ^b	44.3	35.6
Broilers	0	0	0	0	0	0	0	0
Layers	0	0	8.1 ^c	7.4 ^d	0	0	0	0

^a Highest maximum beef or dairy cattle dietary burden suitable for MRL estimates for mammalian meat and milk

^b Highest mean beef or dairy cattle dietary burden suitable for STMR estimates for mammalian meat and milk

^c Highest maximum poultry dietary burden suitable for MRL estimates for poultry meat and eggs

^d Highest mean poultry dietary burden suitable for STMR estimates for poultry meat and eggs

Animal commodity maximum residue levels

A lactating dairy cow feeding study was made available to the Meeting. A review of the laboratory animal and lactating goat metabolism studies showed that DPX-KJM44 is rapidly converted to

aminocyclopyrachlor and significant differences are not expected in residues arising from dosing with DPX-KJM44 or aminocyclopyrachlor. The meeting decided the DPX-KJM44 feeding study could be used to estimate aminocyclopyrachlor residues in meat, edible offal and milk and agreed that in estimating residues levels, the feed levels should be expressed in terms of aminocyclopyrachlor acid equivalents.

The calculations used to estimate highest total residues for use in estimating maximum residue levels, STMR and HR values are shown below.

	Feed level (ppm) for milk residues	Residues (mg/kg) in milk	Feed level (ppm) for tissue residues	Residues (mg/kg) in			
				Muscle	Liver	Kidney	Fat
MRL beef or dairy cattle							
Feeding study ^a	68.5 (73) ^c	< 0.01	68.5 (73) ^c	< 0.01	0.064	0.17	0.015
	150 (160) ^c	0.012	150 (160) ^c	< 0.01	0.082	0.4	0.04
Dietary burden and high residue	81	0.01	81	< 0.01	0.067	0.21	0.019
STMR beef or dairy cattle							
Feeding study ^b	68.5 (73) ^c	< 0.01	68.5 (73) ^c	< 0.01	0.039	0.12	0.01
	150 (160) ^c	< 0.01	150 (160) ^c	< 0.01	0.042	0.31	0.015
Dietary burden and residue estimate	74.5	< 0.01	74.5	< 0.01	0.039	0.13	0.01

^a highest residues for tissues and mean residues for milk

^b mean residues for tissues and mean residues for milk

^c feeding level expressed as acid equivalents = aminocyclopyrachlor, figure in brackets is feed level expressed in terms of DPX-KJM44

The Meeting estimated the following STMR values: milk 0.01 mg/kg; muscle 0.01 mg/kg; 0.039 mg/kg for liver and 0.13 mg/kg for kidney and fat 0.01 mg/kg.

The Meeting estimated the following maximum residue levels: milk 0.02 mg/kg; meat (mammalian except marine mammals) 0.01 mg/kg, fat 0.03 mg/kg and edible offal 0.3 mg/kg.

No information on residues of aminocyclopyrachlor in poultry were available to the meeting, therefore no maximum residue levels can be estimated for poultry commodities. However, Europe was the only region for which the poultry dietary burden was greater than zero. As aminocyclopyrachlor is not approved for use in Europe, the meeting considered there is no likelihood of residues in poultry commodities.

RECOMMENDATIONS

On the basis of the data obtained from supervised residue trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of the residue (for compliance with MRL and estimation of dietary intake) for animal and plant commodities: *Aminocyclopyrachlor*

The residue is not fat soluble.

Commodity		Recommended MRL (mg/kg)		STMR or STMR-P (mg/kg)	HR, HR-P, highest residue (mg/kg)
CCN	Name	New	Previous		
MO 0105	Edible offal (mammalian)	0.3		0.039Liver 0.13Kidney	
MF 0100	Mammalian fats	0.03		0.01	
	Grass forage			74.5 dw	81 dw
AS 0162	Hay and fodder (dry) of grass	150			
MM 0095	Meat (from mammals other than marine mammals)	0.01		0.01	
ML 0106	Milks	0.02		0.01	

dw = dry weight basis

Table of recommendations animal feeds.

Commodity		Recommended MRL (mg/kg)		STMR or STMR-P (mg/kg)	HR, HR-P, highest residue (mg/kg)
CCN	Name	New	Previous		
	Grass forage			74.5 dw	81 dw

dw = dry weight basis

DIETARY RISK ASSESSMENT

Long-term intake

The WHO Panel of the 2014 JMPR established an Acceptable Daily Intake (ADI) of 0-3 mg/kg bw for aminocyclopyrachlor.

The evaluation of aminocyclopyrachlor resulted in recommendations for MRLs and STMR values for raw and processed commodities. Where data on consumption were available for the listed food commodities, dietary intakes were calculated for the 17 GEMS/Food Consumption Cluster Diets.

The IEDIs in the seventeen Cluster Diets, based on the estimated STMRs were 0% of the maximum ADI (3 mg/kg bw). The Meeting concluded that the long-term intake of residues of aminocyclopyrachlor from uses that have been considered by the JMPR is unlikely to present a public health concern.

Short-term intake

The Meeting decided that an ARfD is unnecessary. The Meeting therefore concluded that the short-term intake of residues of aminocyclopyrachlor is unlikely to present a public health concern.

BENZOVINDIFLUPYR (261)

First draft prepared by Ms T. van der Velde-Koerts, Centre for Nutrition, Prevention and Health Services (VPZ), National Institute for Public Health and the Environment (RIVM), The Netherlands

EXPLANATION

Benzovindiflupyr was scheduled for residue evaluation as a new compound by the 2014 JMPR at the Forty-fifth Session of the CCPR (2013). The toxicological review was conducted in 2013, which established an ADI of 0–0.05 mg/kg bw and an ARfD of 0–0.1 mg/kg bw. Additional toxicological data were provided for the metabolites SYN546039 and SYN545720. Benzovindiflupyr was defined by the WHO panel as the only toxicologically significant compound in animals, plants and the environment.

Benzovindiflupyr is a broad-spectrum fungicide belonging to the chemical class of pyrazole carboxamides. Benzovindiflupyr acts as an inhibitor of the fungal complex II respiratory chain, where it inhibits the succinate dehydrogenase enzyme (succinate dehydrogenase inhibitor, SDHI) by blocking the ubiquinone-binding sites in the mitochondrial complex.

The Meeting received information from the manufacturer on identity, metabolism, storage stability, residue analysis, use pattern, residues resulting from supervised trials on soya beans, fate of residue during processing, and livestock feeding studies.

IDENTITY

ISO common name:	benzovindiflupyr
Chemical name	
IUPAC:	N-[(1RS,4SR)-9-(dichloromethylene)-1,2,3,4-tetrahydro-1,4-methanonaphthalen-5-yl]-3-(difluoromethyl)-1-methylpyrazole-4-carboxamide. In the IUPAC convention the symbol 1RS,4SR represents a racemic mixture of 1R,4S and 1S,4R [Syngenta, 2014b],
CAS:	1H-pyrazole-4-carboxamide, N-[9-(dichloromethylene)-1,2,3,4-tetrahydro-1,4-methanonaphthalen-5-yl]-3-(difluoromethyl)-1-methyl-
CAS Registry No:	1072957-71-1
CIPAC No:	-
Synonyms and trade names:	SYN545192; CSCD064398; N-[(1RS,4SR)-9-(dichloromethylidene)-1,2,3,4-tetrahydro-1,4-methanonaphthalen-5-yl]-3-(difluoromethyl)-1-methyl-1H-pyrazole-4-carboxamide (name used in the WHO monograph) N-[(1RS,4SR)-9-(dichloromethylene)-1,2,3,4-tetrahydro-1,4-methanonaphthalen-5-yl]-3-(difluoromethyl)-1-methyl-1H-pyrazole-4-carboxamide; N-[9-(dichloromethylene)-1,2,3,4-tetrahydro-1,4-methanonaphthalen-5-yl]-3-(difluoromethyl)-1-methyl-1H-pyrazole-4-carboxamide; N-[11-(dichloromethylene)tricyclo[6.2.1.0 ^{2,7}]undeca-2,4,6-trien-3-yl]-3-(difluoromethyl)-1-methyl-1H-pyrazole-4-carboxamide 3-difluoromethyl-1-methyl-1H-pyrazole-4-carboxylic acid ((1RS,4SR)-9-dichloromethylene-1,2,3,4-tetrahydro-1,4-methanonaphthalen-5-yl)-amide SMILES: <chem>Cn1cc(c(n1)C(F)F)C(=O)Nc2cccc3c2C4CCC3C4=C(Cl)Cl</chem>
Structural formula:	Structure for PAI (99.4% purity) confirmed by UV-VIS, IR, ¹ H-NMR and MS [Oggenfuss, 2011, SYN545192_10087]

		or
		or
Molecular formula:	C ₁₈ H ₁₅ Cl ₂ F ₂ N ₃ O	
Molecular weight:	398.2 g/mol	

Benzovindiflupyr contains chiral centres at both the bridgehead carbon atoms potentially resulting in four stereoisomeric forms. However, the bicyclic ring is a rigid structure, and therefore only two stereoisomers exist (an enantiomeric pair). Technical benzovindiflupyr consists of a racemic mixture of two enantiomers SYN546526 and SYN546527, at a ratio of 50:50. SYN546526 represents N-[(**1R,4S**)-9-(dichloromethylene)-1,2,3,4-tetrahydro-1,4-methanonaphthalen-5-yl]-3-(difluoromethyl)-1-methylpyrazole-4-carboxamide. SYN546527 represents N-[(**1S,4R**)-9-(dichloromethylene)-1,2,3,4-tetrahydro-1,4-methanonaphthalen-5-yl]-3-(difluoromethyl)-1-methylpyrazole-4-carboxamide [Syngenta, 2014b]. The enantiomers were unresolved using the chromatographic solvent systems in the reports. Both enantiomers were measured within the same single chromatographic peak and they were collectively reported as one concentration [Syngenta 2014b]. Both enantiomers are fungicidally active. No toxicological studies were performed on the individual enantiomers.

PHYSICAL AND CHEMICAL PROPERTIES

Pure active ingredient (PAI)

Parameter	Result	References	Guidelines/method
Purity	99.4% (PAI)		
Appearance:	odourless white powder at 25 °C purity 99.4% (PAI)	[Das, 2010a, SYN545192_10057]	organoleptic and visual assessment
Vapour pressure:	measured 2.0×10^{-5} Pa at 70 °C 7.6×10^{-5} Pa at 80 °C 3.9×10^{-4} Pa at 90 °C extrapolated 3.2×10^{-9} Pa at 25 °C	[Weissenfeld, 2010, SYN545192_10067]	OECD 104 gas saturation method

Parameter	Result	References	Guidelines/method
	purity 99.4% (PAI) The vapour pressure at 25 °C was extrapolated from high temperature measurements to allow the completion of the various experiments within a suitable period of time [Syngenta, 2014a, SYN545192_10468].		
Melting point:	148.4 °C ± 0.5 °C purity 99.4% (PAI)	[Kühne, 2010b, SYN545102_10060]	OECD 102 thermal analysis (differential scanning calorimetry)
Octanol/water partition coefficient:	$\log K_{ow} = 4.3 \pm 0.3$ at 25 °C ± 1 °C in pure water (pH 6.59) purity 99.4% (PAI) The $\log K_{ow}$ value calculated from the ratio of solubilities (19 g/L: 0.98 mg/L) is 4.3 which agrees well with the value determined using the OECD 107 [Syngenta, 2014a, SYN545192_10468].	[Vijayakumar, 2010b, SYN545102_10070]	OECD 107 shake flask method
Solubility:	0.98 mg/L RSD 8.9% in pure water at pH 6.7–7.5, at 25 °C purity 99.4% (PAI)	[Vijayakumar, 2011, SYN545102_10072]	OECD 105 column elution method
	solubility at 25 °C ± 0.5 °C purity 97.7% (TGAI) Acetone 350 g/L Dichloromethane 450 g/L Ethyl acetate 190 g/L Hexane 270 g/L Methanol 76 g/L Octanol 19 g/L Toluene 48 g/L No data are available for PAI [Syngenta, 2014a, SYN545192_10468].	[Vijayakumar, 2010a, SYN545102_10066]	CIPAC MT 157.3 flask method
Specific gravity:	1.466 g/cm ³ at 20.4 °C $D_{4}^{20} = 1.466$ (rel. density) purity 99.4% (PAI)	[Kühne, 2010d, SYN545192_10068]	OECD 109 gas comparison pycnometer
Hydrolysis in water:	0.35 mg/L [pyrazole-¹⁴C]-SYN545192 (radiochemical purity 98.7%) Hydrolytically stable in sterile buffer at pH 4, 5, 7 and 9 for up to 5 days at 50 °C in the dark. Stability was confirmed at all pH values for up to 30 days at 25 °C. No degradation products were detected by HPLC, TLC or HPLC-MS.	[Lowrie, 2009, SYN545192_10010]	OECD 111
Photolysis in water:	0.3 mg/L [phenyl- ¹⁴ C]-SYN54519 (purity 98.5%) or 0.3 mg/L [pyrazole- ¹⁴ C]-SYN545192 (purity 98.6%)	[Wardrope, 2011, SYN545192_10132]	OECD 316 EPA 161-2 OPPTS 835.224

Parameter	Result	References	Guidelines/method
	Moderate decline of parent to 74.8% TAR or 74.4% TAR for phenyl or pyrazole labels, respectively, after 15 days in sterile buffer at pH 7 at 25 °C ± 1 °C using a xenon arc lamp at 53.1 W/m² continuously DT₅₀ = 44.2 days (average of both labels). Photodegradation of the phenyl labelled compound resulted in the production of multiple polar components (11.5% TAR) and diffuse radioactivity (6.3% TAR). No individual compound or region accounted for > 5% TAR. For the pyrazole label, the most significant degradates were NOA449410 at 8.5% TAR and SYN508272 at 2.6% TAR, both at 15 DAT. No other single degradate was observed at > 5% TAR. Photodegradation resulted in the production of ¹⁴CO₂, which reached a maximum mean value of 6.3% TAR in the phenyl samples and 1.1% TAR in the pyrazole samples at 15 DAT.		
Dissociation constant:	no dissociation at pH 2.0–12.0 purity 99.4% (PAI)	[Kühne, 2010e, SYN545192_10069]	OECD 112 titration method

Technical material (TGAI)

Parameter	Result	References	Guidelines
Purity	97.7% (TGAI)		
Appearance:	odourless off-white powder at 25 °C purity 97.7% (TGAI)	[Das, 2010b, SYN545192_10058]	organoleptic and visual assessment
Density:	1.42 g/cm ³ at 22.0 ± 1.0 °C purity 97.7% (TGAI)	[O'Connor, 2013a, SYN545192_10444]	OECD 109 gas comparison pycnometer
Melting range:	145.7 °C (418.9 K), with RSD 0.07% purity 97.7% (TGAI)	[O'Connor, 2013b, SYN545192_10445]	OECD 102 differential scanning calorimetry
Thermal stability	PAI (purity 99.4%) decomposition started at about 285 °C before boiling occurred. No data are submitted for the TGAI.	[Kühne, 2010a, [SYN545192_10059]]	OECD 103, thermal analysis (differential scanning calorimeter)
Stability:	TGAI (purity 97.7%) is stable in nitrogen or air at room temperature.	[Williams, 2011, SYN545192_10088]	OECD 113 differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA)

Formulations

Formulation authorised for use: WG (150 g/kg benzovindiflupyr + 300 g/kg azoxystrobin).

Benzovindiflupyr has not been evaluated by JMPS and therefore no FAO specifications for technical and formulated benzovindiflupyr have been published.

METABOLISM AND ENVIRONMENTAL FATE

The Meeting received information on the fate of benzovindiflupyr in livestock, plant commodities, soil and rotational crops. The test items used in the studies were benzovindiflupyr ^{14}C uniformly labelled in the phenyl ring or at the 5-position of the pyrazole ring as shown in Figure 1.

Figure 1 Benzovindiflupyr ^{14}C labelled in the phenyl ring or the pyrazole ring

Animal metabolism

The Meeting received information on the metabolic fate of benzovindiflupyr in ruminants (lactating goats) and poultry (laying hens). The metabolism in laboratory animals was summarized and evaluated by the WHO panel of the JMPR in 2013.

Lactating goats

One lactating goat (Saanen × Toggenburg) per radiolabel was dosed orally once daily for 7 consecutive days with a gelatin capsule containing [phenyl-¹⁴C]-benzovindiflupyr or [pyrazole-¹⁴C]-benzovindiflupyr [Green, 2012, SYN545192_10184 and additional info in Syngenta, 2014c]. The actual mean daily dose administered was 41 (range 34–50) and 32 (range 30–34) ppm in the dry feed for the phenyl and pyrazole label, respectively. Average feed consumption was 1.5 kg/animal (phenyl label) and 1.9 kg/animal (pyrazole label experiment) as dry weight feed. Average dose rates were 0.89 and 0.98 mg/kg bw/day for the phenyl and pyrazole label, respectively. The age of the goats was 3.0 and 4.5 years for the phenyl and pyrazole label, respectively. Body weights were 70 and 63 kg at the start of the study and 66 and 59 kg at the end of the study for the phenyl and pyrazole label, respectively. Milk was collected twice daily; urine and faeces were collected once daily. Average milk production during application was 2.5 and 2.1 kg/day for the phenyl and pyrazole label experiments, respectively. Aliquots of the PM and AM milk were mixed and this composite 24 h sample was used to generate cream and skimmed milk for that time period following centrifugation. The goats were sacrificed approximately 12 hours after the administration of the final dose and liver, kidney, muscle (hindquarter, forequarter and tenderloin), fat (subcutaneous, omental and perirenal), blood, GI tract and contents, bile were taken post mortem. Samples were stored frozen at –20 °C for 82–139 days until analysis.

Homogenised samples were analysed by combustion LSC. The mean total recovery of the dosed radioactivity was 90% and 86% for the goats dosed with phenyl and pyrazole radiolabelled forms, respectively. The majority of the radioactivity was recovered in faeces (79%/73% TAR, phenyl/pyrazole). The remainder of the dose was recovered in urine (4.5%/5.2% TAR phenyl/pyrazole), GI tract contents (6.8%/7.2% TAR), cage wash (< 0.28% TAR), milk (< 0.16% TAR) and liver (0.33%/0.22% TAR), while only very low levels were found in kidney, muscle, blood or fat (≤ 0.01% TAR each).

Total radioactive residues are summarised in Table 2. The highest radioactivity concentrations in edible tissues were found in the liver (1.3/0.70 mg/kg eq), kidney (0.28/0.18 mg/kg eq), followed by fat (0.098/0.070 mg/kg eq) and muscle (0.070/0.032 mg/kg eq). Total radioactive residues in milk from the phenyl label dosed goat reached a plateau concentration of approximately 0.046 mg/kg eq following 96 hours dosing. Total radioactive residues in milk from the pyrazole label dosed goat reached a plateau concentration of approximately 0.035 mg/kg eq following 72 hours dosing. Residue levels in cream and skimmed milk derived from combined PM and AM milk samples (24 hour samples) from within the plateau milk residue period are summarised in Table 3. The ratio of cream total radioactive residue to skimmed milk total radioactive residue ranged from 3.7:1 to 4.8:1 in all analysed samples of both radiolabelled experiments except one sample (phenyl: 144 hour sampling) where the ratio was larger (12.2:1). No explanation for the increase in ratio in this single sample was evident. No constituent ¹⁴C-residue analysis of the separated cream and aqueous (whey) fractions was undertaken [Syngenta 2014b].

Homogenised samples of liver, kidney and composite muscle were extracted sequentially with acetonitrile (1×), acetonitrile/water 4:1 v/v (1–4×), acetonitrile/water 3:7 v/v (1–2×), water (1×) and acetonitrile (1×). Composite fat was extracted first with dichloromethane (1×) and subsequently with the other solvents. Whole milk (144 hrs) was extracted with dichloromethane (3×), ethyl acetate (2×) and acetone (1×). Extracts and remaining solids were analysed by (combustion) LSC. Extracted residues were, where appropriate, combined and fractionated by liquid/liquid partition. Liver and kidney extracts were subject to β-glucuronidase (pH 5, 37 °C, 18 hrs) to cleave glucuronide and sulphate conjugates and subsequently partitioned with ethyl acetate. Fractions containing significant radioactive residues were subject to TLC with bio-imaging analysis to enable quantification and identification of residues. Residues were identified by co-chromatography with authentic reference standards for parent, SYN546206, SYN546039, SYN546040, SYN546041, SYN546042, SYN546360, SYN546422, SYN508272, NOA449410 and SYN545720.

Extractability of the radioactive residues was ≥ 94% TRR except that of liver (78–89% TRR). Identified radio-components present in extracted residues are summarised in Table 4.

Comparison of 2D-TLC chromatograms of pre- and post-hydrolysis fractions in liver and kidney shows that the released ^{14}C -exocons after hydrolysis originate predominantly from radio-components present on the origin (baseline) of the chromatogram. Unassigned radio-components that chromatograph away from the origin are unlikely to be conjugated metabolites for two reasons:

i) The solvent systems employed in the normal phase 2D-TLC analyses are quite non-polar in nature and the sulphate and glucuronide conjugated metabolites (or other logical conjugates) are intrinsically quite polar in nature and it would therefore be expected that those conjugates would be located on or very close to the origin of these chromatograms,

ii) Significant proportions of the “unassigned” chromatographed radio-components chromatograph well away from the origin of the 2D-chromatograms and in the region of identified “non-conjugated” and non-polar metabolites. The unassigned radio-components are therefore too non-polar to be characteristic of the conjugates characterised in i) above. [Syngenta, 2014c]

Solids remaining after extraction from liver (phenyl PES: 11% TRR, pyrazole PES: 22% TRR,) were further characterised in three parallel experiments. Incubation under mild acid hydrolysis conditions (0.1 M HCl, 37 °C, 4 hrs) rendered only very minor proportions ($\geq 0.9\%$ TRR) of the PES soluble. Following protein solubilisation using sodium dodecyl sulphate (SDS) and then a protein precipitation step, 6.8% TRR (phenyl) and 15% TRR (pyrazole) was shown to be associated with protein. Protease digestion (pH 7, 37 °C, 24 hrs + 48 hrs) solubilised almost all the PES. TLC analysis of the protease hydrolysates showed them to comprise a very complex mixture of highly polar metabolites of which no single one accounted for $> 2.0\%$ TRR (phenyl) or $> 4.4\%$ TRR (pyrazole).

Initial radio-component profiles of fractions of liver and whole milk samples were produced within 82–131 days of sacrifice. While there is no information on the first 82 days of storage, re-analysis of the milk fractions after completion of the analyses (730 days of total storage) demonstrated the radio-component profiles not to have changed significantly during the interim period of frozen storage. Re-analysis of the liver fractions after 694 days of total storage showed a different profile, indicating some change in composition during storage.

Note: The identified metabolite levels in muscle, fat and milk relate only to the free form of the metabolites. Since the unassigned fractions of these matrices were not subjected to glucuronidase treatment, it is not clear how much conjugated metabolites need to be added to these figures. It will however i) not be more than the sum of the “unassigned and baseline” figures and ii) in reality be closer to the polar “baseline” only figure due to the predominantly non-polar character of the “unassigned” residues precluding them from being conjugates.

Table 2 Total Radioactive Residues and extractability in samples from goats treated with [^{14}C]benzovindiflupyr

Radiolabel	Sample	Extracted Radioactivity		Post-extracted solids		TRR ^a

() = The values within parentheses indicate the proportion of the TRR that is in the conjugated forms. Values without parentheses are the sum of both the free and conjugated forms.

^a TRR determined by summation of radioactivity present in the extracts and solids following solvent extraction

^b Unassigned radio components which chromatographed away from the origin in normal phase 2D-TLC.

Milk comprising at least 4–8 discrete components, no single one ≥ 6.5% TRR (≥ 0.003 mg/kg eq)

Liver post-enzyme hydrolysis, comprising at least eight discrete components, no single one ≥ 0.7% TRR (≥ 0.006 mg/kg eq).

Kidney post-enzyme hydrolysis comprising at least 10–19 discrete components, including a poorly resolved region of 14 components which accounted for a total of 8.5% TRR (0.016 mg/kg). All other unidentified components were < 1.3% TRR (< 0.004 mg/kg eq).

Muscle, comprising at least 2–3 discrete components, no single one ≥ 5.2% TRR (≥ 0.002 mg/kg eq).

Fat, comprising at least 2–4 discrete components, no single one ≥ 6.2% TRR (≥ 0.004 mg/kg eq).

^c Polar material on the origin of the radio-chromatogram using normal phase 2D-TLC

^d Extracted residues in fractions that were not analysed because levels of radioactivity were too low for analysis

Milk (2 fractions), No single fraction comprised $\geq 6.9\%$ TRR (≥ 0.002 mg/kg eq)

Liver (3–4 fractions), No single fraction comprised $\geq 2.4\%$ TRR (≥ 0.030 mg/kg eq)

Kidney (3 fractions), No single fraction comprised $\geq 1.7\%$ TRR (≥ 0.004 mg/kg eq)

Muscle (5 fractions), No single fraction comprised $\geq 2.4\%$ TRR (≥ 0.002 mg/kg eq).

Fat (4 fractions), No single fraction comprised $\geq 1.6\%$ TRR (≥ 0.001 mg/kg eq).

^e Radioactivity remaining in the solids after extraction

^f The presence of SYN546360 in goat bile was shown by HPLC-MS. Its location in 2D-TLC chromatograms (the primary technique used for quantitative analysis of Milk and Tissue fractions) was not established in the goat metabolism study. However comparison of goat 2D-TLC chromatograms for milk and goat tissue fractions with those of the rat biotransformation study (where a metabolite standard of SYN546360 was shown to chromatograph between SYN546039 and SYN546206) demonstrated that either no residues or if present only a very minor residue (Goat liver: 0.4% TRR; 0.005 mg/kg eq) could be attributed to this metabolite. Its presence in milk and goat tissues can therefore be assumed to be negligible [Syngenta, 2014b].

Laying hens

Five laying hens (ISA Warren) per radiolabel were dosed orally once daily for 14 consecutive days via gelatin capsules containing [phenyl- ^{14}C]-benzovindiflupyr or [pyrazole-5- ^{14}C]-benzovindiflupyr [Lowrie and Kadow, 2012, SYN545192_10170 and additional information in Syngenta, 2014c]. The actual mean daily dose administered based on measured feed consumption of individual birds was 16–20 and 17–20 ppm in the dry feed, for the phenyl and pyrazole experiments, respectively. Average feed consumption ranged from 0.13–0.15 kg/animal (phenyl treatment) and 0.12–0.14 kg/animal (pyrazole experiment) on dry weight basis. Body weights ranged from 1.6–1.9 kg at the start and 1.7–2.1 kg at the end of the dosing period. Average dose rates were 1.4 mg/kg bw/day for the phenyl and pyrazole labels, each. Hens were pullets (young hens < 1 year old and greater than 23 weeks) and demonstrated good egg laying performance. Excreta were collected daily; eggs were collected twice daily. Eggs were separated into yolk and white. The hens were sacrificed approximately 12 hours after the administration of the final dose and liver, kidney, leg and thigh muscle, breast muscle, peritoneal fat, subcutaneous fat with skin attached, blood, bile, partially formed eggs, carcass and GI tract and contents were taken post mortem. Samples were stored frozen at -20°C for 314–426 days until analysis.

Homogenised samples were analysed by combustion LSC. The kidneys, carcass and bile samples were not analysed. The average recovery of radioactivity was 88% and 93% TAR from birds of the phenyl and pyrazole label experiment, respectively. Of this on average 88% and 92% TAR was accountable in the hen excreta plus cage wash, while 0.28%/1.1% TAR was found in the gastrointestinal tract contents, 0.10%/0.13% TAR in egg yolks + whites, < 0.04% in liver, < 0.02% in muscle samples, < 0.01% in fat samples.

Total radioactive residues are summarised in Table 5. The highest radioactivity concentrations in edible tissues were found in the liver (0.19/0.25 mg/kg eq), followed by fat (0.033/0.045 mg/kg eq) and muscle (0.025/0.036 mg/kg eq). Mean total radioactive residues in egg yolks achieved a plateau concentration of 0.17 mg/kg eq (phenyl label) after 240 hrs dosing and 0.18 mg/kg eq (pyrazole label) after 168 hours dosing. Mean total radioactive residues in egg whites achieved a plateau concentration of 0.04 mg/kg eq (phenyl label) after 168 hrs dosing and 0.03 mg/kg eq (pyrazole label) after 120 hours dosing.

Homogenised composite samples from the five birds per radiolabel were prepared for liver, fat, muscle, egg yolk and egg white. Sub-samples of liver, composite muscle, and egg white were extracted sequentially with acetonitrile (1 $\times$), acetonitrile/water 4:1 v/v (2–3 $\times$), acetonitrile/water 3:7 v/v (1–4 $\times$), water (1 $\times$) and acetonitrile (1 $\times$). Egg yolk and composite fat with skin were extracted first with dichloromethane (1 $\times$) and subsequently with the other solvents. Extracts and remaining solids were analysed by (combustion) LSC. Extracted residues were, where appropriate, combined and fractionated by liquid/liquid partition. Aqueous fractions from liver extracts were subject to β -glucuronidase (pH 5, 37°C , 18 hrs) to cleave glucuronide and sulphate conjugates and subsequently partitioned with diethyl ether. Fractions containing significant radioactive residues were subject to TLC with bio-image analysis to enable quantification and identification of residues. Residues were

identified by chromatographic comparison with authentic synthetic reference standards of parent, SYN546206, SYN546039, SYN546040, SYN546041, SYN546042, SYN546360, SYN508272, NOA449410, SYN545720.

Following solvent extraction, residue extractabilities were $\geq 83\%$ TRR for egg yolk and egg white and 68–73% TRR for skin with subcutaneous fat. Residue extractability was lowest in liver (48–49% TRR) and composite muscle (24–37% TRR). Identified radio-components present in extracted residues are summarised in Table 6.

Comparison of 2D-TLC chromatograms of pre- and post-hydrolysis fractions in liver shows that the released [^{14}C]exocons after hydrolysis originate predominantly from radio-components present on the origin (baseline) of the chromatogram. Unassigned radio-components that chromatograph away from the origin are unlikely to be conjugated metabolites for two reasons:

i) The solvent systems employed in the normal phase 2D-TLC analyses are quite non-polar in nature and the sulphate and glucuronide conjugated metabolites (or other logical conjugates) are intrinsically quite polar in nature and it would therefore be expected that those conjugates would be located on or very close to the origin of these chromatograms,

ii) Significant proportions of the “unassigned” chromatographed radio-components chromatograph well away from the origin of the 2D-chromatograms and in the region of identified “non-conjugated” and non-polar metabolites. The unassigned radio-components are therefore too non-polar to be characteristic of the conjugates characterised in i) above. [Syngenta, 2014c]

Solids remaining after extraction from liver (PES 51–52% TRR) and muscle (PES 63–76%TRR) in both radiolabelled experiments were further characterised in three parallel experiments. Liver and muscle PES were characterised to be similar in nature. Incubation under mild acid hydrolysis conditions (0.1 M HCl, 37 °C, 4 hrs) rendered only very minor proportions of the PES soluble. Following protein solubilisation using sodium dodecyl sulphate solution (SDS) and then a protein precipitation step, almost all of PES were shown to be associated with protein. Protease digestion (pH 7, 37 °C, 24 hrs + 48 hrs) solubilised almost all the PES. Analysis of protease hydrolysates showed them to comprise almost entirely of radio-components that were highly polar in nature.

All tissues, egg yolk and egg white samples were initially extracted and a 2D-TLC radio-component profile obtained from the principal residue-containing fractions within 104–107 days of sacrifice. The same fractions were again analysed using the same 2D-TLC conditions at the end of the analytical phase of the study (after 413–559 days of total storage). While there is no information on the first 104 days of storage, the results demonstrated that there had been no significant changes in the respective radio-component profiles during the interim storage period.

Note: The identified metabolite levels in muscle, skin/fat, egg yolk and egg white relate only to the free form of the metabolites. Since the unassigned fractions of these matrices were not subjected to glucuronidase treatment, it is not clear how much conjugated metabolites need to be added to these figures. It will however i) not be more than the sum of the “unassigned and baseline” figures and ii) in reality be closer to the polar “baseline” only figure due to the predominantly non-polar character of the “unassigned” residues precluding them from being conjugates.

Egg white, comprising at least 6–10 discrete components, no single one $\geq 4.9\%$ TRR (≥ 0.002 mg/kg eq)

Muscle, comprising at least 5–6 discrete components, no single one $\geq 3.7\%$ TRR (≥ 0.001 mg/kg eq)

Fat/skin, comprising at least 4–6 discrete components, no single one $\geq 6.0\%$ TRR (≥ 0.002 mg/kg eq)

^c Liver unassigned radio-components in pre-enzyme hydrolysis organo soluble fraction, which chromatographed away from the origin in normal phase 2D-TLC, comprising at least 8–11 discrete components, no single one $\geq 0.6\%$ TRR (≥ 0.001 mg/kg eq)

^d Liver unassigned radio-components in post enzyme hydrolysis organo soluble fraction which chromatographed away from the origin in normal phase 2D-TLC, comprising at least 10–16 discrete components, no single one $\geq 0.4\%$ TRR (≥ 0.001 mg/kg eq)

^e Liver unassigned highly polar radio-components in post enzyme hydrolysis water soluble partition phase, which

remained at the origin in normal phase 1D-TLC, with a small proportion moving slightly in a more polar solvent system normal phase 1D-TLC.

^f Polar material on origin of the radio-chromatogram using normal phase 2D-TLC

^g Diffuse areas of radioactivity within the chromatogram which cannot be assigned to discrete radioactive components

^h Extracted residues in fractions that were not analysed because levels of radioactivity were too low for analysis.

Liver (2 fractions), no single fraction comprised $\geq 1.4\%$ TRR (≥ 0.003 mg/kg eq)

Egg yolk (4 fractions), no single fraction comprised $\geq 6.1\%$ TRR (≥ 0.011 mg/kg eq)

Egg white (4 fractions), no single fraction comprised $\geq 1.2\%$ TRR (≤ 0.001 mg/kg eq)

Muscle (4 fractions), no single fraction comprised $\geq 1.5\%$ TRR (≤ 0.001 mg/kg eq)

Fat/skin (4 fractions), no single fraction comprised $\geq 1.6\%$ TRR (≤ 0.001 mg/kg eq)

ⁱ Post extraction solids

^j A reference standard of SYN546422 was not chromatographed in the hen study fractions. However, the location of this metabolite in 2D-TLC is very characteristic as it consistently chromatographs between SYN546040 and SYN546042 (just below SYN546040) in the goat metabolism study. In the hen metabolism study no radio-components were observed in this region of the corresponding 2D-TLC analyses of egg and tissue fractions. It was therefore concluded that SYN546422 was not present in the hen egg and tissues [Syngenta, 2014b].

Overview of the metabolic pathway in livestock

Metabolism studies conducted with ruminants (lactating goats) and poultry (laying hens) and based on oral dosing, show that the metabolic pathways in ruminants and poultry are similar. Metabolism observed arose via:

- N-demethylation of the pyrazole ring to form SYN546206
- mono hydroxylation on the alicyclic ring to form the SYN546039 and SYN546040 isomers
- mono hydroxylation on the phenyl ring to form SYN546360
- N-demethylation of the pyrazole ring and subsequent mono hydroxylation of the alicyclic ring or mono hydroxylation of the alicyclic ring and subsequent N-demethylation of the pyrazole ring to form SYN546041 and SYN546042 isomers
- oxidative opening of the alicyclic ring to form SYN546422 (ruminants only)
- cleavage between the pyrazole and phenyl rings of parent or mono hydroxylated metabolites SYN546039/SYN546040 to form SYN508272
- conjugation of N-demethylated metabolite SYN546206, predominantly as its glucuronide conjugate
- conjugation of dihydroxylated metabolite SYN546422, predominantly as its glucuronide and/or sulphate conjugate (ruminants only)
- conjugation of mono hydroxylated metabolites SYN546039/SYN546040 and SYN546360, predominantly as their glucuronide and/or sulphate conjugates
- conjugation of mono hydroxylated N-demethylated metabolites SYN546041/SYN546042, predominantly as their glucuronide and/or sulphate conjugates
- conjugation of cleavage metabolite SYN508272 predominantly as its glucuronide conjugate.

a = Identified in hen tissues and eggs and goat bile as a very minor metabolite.

b = Identified in hen and goat commodities as a very minor metabolite

c = Identified in goat commodities only

Dotted arrows indicate an alternative pathway to continuous arrows.

All metabolites were present in their free (non-conjugated) forms in milk, egg, muscle and fat containing tissues; possible conjugates have not been released in the metabolism study. In liver and kidney all metabolites were present in their free and conjugated forms. The conjugates were characterised as glucuronides and/or sulphate esters.

Figure 2 Metabolic pathway of benzovindiflupyr in livestock

Plant metabolism

The Meeting received information on photolysis on leaves and the metabolic fate of benzovindiflupyr after foliar application on fruits (tomatoes), cereals (wheat) and pulses & oilseeds (soya beans).

Photolysis on leaves

To determine whether leaf photolysis is an appreciable route of degradation, the leaves of six green bean plants were treated topically with an unspecified formulation containing ^{12}C and ^{14}C -pyrazole-labelled-benzovindiflupyr [Syngenta, 2014d]. Four suitable healthy leaves of each plant were marked with a 5 cm diameter circle. The leaves on three plants were sprayed with the formulated material without adjuvant. The leaves on three other plants were sprayed with the formulated materials with adjuvant. Three different treatments were performed:

- The treated leaves of two of the plants (one with and one without adjuvant) were placed underneath artificial sunlight derived from a xenon lamp irradiation source. The treated leaves were placed as flat as possible underneath a quartz sheet and illuminated with a 14 hr light and 10 hr dark cycle.
- Two of the plants (one with and one without adjuvant) were placed in the greenhouse with a 14 hr light and 10 hr dark cycle.
- Two of the plants (one with and one without adjuvant) were placed outdoors between 3–10 July 2008, with the treated leaves facing south where possible.

Treated leaves from each plant were sampled at 2 hrs after treatment and at DAT=1, 4 and 7. The leaves underneath the Suntest were scorched brown and dried in some cases, especially at the 7 DAT sampling. Whole leaves were extracted twice with methanol/water (70:30, v/v) and radioactivity in the extracts and remaining solids were quantified by (combustion) LSC.

Extract recoveries were 70–94% TAR, while remaining solids represented 0.1–4.4% TAR. The missing radioactivity was assumed to have been translocated into the areas of the plant and/or lost by evaporation. At DAT =7 total recovery was > 98% TAR.

HPLC chromatograms of the extracts demonstrated very minor degradation in all three situations at DAT=7. The minor degradates formed gave qualitatively similar chromatographic pattern. The highest level of degradation was found on the leaves grown in a greenhouse, either with or without adjuvant.

Metabolism in tomatoes

The metabolic fate of benzovindiflupyr was studied in indoor-grown tomatoes (variety F1 Orange Pixie, a dwarf variety) after four foliar spray applications to the plants [Oddy, 2011, SYN545192_10117]. Two radio-labelled forms were used in the study, [phenyl- ^{14}C]-BVFP and [pyrazole- ^{14}C]-BVFP (see Figure 1). Plants were grown in containers in sandy loam soil. The phenyl and pyrazole test items were applied at an actual rate of $0.138 + 0.132 + 0.129 + 0.128$ kg ai/ha and $0.138 + 0.131 + 0.129 + 0.127$ kg ai/ha, respectively, at weekly intervals. The spray solution was applied as an EC formulation to 6 week old plants (BBCH 71–72) in a spray volume of 600 L/ha using a lance and trigger sprayer with CO_2 propellant to give as even a cover as possible. Mature tomato fruits (176–663 g) were harvested 1 and 14 days after the final application. At each harvest interval fruits were surface washed immediately following sampling by immersing the fruit for 30 sec in acetonitrile (2 $\times$). Samples washes and samples were stored frozen at -18°C for 17–23 days until extraction and 21–22 months until last analysis.

The washed frozen fruit was homogenised and sequentially extracted with acetonitrile (1 $\times$), acetonitrile/water 4/1 v/v (3 $\times$), acetonitrile/water 3/7 v/v (1 $\times$), water (1 $\times$), and acetonitrile (1 $\times$). Radioactivity in wash, extracts and post-extraction solids (PES) was determined by LSC and combustion/LSC. The total radioactive residues (TRR) in tomato fruits taken at 1 and 14 days after the final application are shown in Table 7. The TRRs in the samples derived from the pyrazole experiment were higher than those derived from the phenyl experiment. The majority of the radioactivity (65–79% TRR) could be washed off by acetonitrile. The total extractability of residues into wash and solvents for all samples was $\geq 99\%$ TRR.

Proportionate aliquots of the acetonitrile wash and extracts 1–4 were combined; extracts 5–7 were not analysed further. The combined extracts were concentrated by evaporation and residues were

partitioned into diethyl ether/hexane (3:1, v/v). The resulting organic phase was characterised using 2D-TLC with phosphor image analysis. The remaining aqueous phase was not analysed further. Radiolabelled components were co-chromatographed with authentic reference standards of parent, SYN546206, SYN546039, SYN546040, SYN546041, SYN546042, NOA449410, SYN545720, SYN508272 using two dissimilar solvent systems. Results are shown in Table 8. In total a high level of identification was achieved in all tomato fruits (> 91.8% TRR).

The surface wash was analysed by 2D-TLC at the start and end of the analytical phase of the study to demonstrate storage stability. The original samples were re-analysed at the end of the analytical phase of the study, following 21–22 months of storage. Comparison of the initial and final radiolabelled component profiles obtained showed that no significant change in the profiles had occurred during the interim period of storage. Storage stability data do not exist for the 1 DALT 1 and 14 DALT extracts (confirmed, Syngenta, 2014b). However, since the majority of the radioactive residue (65–79% TRR) is derived from the surface wash, and 90.8–95.1% TRR is identified as parent, this is considered to have no impact on the results of this study.

Metabolism in wheat

The metabolic fate of benzovindiflupyr was studied in indoor-grown spring wheat (variety Tybalt) after two foliar spray application to the plants [Simmonds and Mackenzie, 2011, SYN545192_10136]. Two radiolabelled forms were used in the study, [phenyl-¹⁴C]-BVFP and [pyrazole-¹⁴C]-BVFP (see Figure 1). Plants were grown in containers in sandy loam soil. The phenyl and pyrazole test items were applied at an actual rate of 2 times 0.14 kg ai/ha, at a 35 day interval. The first application was conducted at BBCH 31 and the second at BBCH 69. The spray solution was applied as an EC formulation in a spray volume of 300 L/ha using a lance and trigger sprayer with CO₂ propellant to spray from above. Samples were collected at BBCH 39 (forage, 9 days after the first application), BBCH 77 (hay, 10 days after the second application) and BBCH 89 (mature grain and straw, 40 and 41 days after the second application). The hay samples were laid out in the greenhouse to dry for 4 days. Sample sizes were 0.71–0.91 kg forage, 0.61–0.70 kg hay, 1.2–2.0 kg straw and 2.1 kg grain. Samples were stored frozen at –18 °C for 18–60 days until extraction and 19–23 months until analysis.

Wheat forage, hay and straw were homogenised and sequentially extracted with acetonitrile (1×), acetonitrile/water 4/1 v/v (2×–4×), acetonitrile/water 3/7 v/v (1×), water (1×) and acetonitrile (1×). Wheat grain was homogenised and sequentially extracted with acetonitrile (1×), acetonitrile/water 4/1 v/v (3×) and acetonitrile/water 1/1 v/v (2×). Radioactivity in extracts and post-extraction solids (PES) was determined by LSC and combustion/LSC. The total radioactive residues (TRR) in forage, hay, straw and grain are shown in Table 9. Residue levels derived from the two radiolabelled experiments were generally similar on a commodity basis. The total level of extractability was ≥ 97%TRR for all commodities.

Proportionate aliquots of the acetonitrile and acetonitrile/water (4/1) extracts were combined; the other fractions were not analysed further. The combined extracts were concentrated by evaporation and if necessary partitioned between water and diethyl ether/hexane (3:1, v/v).

All fractions were analysed by 2D-TLC with phosphor image analysis. Identification was conducted by co-chromatography with authentic reference standards of parent, SYN546206, SYN546039, SYN546040, SYN546322, SYN546323, SYN546041, SYN546042, NOA449410, SYN545720, SYN508272 using two dissimilar solvent systems. Results are shown in Table 10.

Selected straw and grain fractions were subjected to hydrolysis procedures involving the use of bovine rumen fluid, pectinase enzyme or mild base followed by pectinase enzyme to release the metabolites and to characterise the nature of the conjugates. Cleavage following pectinase hydrolysis (pH 5, 18 hrs at 30 °C) alone characterised the residue as a glycoside conjugate. Cleavage following mild base (0.05 M NaOH, 18 hrs, room temperature) and pectinase hydrolysis (pH 5, 18 hrs at 30 °C) characterised the residue as malonyl glycoside conjugate. Cleavage following bovine rumen fluid (pH 7, 24 hrs at 39 °C), effected greater hydrolytic conversion compared to pectinase and base pectinase. Hydrolysates were adjusted to pH 2–3 and partitioned into diethyl ether. The remaining aqueous phase was not analysed further. The resulting organic phase was characterised using 2D-TLC. Results

are shown in Table 10. Several of metabolites were present in the free and conjugated form. Significant proportions of the SYN546039 conjugates in straw and grain were characterised as glycoside and malonyl glycoside conjugates. In total > 86% TRR was identified for each commodity.

Combined extracts were analysed by TLC within 1 to 5 months of sample harvest and were analysed again following 19 to 23 months frozen storage to demonstrate storage stability. Comparison of the initial and final radio-component profiles obtained showed no significant change in the profiles had occurred during the interim period of storage.

^a Unassigned radio-components which chromatographed away from the origin in 2D-TLC (normal phase)

Forage, phenyl label: comprising at least 4 discrete components, no single one > 0.6% TRR (> 0.018 mg/kg eq)

Forage, pyrazole label: comprising at least 4 discrete components, no single one > 0.5% TRR (> 0.011 mg/kg eq)

Hay, phenyl label: comprising at least 4 discrete components, no single one > 1.5% TRR (> 0.074 mg/kg eq)

Hay, pyrazole label: comprising at least 4 discrete components, no single one > 1.3% TRR (> 0.083 mg/kg eq)

Straw, phenyl label: comprising at least seven discrete components, no single one ≥ 0.4% TRR (≥ 0.032 mg/kg eq)

Straw, pyrazole label: comprising at least six discrete components, no single one ≥ 0.5% TRR (≥ 0.045 mg/kg eq)

Grain, phenyl label: comprising at least eight discrete components, no single one ≥ 0.8% TRR (≥ 0.001 mg/kg eq)

Grain, pyrazole label: comprising at least seven discrete components, no single one ≥ 0.9% TRR (≥ 0.001 mg/kg eq)

^b Polar material on origin of the radiochromatogram using 2D-TLC (normal phase)

Straw, pyrazole/phenyl label from fraction F4 (≤ 0.8% TRR, ≤ 0.065 mg/kg eq) and F5 (≤ 5.4% TRR, ≤ 0.489 mg/kg eq).

Polar material from phenyl label F5, likely to comprise more than one radio-component. Polar material from pyrazole label F5: Further 2D TLC using a more polar solvent system (2D-TLC SSC) showed this to comprise at least three discrete components no single one of which ≥ 0.9% TRR (≥ 0.081 mg/kg).

^c The remainder comprises diffuse areas of radioactivity within the chromatogram which cannot be assigned to discrete radioactive components.

^d Extracted residues in fractions that were not analysed, because these fractions contained very low levels of radioactivity.

No single fraction comprised > 0.9% TRR (> 0.027 mg/kg eq) in forage, > 0.7% TRR (> 0.044 mg/kg eq) in hay, ≥ 1.7% TRR (≥ 0.154 mg/kg eq) in straw, ≥ 2.5% TRR (≥ 0.002 mg/kg eq) in grains in either radiolabelled experiment.

^e Radioactivity remaining in the debris after extraction with solvent.

Metabolism in soya beans

The metabolic fate of benzovindiflupyr was studied in indoor-grown soya beans (variety S12-C2) after two foliar spray application to the plants [Oddy, 2012, SYN545192_10102]. Two radiolabelled forms were used in the study, [phenyl-¹⁴C]-BVFP and [pyrazole-¹⁴C]-BVFP, subsequently referred to as phenyl and pyrazole test item (see Figure 1). Plants were grown in containers in sandy loam soil. The phenyl and pyrazole test items were applied at an actual rate of two times 0.12–0.13 kg ai/ha, at a 22 day interval. The first application was conducted at BBCH 55–60 and the second at BBCH 75. The spray solution was applied as an EC formulation in a spray volume of 300 L/ha using an automated track sprayer. Commodities were taken at BBCH 70 (forage, 11 days after first application), BBCH 85 (hay, 13 days after second application), and BBCH 89 (mature bean, 30 days after second application). Forage hay samples were left in the greenhouse to air dry for 6 days. Mature soya bean pods were dried for 2 days, after which the seeds were taken from the pods. Samples (0.11 kg fresh forage, 0.10 kg dry hay, 0.25 kg dry seeds) were stored frozen at –15 °C for 20–37 days until extraction and 29–31 months until analysis.

Soya bean forage was homogenised and sequentially extracted with acetonitrile (1×), acetonitrile/water 4:1, v/v (2×), acetonitrile/water 3:7, v/v (1×), water (1×) and acetonitrile (1×). Soya bean hay and beans were homogenised and sequentially extracted with hexane (3×), diethyl ether

(2×), acetonitrile (2×), acetonitrile/water 4:1 v/v (2×–7×), acetonitrile/water 3:7 v/v (1×–2×), water (1×), and acetonitrile (1×). Radioactivity in extracts and post-extraction solids (PES) was determined by LSC and combustion/LSC. Total radioactive residues (TRR) present in the soya bean commodities are shown in Table 11. Residue levels in the soya bean seeds derived from the pyrazole experiment were approximately three times higher than those in the phenyl experiment. The total level of extractability was $\geq 99\%$ TRR (forage), $\geq 98\%$ TRR (hay), $\geq 89\%$ TRR (beans, phenyl experiment) and $\geq 98\%$ TRR (beans, pyrazole experiment).

For soya bean forage proportionate aliquots of the acetonitrile and acetonitrile/water 4:1, v/v, extracts were combined and the resulting fraction ($\geq 98\%$ TRR) was analysed by 2D-TLC. An aliquot of the combined extracts was subjected to hydrolysis procedures involving the use of bovine rumen fluid (pH 7, 24 hrs, 39 °C) to release the metabolites. The hydrolysate was analysed by 2D-TLC.

For soya bean hay proportionate aliquots of hexane, diethyl ether and acetonitrile extracts were combined and resulting fractions containing 76% TRR (phenyl experiment) and 67% TRR (pyrazole experiment) were analysed by 2D TLC. Similarly, proportionate aliquots of the acetonitrile/water extracts were combined and the resulting fractions containing 18% TRR (phenyl experiment) and 26% TRR (pyrazole experiment) were analysed by 2D TLC and 1D-TLC. An aliquot of the combined acetonitrile/water extracts was subjected to hydrolysis procedures involving the use of bovine rumen fluid, pectinase enzyme (pyrazole experiment only), and mild base followed by pectinase enzyme (pyrazole experiment only) to release the metabolites and to characterise the nature of the conjugates. The hydrolysates were analysed by 2D-TLC.

Cleavage following bovine rumen fluid (pH 7, 24 hrs at 39 °C) was the most effective at hydrolysing baseline conjugate material and effected greater hydrolytic conversion compared to pectinase and base pectinase. Cleavage following pectinase hydrolysis (pH 5, 18 hrs at 30 °C) alone is the least effective hydrolysis method and characterised the residue as a glycoside conjugate. Cleavage following mild base (0.05 M NaOH, 18 hrs, room temperature) and pectinase hydrolysis (pH 5, 18 hrs at 30 °C) characterised the residue as malonyl glycoside conjugate.

For soya bean seeds, proportionate aliquots of hexane, diethyl ether and acetonitrile were combined. The resulting fraction (phenyl: 35% TRR; pyrazole: 10% TRR) was concentrated by evaporation to an oil, dissolved in hexane and partitioned into acetonitrile/water (9:1, v/v) to remove endogenous oil. The hexane phase (phenyl: 7.2% TRR; pyrazole: 1.2% TRR) was not further analysed. The aqueous acetonitrile fraction (phenyl: 24% TRR; pyrazole: 8.7% TRR) was analysed by 2D-TLC. Similarly, proportionate aliquots of the primary acetonitrile/water extracts were combined and the resulting fractions (phenyl: 48% TRR; pyrazole: 85% TRR) were analysed by 2D-TLC. An aliquot of the combined primary acetonitrile/water extracts was subjected to a protein precipitation clean-up step: addition of acetone and cooling for 18 hrs at 4 °C. The resulting supernatant (phenyl: 46% TRR; pyrazole: 82% TRR) was analysed by 2D-TLC and 1D-TLC. A separate aliquot of the combined primary acetonitrile/water extracts was concentrated and subjected to hydrolysis procedures involving the use of bovine rumen fluid (pH 7, 24 hrs at 39 °C). The resulting hydrolysate was partitioned between water and diethyl ether/hexane (9:1 v/v). The organic phase (phenyl: 41% TRR; pyrazole: 55% TRR) was analysed by 2D-TLC and 1D-TLC. The aqueous phase derived from the phenyl experiment (8.1% TRR) was not analysed further. The aqueous phase derived from the pyrazole experiment (30% TRR) was subjected to acid hydrolysis (0.5 M HCl, 6 hrs, 100 °C) and the resulting hydrolysate was partitioned into diethyl ether/hexane 4:1 v/v. The organo soluble fraction (22% TRR) was analysed by 2D-TLC. The aqueous phase (0.0% TRR) was not analysed further.

All fractions were analysed by 2D-TLC and/or 1D-TLC with phosphor image analysis. Identification was conducted by co-chromatography with authentic reference standards of parent, SYN546206, SYN546039, SYN546040, SYN546041, SYN546042, NOA449410, SYN545720, SYN508272, SYN545720-aspartic acid conjugate, SYN545720-monosaccharide conjugate using two dissimilar solvent systems. Results are shown in Table 12.

In soya bean forage and hay, high levels of identification of the extracted residues were achieved ($\geq 83\%$ TRR). A significant proportion of the conjugates of SYN546039 in hay was characterised as glycoside (minor proportion) and malonyl glycoside (major proportion) conjugates.

In soya bean seeds, high levels of identification of the extracted residues were achieved for the pyrazole experiment (67% TRR) but lower levels of identification were found for the phenyl experiment (41% TRR) where absolute residue levels were lowest. Significant proportions of the conjugated residue of SYN545720 in seeds were identified as the aspartic acid conjugate (12% TRR) and monosaccharide conjugate (11% TRR).

Combined extracts were analysed by TLC within 3 months of sample harvest and were analysed again following 29-31 months frozen storage to demonstrate storage stability. Comparison of the initial and final radio-component profiles obtained showed no significant change in the profiles during the interim period of storage.

Overview of the metabolic pathway in plants

Metabolism studies conducted with crops representative of cereal/grass (spring wheat), fruits (tomato) and pulses/oilseeds (soya bean) and based on foliar treatment show that the metabolic pathways in the three crop groups are similar. The nature of the terminal residue depends on the relative importance of the various routes of metabolism and the nature and extent of the conjugation reactions. The level of metabolism of benzovindiflupyr was most extensive in pulses/oilseeds (soya bean). Metabolism observed arose via:

- N-demethylation of the pyrazole ring to form SYN546206
- mono hydroxylation on the alicyclic ring to form the SYN546039 and SYN546040 isomers
- subsequent N-demethylation of the pyrazole ring and mono hydroxylation of the alicyclic ring or subsequent mono hydroxylation of the alicyclic ring and N-demethylation of the pyrazole ring to form SYN546041 and SYN546042 isomers
- cleavage between the pyrazole and phenyl rings of parent or mono hydroxylated metabolites SYN546039/SYN546040 to form SYN508272 and subsequent hydrolysis of the amide functionality of SYN508272 to form NOA 449410 and subsequent demethylation to form SYN545720
- cleavage between the pyrazole and phenyl rings of the N-demethylated metabolites SYN546206 or SYN546041/SYN546042 to form SYN545720
- conjugation of N-demethylated metabolite SYN546206
- conjugation of mono hydroxylated metabolites SYN546039/SYN546040, predominantly as their glycoside and malonyl glycoside conjugates
- conjugation of mono hydroxylated and N-demethylated metabolites SYN546041/SYN546042
- conjugation of hydroxylated cleavage metabolites NOA449410 and SYN545720, the latter metabolite found predominantly as its aspartic acid and sugar conjugates.

In tomato fruits, wheat grains, wheat forage/hay/straw, soya bean forage/hay the major compound in the residue is parent. In soya bean seeds the major compound is the cleavage compound SYN545720 with significant amounts of parent present. The major pathway in soya bean seeds is cleavage between the pyrazole and phenyl rings combined with N-demethylation of the pyrazole moiety (either before or after cleavage) to form SYN545720 followed by conjugation of SYN545720 to aspartic acid and sugar. The overall metabolic pathways in rotated crops are similar to those observed in primary crops.

Figure 3 Metabolic pathway of benzovindiflupyr in plant commodities

Environmental fate in soil

The Meeting received information on aerobic/anaerobic degradation in soil, field dissipation studies, photolysis in soil and confined/field rotational crop studies. In conformance with the JMPR manual 2009 for foliar treatments, only confined and field rotational crops studies were considered for the current evaluation. In addition, The Meeting considered photolysis studies in/on soil relevant for the present evaluation. The fate and behaviour of benzovindiflupyr in the environment was investigated using the [^{14}C]pyrazole and [^{14}C]phenyl labelled compound (see Figure 1).

Photolysis studies in/on soil

The photolysis of [^{14}C]phenyl labelled and [^{14}C]pyrazole labelled benzovindiflupyr was investigated on both dry and moist soil surfaces [McCorquodale and White, 2012, SYN545192_10186]. Soil characteristics are indicated in Table 13. At day 0 moist soil was adjusted to pF2 moisture tension. Dry soil tests used air dried soil. In each case, benzovindiflupyr was applied, at rates equivalent to 0.25 kg ai/ha, to thin layers (ca 2 mm) of loamy soil in individual photolysis vessels. The treated soils were irradiated using light from a xenon arc lamp. The emitted light was filtered to give a spectral distribution close to that of natural sunlight at a mean light intensity of 48–58 W/m². The samples were maintained at 20 ± 2 °C and were continuously irradiated for 30 days, the equivalent of 56–69 days summer sunlight at latitudes 30–50 °N. CO₂ and volatile organics were trapped with 2 mol (M) NaOH. In each test, duplicate irradiated samples were taken for analysis at 0, 5, 10, 15, 20, 25 and 30 days after treatment (DAT) and traps for volatiles were replaced with fresh solution. Dry soils received no moisture maintenance. Moist soils were checked daily and moisture adjusted by addition of water if required to maintain soil close to the target weight at pF2 moisture tension. Dark control samples were also prepared and maintained at 20 °C and analysed at 0 and 30 DAT.

Extraction procedures were started on the day of sampling. Each soil sample was extracted with 0.01 M CaCl₂ and twice with acetone. Extracts, traps and remaining post-extracted soil residue were analysed by (combustion) LSC. Extracts were analysed by HPLC. Selected extracts were analysed by 1D-TLC to confirm both the co-chromatography with reference standards and the quantification of the main components. HPLC-MS-MS was also used to provide qualitative confirmation of the identification of parent, SYN546039, SYN508272 and NOA449410.

A mass balance for each sample was determined by summation of the radioactivity recovered in the soil extracts, the total ¹⁴CO₂ evolved and the post-extracted soil residues. The mean mass balance from the irradiated soils was 99% and from the dark controls was 99%. Benzovindiflupyr degraded slowly under irradiated conditions with no significant degradation in the dark controls.

Under dry, irradiated conditions, the amount of parent declined over the irradiation period to levels of 88.4% and 74.4% TAR by 30 DAT in soil treated with the [^{14}C]phenyl and [^{14}C]pyrazole labelled parent compound, respectively. In moist, irradiated soil, the amount of parent declined over the course of the irradiation period to levels of 89% and 88% TAR by 30 DAT in the phenyl and pyrazole labelled experiments, respectively. The DT₅₀ values were calculated using non-linear regression and single first-order kinetics (SFO) and are 144 days in dry soil and 244 days in moist soil. Corrected for latitude, the DT₅₀ is 298 and 501 for dry and moist soil, respectively, at 30–50 °N (OECD).

In general, a similar degradation pattern was observed in both dry and moist irradiated soil. Photodegradation of benzovindiflupyr resulted in the cleavage of the carboxamide link to produce the pyrazole amide, SYN508272, and the pyrazole acid, NOA449410. Levels of SYN508272 and NOA449410 were higher in dry soil, with amounts reaching maximum mean values of 6.5% and 2.8% TAR, respectively. In moist soil, the maximum mean levels of SYN508272 and NOA449410 were 1.1% and 2.3% TAR, respectively. The demethylated pyrazole acid, SYN545720, was identified in soil extracts from dry soil only, and reached a maximum level of 0.6% TAR. The hydroxylated degradate, SYN546039, was detected at a mean maximum level of 3.7% TAR, but only in the moist irradiated soil treated with the phenyl label. Minor, unidentified components accounted for a combined mean maximum value of 3.5% TAR across all the samples. Carbon dioxide was a minor

($\leq 2.5\%$ TAR) product of photolysis. Unextracted residues increased during the irradiation but did not exceed $> 9.0\%$ TAR in any of the samples.

Confined rotational crop studies

A confined rotational crop study was designed to provide information on the uptake and metabolism of benzovindiflupyr in rotational crops [Roohi and Adams, 2012, SYN545192_10246]. Two radiolabelled forms were used in the study: [phenyl- ^{14}C]-benzovindiflupyr and [pyrazole- ^{14}C]-benzovindiflupyr. For each radiolabelled form, a single spray application onto the surface of bare soil was performed employing an EC formulation (A170560) at a spray volume of 300 L/ha. The soil characteristics were: USDA sandy loam, pH (H_2O) 5.8, 3.2% om, CEC = 9.4 meq/100 g. The actual application rates achieved were 0.54 kg ai/ha and 0.53 kg ai/ha for the pyrazole and phenyl experiments respectively. After application, the soil was kept in containers under greenhouse conditions and at intervals of 30, 90 and 300 days after application three representative rotational crops were sown into the treated soil. The crops selected were lettuce (variety Tonova), spring wheat (variety Tybalt) and turnip (variety Tokyo Cross), respectively. For each plant back interval and for each radiolabelled experiment the following crop samples were taken: immature lettuce (BBCH 41–43), mature lettuce (BBCH 49), mature turnip roots and leaves (BBCH 49), wheat forage (BBCH 39), wheat hay (BBCH 39–69, sampled 59 days after planting); wheat straw and grain (BBCH 89). Soil samples (0–20 cm) were taken at the time of each sowing (i.e. DAT = 30, 90, 300). Lettuce samples (0.07–1.1 kg) were harvested by cutting just above the soil surface using a knife and any dead leaves and loose soil were removed. Turnips were harvested by hand and any loose soil was removed. The leaves (1.6–2.9 kg) and roots (0.55–1.1 kg) were separated using a knife. If necessary, large roots were cut into smaller pieces. Wheat forage (0.30–1.3 kg) was harvested by cutting the plants with scissors 1 cm above the soil surface. The forage was cut into pieces of 5 cm length. Wheat hay (0.13–0.73 kg) was harvested as wheat forage and then left to dry for 6–10 days in a glasshouse. Mature wheat was harvested as wheat forage and intact ears of grain were removed from the straw using scissors. Grain (0.34–0.70 kg) and chaff were separated and the chaff was added to the straw samples (0.34–0.55 kg). The samples were stored at -18°C for 6–45 months.

Soil samples were not analysed (confirmed, Syngenta, 2014b). Plant commodities were homogenised and the total radioactive residue (TRR) determined by combustion LSC. In the pyrazole experiment, with the exception of the 30 day mature lettuce and the 90 and 300 day grain, all samples contained radioactive residues $> 0.01 \text{ mg/kg eq}$ (see Tables 14–21). In the phenyl experiment, with the exception of the lettuce and grain, all samples contained radioactive residues $> 0.01 \text{ mg/kg eq}$ (see

Tables 14–21). Maximum levels were 0.030 mg/kg eq in lettuce leaves, 0.031 mg/kg eq in turnip roots, 0.026 mg/kg eq in turnip leaves, 0.11 mg/kg eq in wheat forage, 0.34 mg/kg eq in wheat hay, 0.77 mg/kg eq in wheat straw and 0.014 mg/kg eq in wheat grain.

The samples with radioactive residues > 0.01 mg/kg eq were sequentially extracted with solvents of increasing polarity: acetonitrile (1×), acetonitrile/water (4:1, v/v) (2–3×), acetonitrile/water (3:7, v/v) (1×), water (1×), acetonitrile (1×). For grain this sequence was extended with an additional sequence of acetonitrile/water (3:7, v/v) (1×), water (1×), acetonitrile (1×). Radioactivity in extracts and solids was determined by (combustion) LSC. The overall levels of extractability were high with > 80% TRR extracted in all commodities.

For each commodity, extracts containing significant levels of radioactivity were combined, concentrated and re-suspended in water (pH 2). This aqueous concentrate was then partitioned with hexane/diethyl ether (1:3 v/v) in the ratio 3:1 v/v with the aqueous fraction. The resulting organic phase was analysed by 1D- or 2D-TLC for quantification and identification of the components. Identified components in these organic partition fractions were thereby shown to be present in the free form (unconjugated). When the residue in the aqueous fraction was considered significant, a sub-sample was subjected to hydrolysis by rumen technology (bovine rumen fluid, pH 7, 24 hrs at 39 °C, under nitrogen). The resulting hydrolysates were analysed by 2D-TLC and 1D-TLC methods. Identified components were thereby shown to have originally been present in the conjugated form in the initial sample extracts. Where significant radioactivity remained in the post-extraction solids, selected samples were subjected to additional extraction procedures employing 0.1 M HCl (at 37 °C for 6 hrs) or 0.5 M HCl (at 90 °C for 6 hrs) or sodium dodecyl sulphate (SDS), (at 90 °C for 2 hours) in parallel experiments. Identification was by comparison with authentic reference standards of parent, SYN546206, SYN546039, SYN546040, SYN546041, SYN546042, NOA449410, SYN545720 and SYN508722 using two dissimilar solvent systems. Analytical standards for parent, SYN546039, SYN546042, NOA449410, SYN545720 and SYN508722 were confirmed to be stable during hydrolysis by rumen technology.

Results are shown in Tables 14–21. Overall, residue identification accountability was > 80%. In samples where the TRR was low (< 0.03 mg/kg eq) the level of identification was lower: averaging 70% for lettuce, 45% for turnip leaves. In wheat commodities accountability was lower: identification averaged 66% in wheat forage, 61% in wheat hay and 50% in wheat straw. Wheat grain had very low residues (< 0.01–0.014 mg/kg eq) and most extracts were not amenable to chromatographic examination.

The pattern of metabolites found in the samples from the pyrazole experiment was different from that found in the samples from the phenyl experiment because of the presence of metabolites that retained only the pyrazole ring (i.e. NOA449410, SYN545720 and SYN508722).

Storage stability

Chromatographic profiles of all initial crop extracts were obtained within 190 days of harvest. The original extracts were stored at ≤ −18 °C and were then re-analysed at 155 weeks after harvest (i.e. at the end of the analytical phase of the study). Selected samples were immature lettuce (analysed 94 and 1079 days after harvest), turnip leaves (analysed 42 and 1079 days after harvest), turnip roots (analysed 90 and 1082 days after harvest), turnip leaves (analysed 90 and 1082 days after harvest), turnip roots (analysed 90 and 1082 days after harvest) and wheat straw (analysed 48 and 1016 days after harvest). Comparison of the initial and final radio-component profiles obtained from the selected samples showed that no significant change in the profiles had occurred during the interim period of storage.

The figures in Tables 14–21 are the total radioactive residue for each metabolite reported expressed as mg/kg parent equivalents. The main figures are the sum of both the free and conjugated forms. The figures in parentheses indicate the portion of the radioactive residue in the conjugated form(s).

N/A = Not applicable (Sample not analysed or metabolite not possible in phenyl label).

N/D = Not detected

DAT = Days after soil treatment

DAS = Days after sowing of the rotational crops

^a TRR determined by summation of radioactivity present in the extracts and solids following solvent extraction and set as 100% TRR.

^b TRR determined by direct quantification employing combustion/LSC.

^c Unassigned radio-components which chromatographed away from the origin using 2D-TLC SSD, comprising 1–41 discrete components (depending on matrix), none greater than 5.0% TRR (each < 0.01 mg/kg eq)

^d Polar material remaining on the origin on the TLC plate using 2D-TLC SSD

^e The remainder consists of areas of the chromatogram which cannot be assigned to discrete radioactive components.

^f Extracts or aqueous partition fractions that were considered too low for analysis: < 5% TRR or < 0.01 mg/kg eq

^g Radioactivity remaining in the solids after the initial solvent extractions.

Field rotational crop studies

Four rotational crop field trials have been conducted in the EU to investigate the magnitude of residues in rotational crops following a single application to bare soil at 0.200 kg ai/ha. Additionally, four rotational crop field trials have been conducted in the USA to investigate the magnitude of residues in rotational crops following three foliar applications at 14 day intervals and at a rate equivalent to 0.100 kg ai/ha per application to target crops of peanuts and soya beans.

Study 1

Two field crop rotation trials were carried out in Northern Europe during 2010 and 2011 [Ellis, 2012b, A17056B_10004]. Plots (72–75 m² each) were treated with a single application to bare soil at a nominal rate of 0.20 kg ai/ha using an EC formulation (A17056B). Plots received minimal cultivation with a harrow or rototill to 5 cm depth 8–13 days prior to drilling of the rotational crops. Rotational crops were planted into the treated soil at 28–30, 60–61 or 355–365 days after application. The 355–365 day rotation crops were planted on the same plot as the 28–30 day plots, after the first rotation crops were harvested and removed. Experimental conditions for trial S10-00261-01 and S10-00261-02 are indicated in Table 22. Crops sampled at immature stages were spinach (leaves) at BBCH 42–43 (DAT 81/71, 91/99, 420/420) and spring wheat (whole plant) at BBCH 39 (DAT 88/90, 98/107, 429/436) for trial 01/02. Mature samples were taken for spinach at BBCH 49 (DAT 91/86, 100/111, 434/432), for spring wheat (grain and straw) at BBCH 89 (DAT 144/155, 161/170, 505/525) and for carrot (root and tops with leaves) at BBCH 49 (DAT 149/131, 156/170, 491/467) for trial 01/02. Samples were taken randomly across each plot from at least 12 points. Spinach leaves were cut above ground using scissors, a knife or a sickle. Wheat forage whole plants were taken by hand or with scissors/secateurs or a sickle. Wheat grain and straw samples were produced by threshing the whole plant samples using a plot harvester. Carrot plants were taken by hand and the soil washed off. Sample sizes were in accordance with appendix V of the FAO manual: 1.0–2.0 kg spinach leaves from at least 12 plants, 1.0–1.4 kg wheat forage from at least 12 plants, 1.0–1.4 kg wheat grain and 0.50–0.73 kg wheat straw from at least 50 plants, 2.0–2.3 kg carrot roots and 1.0–1.2 kg carrot tops from at least 12 plants. Samples were stored frozen within 1–6 hrs after harvest at –18 °C for a maximum period of 10 months until analysis. The storage period of 10 months is covered by the storage stability studies on parent, SYN546039 and SYN546206 in commodities with high water content, high starch content and wheat straw. During shipment, temperatures were out of range for short periods of less than 12 hrs. Since the samples remained frozen, this is considered to have no impact on the study.

Soil samples have not been analysed for parent or its soil metabolites (confirmed, Syngenta, 2014b). Wheat forage, grain and straw from the 30 and 60 day plant back intervals were analysed for parent and SYN546039 using HPLC-MS-MS method GRM042.03A with matrix matched standards for grain and straw and minor modifications for parent. Parent compound was analysed directly in the initial acetonitrile/water extract. This modification (A) was shown to have no impact on the validity of the analysis. All other crop samples were analysed for parent, SYN546039 and SYN546206 using HPLC-MS-MS method GRM042.08A with matrix matched standards. Methods GRM042.03A and GRM042.08A are considered valid for the purpose of this study (commodity type and concentration level of the analytes). Average concurrent recoveries were within 70–120% for each analyte and matrix and control samples had residues < 0.01 mg/kg, showing adequate performance at the time of analysis of the samples.

No residues of parent, SYN546039 or SYN546206 were found at or above the LOQ of 0.01 mg/kg in any of the treated samples.

Study 2

Two field crop rotation trials were carried out in Southern Europe during 2010 and 2011 [Ellis, 2012c, A17056B_10005]. Plots (24–90 m²) were treated with a single application to bare soil at a nominal rate of 0.20 kg ai/ha using an EC formulation (A17056B). Plots were lightly cultivated (plot 01) or cultivated with a motor hoe to a depth of 20 cm (plot 02) 1–8 days prior to drilling rotational crops. Rotational crops were planted into the treated soil at 28–32, 60–69 or 357–366 days after application. The 357–366 day rotation crops were planted on the same plot as the 28–32 day plots, after the soil was cultivated to a depth of 20 cm, including the remains of the first rotation crops. Experimental conditions for trials S10-00262-01 and S10-00262-02 are indicated in Table 22. Crops sampled at immature stages were spinach (leaves) at BBCH 41–43 (DAT 79/66, 108/97, 416/416) and spring wheat (whole plant) at BBCH 39 (DAT 69/75, 111/97, 416/423) for trial 01/02. Mature samples were taken for spinach at BBCH 49 (DAT 86/75, 118/104, 429/423), for spring wheat (grain and straw) at BBCH 89 (DAT 118/125, 192/152, 471/480) and for carrot (root and tops with leaves) at BBCH 49

(DAT 154/152, 169/159, 483/483) for trial 01/02. Spinach leaves were cut above ground using a knife. Wheat forage whole plants were cut above ground using a knife, scissors or secateurs. Wheat grain and straw samples were threshed by using a plot or portable combine. Carrot plants were collected by hand and roots and tops were separated in the field using a knife or a spade. Sample sizes were generally in accordance with appendix V of the FAO manual: 1.0–2.6 kg spinach leaves from at least 12 plants, 1.1–3.5 kg wheat forage from at least 12 plants, 1.0–1.5 kg wheat grain and 0.57–1.7 kg wheat straw from at least 12 plants, 2.0–4.0 kg carrot roots and 1.0–2.0 kg carrot tops from at least 12 plants. Sample size for mature spinach leaves from the 366 day plant back interval in trial 01 is rather small (0.30 kg), but since this sample was retrieved from at least 50 plants this is considered acceptable. Samples were stored frozen within 1–5 hrs after harvest at –18 °C for a maximum period of 10 months until analysis. The storage period of 10 months is covered by the storage stability studies on parent, SYN546039 and SYN546206 in commodities with high water content, high starch content and wheat straw. During shipment, temperatures were out of range for short periods of less than 6 hrs. Since the samples remained frozen, this is considered to have no impact on the study.

Soil samples have not been analysed for parent or its soil metabolites (confirmed, Syngenta, 2014b). Wheat forage, grain and straw from the 30 and 60 day plant back intervals were analysed for parent and SYN546039 by HPLC-MS-MS method GRM042.03A with matrix matched standards and minor modifications for parent. Parent compound was analysed directly in the initial acetonitrile/water extract. This modification (A) was shown to have no impact on the validity of the analysis. All other crop samples were analysed for parent, SYN546039 and SYN546206 using HPLC-MS-MS method GRM042.08A with matrix matched standards. Methods GRM042.03A and GRM042.08A are considered valid for the purpose of this study (commodity type and concentration level of the analytes). Average concurrent recoveries were within 70–120% for each analyte and matrix and control samples had residues < 0.01 mg/kg, showing adequate performance at the time of analysis of the samples.

No residues of parent, SYN546039 or SYN546206 were detected at or above the LOQ of 0.01 mg/kg in any of the treated samples, except in treated wheat straw:

- In trial S10-00262-02 for wheat planted 28 days after application, parent was found at 0.014 mg/kg in wheat straw (DAT 125)
- In trial S10-00262-02 for wheat planted 60 days after application, parent was found at 0.012 mg/kg in wheat straw (DAT 152).

Study 3

Four field crop rotation trials were carried out in the USA during 2009, 2010 and 2011 [Mäyer, 2012, A17056B_50013]. Plots with target crops of peanuts or soya beans were treated with three foliar applications at 14 day intervals at a nominal rate of 0.100 kg ai/ha using an EC formulation. All applications incorporated a crop-oil concentrate or non-ionic surfactant adjuvant in the spray. The peanut and soya bean target crops were harvested and removed from the field according to agronomical practices. Experimental conditions are indicated Table 22. In trial E10-9681 (Seven Springs, NC), spinach, radish, and wheat were planted into the treated soil at 30 days after the last application. Wheat grain and straw were harvested at DAT 228, wheat hay at DAT 182, wheat forage at DAT 91, roots/tops at DAT 157 and leafy crops at DAT 158. In trials E11-9678 (Elko, SC), C18-9679 (Richland, IA) and E13-9680 (Madil, TX), lettuce or spinach, radish or turnip and wheat were planted into the treated soil at 180 days after the last application. For trials E11-9678, C18-9679, E13-9680 wheat grain and straw were harvested at DALT 289/275/278, wheat forage and hay at DAT 231/233/231, roots/tops at DAT 231/231/278 and leafy vegetables at DAT 231/231/300. Wheat forage and wheat hay were collected from 12 separate areas of the plot. Wheat grain, wheat straw, radish top, radish root and leafy vegetable samples were collected from at least 12 plants and/or 12 separate areas of the plot at normal crop maturity. Samples were at least 2 kg (roots) or at least 1 kg (tuber tops, leafy vegetables, wheat forage and wheat grains) or at least 0.5 kg (wheat straw and wheat hay). Exceptions are 0.6–1.0 kg for tuber tops and 0.26–0.28 kg for wheat forage in trial E10-9681 (30 day PBI), 1.1–1.5 kg for 40 tubers in trial E11-9678 (180 day PBI), 0.8–0.9 kg for tuber tops in trial (E13-

9680) [Syngenta, 2014b]. In trial E10-9681, plant growth was retarded because of abnormally cold weather and therefore it was not possible to collect at least 1 kg wheat forage from the plot. Two replicate field samples were taken from each plot. Adhering soil was removed from radish roots by light brushing. Wheat hay was harvested on the same date as wheat forage and was dried for 2 days in a shelter (E10-9681), 2 days in the field (E11-9678), 6 days in the field (E13-9680) or 10 days in a shed (C18-9679) [Syngenta, 2014b].

Samples were stored at -20°C for a maximum period of 24 months until analysis [Syngenta, 2014b]. The storage period of 24 months is covered by the storage stability studies on parent, SYN546039 and SYN546206 in commodities with high water content, high starch content and wheat straw.

Soil samples have not been analysed for parent or its soil metabolites (confirmed, Syngenta, 2014b). Crop samples from the 180 day plant-back interval plots were analysed for parent and SYN546039 by HPLC-MS-MS method GRM042.03A. Parent compound was cleaned-up together with the SYN546039 hydrolysate as in the original method. Method GRM042.03A is considered valid for the purpose of this study (commodity type and concentration level of the analytes). Samples were re-analysed for SYN546206 by modification A of HPLC-MS-MS method GRM042.08A. Crop samples from 30 day plant-back interval plots were analysed for parent, SYN546039 and SYN546206 using modification A of HPLC-MS-MS method GRM042.08A. Modification A of method GRM042.08A is considered insufficiently validated for the determination of parent, SYN546039 and SYN546206 in radish roots and tops (30 day PBI samples) and in addition insufficiently validated for the determination of SYN546206 in lettuce, radish roots & tops and turnip roots & tops (180 day PBI samples) (see analytical section). Average concurrent recoveries for a limited number of samples were within 70–120% for each analyte and matrix and control samples had residues < 0.01 mg/kg, showing adequate performance at the time of analysis of the samples

No residues of parent, SYN546039 or SYN546206 were detected at or above the LOQ of 0.01 mg/kg in any of the treated samples, except in wheat:

- In trial E10-9681 with soya bean as primary crop and wheat planted 30 days after application, parent and SYN546039 were found at an average concentration of 0.022 mg/kg (range 0.012–0.033 mg/kg) and 0.021 mg/kg (range 0.015–0.028 mg/kg), respectively, in wheat forage (DALT 91). Two field samples were taken and each sample was extracted twice.
- In trial E10-9681 with soya bean as primary crop and wheat planted 30 days after application, SYN546039 was found at an average concentration of 0.016 mg/kg (range 0.016–0.017 mg/kg) in wheat straw (DAT 228). Two replicate field samples were taken and each sample was extracted twice.

Note: Since residues were found at the 30 day plant back interval, the 30 day PBI trial is considered the most critical trial (spinach, radish and wheat). The wheat forage samples of the 30 day PBI trial are considered not representative, because wheat growth is retarded because of abnormally cold weather and consequently it was not possible to collect a sufficient (representative) amount of sample from the plot. In addition, modification A of method GRM042.08A is considered insufficiently validated for the determination of parent, SYN546039 and SYN546206 in radish roots and tops (30 day PBI samples).

Environmental fate in water/sediment systems

No data submitted.

RESIDUE ANALYSIS

The Meeting received information on enforcement/monitoring methods for the determination of benzovindiflupyr and its metabolites in plant and animal commodities. In addition the Meeting received information on analytical methods for the determination of benzovindiflupyr and its metabolites as used in the various study reports (supervised residue trials, storage stability studies, processing studies, feeding studies). The analytical methods have been evaluated according to the guidance provided by OECD (Series on Pesticides number 39) as indicated on page 25 of the FAO manual 2009.

Validation results are required for every commodity submitted for MRL-setting: at least one full validation for a commodity within the five defined crop groups (high acid content, high water content, high oil content, high protein content, high starch content) and a reduced validation for every other commodity within a certain crop group. Where validation results do not meet the criteria given below, this is indicated.

When the analytical method is validated according to a full validation scheme, it means that:

- at least five recovery experiments per level were conducted on at least two levels (LOQ and $10\times$ LOQ) and average recovery per level was shown to be between 70–120% and the relative standard deviation (RSD_r or CV) per level was shown to be $< 20\%$
- at least two control samples were analysed and were shown to be below $0.3\times$ LOQ
- the calibration was conducted with at least five single points or at least three duplicate points and was shown to be linear (either standards in solvent or matrix matched standards).

When the analytical method is validated according to a reduced validation scheme, it means that:

- a full validation is available for a crop in the same crop group (high acid content, high water content, high oil content, high protein content, high starch content)
- at least three recovery experiments per level were conducted on at least two levels (LOQ and $10\times$ LOQ) and the average recovery per level was shown to be between 70–120% and the relative standard deviation (RSD_r or CV) per level was $< 20\%$
- at least two control samples were analysed and shown to be below $0.3\times$ LOQ
- the calibration was conducted with at least five single points or at least three duplicate points and was shown to be linear (only relevant for matrix matched standards; standards in solvent are already covered by full validation).

Analytical methods for enforcement in plant and animal commodities

FDA PAM Multi-Residue Method

The suitability of the FDA Pesticide Analytical Manual (PAM-I) Multi-Residue Method (MRM) to analyse for benzovindiflupyr and its three metabolites (SYN546039, SYN545720 and SYN546206) in non-fatty and fatty foods was tested using the FDA MRM Testing Protocol [Barker and Ballard, 2012, SYN546039_50003]. The FDA MRM Testing Protocol [FDA, 1999] consists of several protocols: one protocol for determining if the compounds are naturally fluorescent (protocol A); one protocol for methylation of acidic analytes, in case the native volatility is insufficient for GC determination (protocol B); two protocols for determining GC characteristics of chemicals (protocol C and G); three protocols by which chemicals can be evaluated through the FDA multi-residue testing program (protocols D, E and F); Based on its molecular structure, benzovindiflupyr and its metabolites, were taken through protocols A, B, C, D and F.

Protocol A (PAM I, Section 401, module DL2) demonstrated that benzovindiflupyr, SYN546039 or SYN546206 had no detector response in a HPLC system with fluorescence detection, even with 10,000 ng on column. Signals were reported for SYN545720 but did not provide enough response to warrant further investigation (greater than 10,000 ng required 50% FSD). Further work on this protocol was terminated.

Protocol B showed that compound SYN545720 could be methylated. However, 150 ng of SYN545720-methyl ester could not be detected with GC-ECD (module DG1). Further work on this protocol was terminated due to poor sensitivity of the methyl ester.

Protocol C experiments demonstrated that benzovindiflupyr SYN546039 and SYN546206 were found to be suitable for detection by GC-ECD using module DG10. None of the modules tested

(GC-ECD modules DG1, DG7, DG10 or GC-NPD module DG17) gave a suitable response for SYN545720. For compounds which can only be determined by ECD, the extract must be cleaned up by Florisil chromatography before determination.

Protocol D (for non-ionic chemicals in non-fatty foods) showed that benzovindiflupyr and its metabolites SYN546039 and SYN546206 could not be recovered through the section 301 C1 Florisil clean-up elution procedure. Further testing through Protocol D was terminated.

Protocol F (for moderately non-polar chemicals in fatty foods) showed that only benzovindiflupyr was recovered through either the C1 or C2 Florisil clean-up elution procedure. Recovery was 60% (50% ethyl ether eluent) for C1 and 106% (eluent 3) for C2 clean-up procedures. When corn oil was fortified with parent at 0.05 and 0.50 mg/kg and extracted using Section 304 E3 conditions, recovery was poor. Recoveries through the Section 304 E3 + C1 procedure averaged 32% and 57% for the 0.05 and 0.50 mg/kg fortified samples, respectively. Recoveries through the Section 304 E3 + C2 procedure averaged 56% and 58% for the 0.05 and 0.50 mg/kg fortified sample, respectively.

Conclusion: Data generated from testing of benzovindiflupyr and its metabolites SYN546039, SYN545720 and SYN546206 through Protocols A, B, C, D and F indicate that none of the compounds of interest are successful candidates for enforcement by the FDA PAM I multi-residue methods for non-fatty or fatty foods.

QuEChERS method

In the published multi-residue QuEChERS method [ECS, 2009] homogenised samples (5.0 g) were mixed with acetonitrile/water (1:1, v/v, plant matrices) or acetonitrile (animal matrices). Fat samples were heated to approximately 40 °C before mixing with acetonitrile. Thereafter, magnesium sulfate (to bind water), sodium chloride (to salt out the analyte), trisodium citrate dihydrate and disodium hydrogen citrate sesquihydrate (slightly acidic buffer) were added. After mixing, the sample was centrifuged. The upper acetonitrile phase was cleaned-up by a dispersive solid phase extraction purification step using PSA (primary and secondary amine exchange material) and magnesium sulfate. The mixture was centrifuged and the upper clear acetonitrile phase was concentrated using a stream of air. The final extract was diluted with water/acetonitrile (9/1, v/v, or 1/4, v/v). Samples were analysed by HPLC-MS-MS at their appropriate mass transitions.

The determination of parent using QuEChERS method was validated according to the full validation scheme in oranges (whole fruit), wheat (grain), lettuce (head), oilseed rape (seed) and coffee bean (roasted) [Winter and Armann, 2012, SYN545192_10193]. HPLC-MS-MS mass transitions m/z 396 $\rightarrow$ 368 and m/z 396 $\rightarrow$ 91 were used for quantification or confirmation; no preference could be seen in the results. The reported LOQ was 0.01 mg/kg for each commodity and each analyte. Average recoveries at 0.01 mg/kg and 0.1 mg/kg of parent were within 70–120% limits and RSDs were within 20%. Linearity of detector response (coefficient of determination $R^2 > 0.99$) was observed in the range of 0.25–50 ng/mL standards using five or six matrix-matched standards. This range covers at least 0.3–12LOQ in the samples. Significant matrix effects ($> 20\%$) were found for all matrices and therefore matrix-matched standards were used for quantification for all matrices. No interfering peaks $> 0.3\text{LOQ}$ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

The determination of parent by the QuEChERS method was independently validated according to the full validation scheme on lettuce (head), oilseed rape (seed) and coffee bean (roasted) [Watson, 2012a, SYN545192_10172]. The validation was performed for both MS-MS transitions. The reported LOQ was 0.01 mg/kg for each commodity and each analyte. Average recoveries at 0.01 mg/kg and 0.1 mg/kg of parent were within 70–120% limits and RSDs were within 20%. Linearity of detector response (coefficient of determination $R^2 > 0.999$) was observed in the range of 0.25–50 ng/mL standards using six matrix-matched standards. This range is equivalent to 0.25–25LOQ in the samples. Significant matrix effects ($> 20\%$) were observed for oilseed rape seed and coffee bean matrix for both transitions and therefore matrix-matched standards were used for quantification for all matrices. No interfering peaks $> 0.3\text{LOQ}$ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

The determination of parent using the published multi-residue QuEChERS method (EN 15662:2009) was validated according to the full validation scheme in bovine meat, liver, kidney, fat, milk and chicken eggs [Class and Göcer, 2011, SYN545192_10150]. HPLC-MS-MS mass transition m/z 396 $\rightarrow$ 91 was used for quantification; m/z 396 $\rightarrow$ 368 was used for confirmation. The reported LOQ was 0.01 mg/kg for each commodity and each analyte. Average recoveries at 0.01 mg/kg and 0.1 mg/kg of parent were within 70–120% limits and RSDs were within 20%. Linearity of detector response (correlation coefficient $r > 0.99$ for $1/\times$ weighted regression) was observed in the range of 0.05–5 ng/mL (fat) or 0.10–10 ng/mL (other matrices) using seven standards in solvent. This range is equivalent to 0.20–20LOQ in the samples [Syngenta, 2014c]. Significant matrix effects ($> 20\%$) were not observed and standards in solvent were used for calibration. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

The determination of parent using the published multi-residue QuEChERS method (EN 15662:2009) was independently validated according to the full validation scheme in bovine liver, fat, milk and chicken eggs [Watson, 2012b, SYN545192_10169]. HPLC-MS-MS mass transition m/z 396 $\rightarrow$ 91 was used for quantification; m/z 396 $\rightarrow$ 368 was used for confirmation. The reported LOQ was 0.01 mg/kg for each commodity and each analyte. Average recoveries at 0.01 mg/kg and 0.1 mg/kg of parent were within 70–120% limits and RSDs were within 20%. Linearity of detector response (coefficient of determination $R^2 > 0.99$ for $1/\times$ weighted regression) was observed in the range of 0.05–5 ng/mL (fat) or 0.10–10 ng/mL (other matrices) using seven standards in solvent. This is equivalent to 0.2–20LOQ in the samples. Significant matrix effects ($> 20\%$) were not observed and standards in solvent were used for calibration. No interfering peaks > 0.3 LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

Conclusion: The multi-residue QuEChERS method is considered valid for use as enforcement method in plant commodities with high acid content (oranges), high water content (lettuce), high starch content (wheat grain), high oil content (oilseed rape, coffee beans) and animal commodities (meat, liver, kidney, fat, milk and eggs) with an LOQ of 0.01 mg/kg for benzovindiflupyr (parent).

Analytical methods used in study reports in plant commodities

HPLC-MS-MS method GRM042.03A

HPLC-MS-MS method GRM042.03A, version 4 August 2011, [Braid and Lin, 2011b, SYN545192_10118] is intended for use as pre-registration method for the determination of parent, and SYN546039 (free and conjugates) in plant commodities. The original method or its modification was used in field rotational crop studies and storage stability studies.

High water content commodities (10 g) were extracted by homogenisation in 80/20 (v/v) acetonitrile/water. Dry matrices (5 g, e.g. grains, hay, straw) were pre-soaked with 25 mL water for 30 min prior to homogenisation. An aliquot of the extracts was evaporated at 50 °C under a stream of air or nitrogen to remove the acetonitrile and to concentrate the sample. The remaining aqueous extract was acidified with 1 M HCl and partitioned with iso-hexane to separate parent off. The iso-hexane fraction was evaporated to dryness and taken up in 50/50 v/v acetonitrile/water for direct determination of parent by HPLC-MS-MS. Alternatively the parent fraction (in iso-hexane) may be stored refrigerated and then combined with the post-hydrolysis extract for sample clean-up if required. The remaining aqueous acidic fraction was diluted to 0.5 M HCl and heated at 100 °C for 6 hours to hydrolyse conjugates of SYN546039. If necessary, the parent fraction in iso-hexane was diluted with methanol and evaporated to remove the iso-hexane and to concentrate the sample. The hydrolysate (together with the parent fraction if necessary) was cleaned-up using an SPE cartridge. SYN546039 (and parent if included at this stage) was eluted with 50/50 (v/v) acetonitrile/water. Following dilution, samples were analysed by HPLC-MS/MS. The primary transition monitored for parent was m/z 396 $\rightarrow$ 91 with confirmatory transition m/z 396 $\rightarrow$ 368. For SYN546039 the primary transition monitored was m/z 412 $\rightarrow$ 91 with confirmatory transition m/z 412 $\rightarrow$ 340. The reported LOQ is 0.01 mg/kg for both parent and SYN546039. Samples with expected residues > 0.1 mg/kg need to be diluted before analysis.

The analysis conditions as specified in the method description need to be followed carefully. Since parent compound degrades under the hydrolysis conditions used to hydrolyse conjugates of SYN546039 into their free form, parent is separated from the sample before hydrolysis. Change in hydrolysis conditions may result in either incomplete deconjugation or degradation of SYN546039 (free). Parent compound has been observed to adsorb to glass surfaces in solutions with < 50% organic solvent. These considerations have been dealt with in the described analytical method.

HPLC-MS-MS Method GRM042.03A was validated [Lin, 2012, SYN545192_50049] according to the full validation scheme for apples, grapes, wheat commodities (forage, grain, hay and flour), spinach, peanuts, coffee beans, carrot roots, orange juice and sugarcane. The validation was performed for the quantification transition ions as well as for the confirmation transition ions. Fortifications of parent compound were performed before extraction and parent compound was quantified after the SPE clean-up stage for all commodities. Fortifications of SYN546039 were performed after the acid hydrolysis step. The reported LOQ was 0.01 mg/kg for each commodity and each analyte. Average recoveries at 0.01 mg/kg and 0.1 mg/kg of parent or SYN546039 (free) were within 70–120% limits and RSDs were within 20%. For wheat forage and wheat hay recoveries at 0.01 mg/kg and 0.5 mg/kg were also within these ranges. Linearity of detector response (coefficient of correlation $r > 0.99$) was observed in the range 0.02–0.5 ng/mL using 5–6 single standards. Equivalent concentrations in the samples were not stated. The magnitude of the matrix effect was considered not to be significant (< 20% suppression or enhancement) with the exception of coffee beans. Matrix matched standards were used for coffee beans; standards in solvent were used for all other matrices. No interfering peaks > 0.3LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

Reduced validation data were available for the determination of parent and SYN546039 (free) in wheat (forage, hay, grain, straw), lettuce, spinach, turnips (roots, tops) and radish (roots, tops) [Mäyer, 2012, A17056B_50013]. Parent was analysed after SPE clean-up. Fortifications of both parent and SYN546039 were performed prior to extraction. Average recoveries at 0.01 mg/kg ($n=3$) and 0.1 mg/kg ($n=1$) were within 70–120% limits and RSDs were within 20%. Linearity of detector response (coefficient of correlation $r > 0.99$ for $1/\times$ weighted regression) was observed in the range 0.1–2 ng/mL or 0.02–1 ng/mL using five single matrix matched standards. No interfering peaks > 0.005 mg/kg) were detected in any of the control extracts.

Reduced validation data were available for the determination of parent and SYN546039 (free) in wheat straw and carrot (roots, tops) [Ellis, 2012b/c, A17056B_10004, A17056B_10005]. Parent was analysed directly in the initial acetonitrile/water extract. Average recoveries at 0.01 mg/kg ($n=3$), 0.05 mg/kg ($n=2$) and 0.1 mg/kg ($n=1$) were within 70–120% limits and RSDs were within 20% at 0.01 mg/kg. Linearity of detector response (coefficient of correlation $r > 0.999$) was observed in the range 0.02–4 ng/mL using five single matrix matched standards. No interfering peaks > 0.3LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

Modification A of HPLC-MS-MS method GRM042.03A was used for quantification of parent and SYN546039 in storage stability study 1 [Watson, 2013, SYN545192_10137]. Parent and SYN546039 were determined directly in the acetonitrile/water (80/20) extract without further clean-up. The hydrolysis step was not included for the purpose of this study. Validation data were available for spinach, orange, wheat grain, wheat straw and potato at the fortification level used in the storage stability study. Parent or SYN546039 (free) were added before extraction as a single analyte per sample. Average recoveries at 0.2 mg/kg of parent or SYN546039 (free) were within 70–120% limits and RSDs were within 20% ($n=12$). Linearity of detector response (coefficient of correlation $r > 0.99$) was observed in the range 0.02–10 ng/mL using 5–6 single matrix matched standards. No interfering peaks > 0.3LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

Modification B of HPLC-MS-MS method GRM042.03A was used for quantification of parent and SYN546039 in storage stability study 3 [Hagan and Bertrand, 2012, SYN545192_50177]. Samples were extracted with acetonitrile/water (80:20, v/v). An aliquot of the extracts was evaporated at 50 °C under a stream of air or nitrogen to remove the acetonitrile and to concentrate the sample. The remaining aqueous extract was acidified with 1 M HCl and cleaned-up using an SPE cartridge. Parent and SYN546039 were eluted with acetonitrile/water (60:40, v/v). The hydrolysis step was not

included for the purpose of this study. Validation data were available for maize flour and maize meal, raisins, dried apple and apple juice at the fortification level used in the storage stability study. Parent or SYN546039 (free) were added before extraction as a single analyte per sample. Average recoveries at 0.2 mg/kg of parent or SYN546039 (free) were within 70–120% limits and RSDs were within 20% (n=8). Linearity of detector response (coefficient of correlation $r > 0.99$, $1/\times$ weighted regression) was observed in the range 0.02–1 ng/mL using seven single standards in solvent. No interfering peaks (> 0.02 ng/mL standard signal) were detected in any of the control extracts.

Conclusion:

- HPLC-MS-MS method GRM042.03A is considered valid for the determination of parent and SYN546039 (free) in the range 0.01–0.1 mg/kg for apples, grapes, wheat (forage, grain, hay, straw, flour), spinach, lettuce, peanuts, coffee beans, carrot (roots and leaves), turnip (roots and leaves), radish (roots and leaves), orange juice and sugarcane. The valid range is extended to 0.5 mg/kg for wheat forage and wheat hay.
- The original method indicates to fortify the sample with the free form of SYN546039 after the acid hydrolysis procedure, and thereby only validates the SPE clean-up part. However, reduced validation data are available, where SYN546039 was added before extraction and therefore, the full analytical procedure including extraction, liquid-liquid partition and hydrolysis was validated for the free form of SYN546039.
- Efficiency of extraction and hydrolysis for SYN546039 including its conjugates has been verified in a radio-validation study using method GRM042.04A, where the extraction and hydrolysis procedures are identical to those in method GRM042.03A. Based on this study, HPLC-MS-MS method GRM042.03A is considered sufficiently validated for the determination of the free and conjugated forms of SYN546039.
- Modification A of HPLC-MS-MS method GRM042.03A is considered valid for the determination of parent and SYN546039 (free) at the level of 0.2 mg/kg for spinach, orange, wheat grain, wheat straw and potato for the purpose of storage stability studies only.
- Modification B of HPLC-MS-MS method GRM042.03A is considered valid for the determination of parent and SYN546039 (free) at the level of 0.2 mg/kg for spinach, orange, maize flour and maize meal, raisins, dried apple and apple juice for the purpose of storage stability studies only.

HPLC-MS-MS methods GRM042.04A and POPIT MET.134 rev 01

HPLC-MS-MS Method GRM042.04A, version 4 August 2011, [Braid and Lin, 2011c, SYN545192_10119] is intended for use as pre-registration method for the determination of parent, SYN546039 (free and conjugates) and SYN545720 (free and conjugates) in soya bean commodities. The original method or its modification was used in supervised residue trials on soya beans, processing studies on soya beans and storage stability studies.

In the original method, soya bean forage (10 g) was extracted by homogenisation in 80/20 v/v acetonitrile/water. Soya bean hay (5 g) was pre-soaked with 25 mL water for 30 min prior to homogenisation. Soya bean seeds (10 g) were extracted by homogenisation with 50/50 v/v acetonitrile/water. Soya bean oil (10 g) was dissolved in 50 mL n-hexane and residues were extracted by partition into 80/20 v/v acetonitrile/water. At this stage, an aliquot of the extract may be diluted with 50/50 acetonitrile/water for direct determination of parent by HPLC-MS-MS (soya bean oil). For further clean-up, an aliquot of the extract was evaporated at 50 °C under a stream of air or nitrogen to remove the acetonitrile and to concentrate the sample. The remaining aqueous extract was acidified with 1 M HCl and partitioned with iso-hexane to separate parent off. The iso-hexane fraction was evaporated to dryness and taken up in 50/50 v/v acetonitrile/water for direct determination of parent by HPLC-MS-MS (soya bean forage, hay and seed). Alternatively the parent fraction (in iso-hexane) may be stored refrigerated and then combined with the post-hydrolysis extract for sample clean-up if required. The remaining aqueous acidic fraction was diluted to 0.5 M HCl and heated at 100 °C for 6

hours to hydrolyse SYN546039 conjugates in all crop commodities and SYN545720 conjugates in soya bean seed. If necessary, the parent fraction in iso-hexane was diluted with methanol and evaporated to remove the iso-hexane and to concentrate the sample. The hydrolysate (together with the parent fraction if necessary) was cleaned-up on a SPE cartridge. SYN545720 was eluted with 50/50 v/v methanol/water and SYN546039 (and parent if included at this stage) were eluted with 50/50 v/v acetonitrile/water. Following dilution, samples were analysed separately by HPLC-MS/MS. The primary transition monitored for parent was m/z 396→91 with confirmatory transition m/z 396→368. For SYN546039 the primary transition monitored was m/z 412→91 with confirmatory transition m/z 412→340. The primary transition monitored for SYN545720 is m/z 161→141 with confirmatory transition m/z 161→66. Samples with expected residues > 0.1 mg/kg need to be diluted before analysis.

The analysis conditions as specified in the method description need to be followed carefully. Since parent compound degrades under the hydrolysis conditions used to hydrolyse conjugates of SYN546039 and SYN545720 into their free form, parent is separated from the sample before hydrolysis. Change in hydrolysis conditions may result in either incomplete deconjugation or degradation of SYN546039 (free). Parent compound has been observed to adsorb to glass surfaces in solutions with < 50% organic solvent. These considerations have been dealt with in the described analytical method.

The original HPLC-MS-MS Method GRM042.04A was validated [Lin, 2012, SYN545192_50049] according to the full validation scheme for soya bean commodities (forage, oil, seed and milk). For soy milk, the extraction scheme as for forage was used [Syngenta, 2014b]. The validation was performed for the quantification transition ions as well as for the confirmation transition ions. Fortifications of parent compound were performed before extraction and parent compound was quantified after the acetonitrile/water extraction stage for soya bean oil, after the iso-hexane liquid-liquid partition stage for soya bean seeds, and after the SPE clean-up stage for soya bean forage and soya bean milk. Fortifications of SYN546039 and SYN545720 were performed after the acid hydrolysis step. The reported LOQ was 0.01 mg/kg for each commodity and each analyte. Average recoveries at 0.01 mg/kg and 0.1 mg/kg of parent or SYN546039 (free) or SYN545720 (free) were within 70–120% limits and RSDs were within 20%. For soya bean forage recoveries at 0.01 mg/kg and 0.5 mg/kg were also within these ranges. Linearity of detector response (coefficient of correlation $r > 0.99$, no weighing) was observed in the range 0.02–0.5 ng/mL for parent and SYN546039 using six standards. Linearity of detector response (coefficient of correlation $r > 0.99$, no weighing) was observed in the range 0.05–0.5 ng/mL for SYN545720 using five standards. Equivalent concentrations in the samples were not stated. The magnitude of the matrix effect was considered not to be significant (< 20% suppression or enhancement), with the exception of SYN546039 in soya bean seed and SYN545720 in soya bean forage. Standards in solvent were used for soya bean oil and soya bean milk; matrix matched standards were used for soya bean seeds and soya bean forage. No interfering peaks > 0.3LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

HPLC-MS-MS Method POPIT MET.134, Rev01, version 10 January 2012, [Volpi, 2012, SYN545192_10195] is a modification of HPLC-MS-MS method GRM042.04A and is intended for analysis of soya bean seeds only. Rev 01 is identical to the original version of 23 May 2011, except for some textual changes. The method was used in the Brazilian supervised residue trials on soya bean seeds. Extraction was conducted as described for GRM042.04A, except that 5 g soya bean seeds were taken instead of 10 g and extraction volumes were adapted accordingly. Parent was directly analysed after iso-hexane liquid-liquid partition without further clean-up. The hydrolysate, containing SYN545720 and SYN546039, was cleaned-up on a SPE cartridge. SYN545720 and SYN546039 were eluted with acetonitrile instead of 50/50 v/v methanol/water or 50/50 v/v acetonitrile/water, respectively. Following dilution, samples were analysed by HPLC-MS/MS using different transition ions. The primary transition monitored for parent was m/z 396→91 with confirmatory transition m/z 396→131. For SYN546039 the primary transition monitored was m/z 412→340 with confirmatory transition m/z 412→91. The primary transition monitored for SYN545720 is m/z 161→141 with confirmatory transition m/z 161→66.

HPLC-MS-MS Method POPIT MET.134 rev01 was validated [Volpi, 2012, SYN545192_10195] according to the full validation scheme for soya bean seeds. The validation was performed only for the quantification transition ions. Fortifications of parent compound were performed before extraction and parent compound was quantified after the iso-hexane liquid-liquid partition stage. Fortifications of SYN546039 and SYN545720 were performed after the acid hydrolysis step. The reported LOQ was 0.01 mg/kg for each commodity and each analyte. Average recoveries at 0.01 mg/kg and 0.1 mg/kg of parent or SYN546039 (free) or SYN545720 (free) were within 70–120% limits and RSDs were within 20%. Linearity of detector response (coefficient of determination $R^2 > 0.99$) was observed in the range of 0.5–16 ng/mL for parent and 0.25–8.0 ng/mL for SYN545039 and SYN545720 using six duplicate standards. This is equivalent to 0.5–16LOQ in the samples. Standards for parent were prepared in solvent; standards for SYN545039 and SYN545720 were prepared in matrix. No interfering peaks $> 0.3\text{LOQ}$ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

Modification A of HPLC-MS-MS method GRM042.04A was used for quantification of parent and SYN546039 in storage stability study 1 [Watson, 2013, SYN545192_10137]. Dry broad bean seeds (5 g) were pre-soaked in water prior to extraction. Parent and SYN546039 were determined directly in the acetonitrile/water (80/20) extract from dry broad beans without further clean-up. Dry soya bean extracts required further clean-up. Parent was determined in dry soya bean extracts after the iso-hexane partition step, while SYN546039 was determined after SPE clean-up. The hydrolysis step to free the conjugated residues of SYN546039 was not included for the purpose of the study. Parent or SYN546039 (free) were added before extraction as a single analyte per sample. Additional validation data were available for dry soya beans and dry broad beans at the fortification level used in the storage stability study. Average recoveries at 0.2 mg/kg of parent or SYN546039 (free) were within 70–120% limits and RSDs were within 20% ($n=12$). Linearity of detector response (coefficient of correlation $r > 0.999$) was observed in the range 0.02–10 ng/mL using 5–6 single matrix matched standards. No interfering peaks $> 0.3\text{LOQ}$ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

Modification B of HPLC-MS-MS method GRM042.04A was used for quantification of parent and SYN546039 in storage stability Study 3 [Hagan and Bertrand, 2012, SYN545192_50177]. Soya bean flour and soya bean milk were extracted with 50/50 v/v acetonitrile/water. Soya bean oil and maize oil were dissolved in 50 mL n-hexane and residues were extracted by partition into 80/20 v/v acetonitrile/water. For further clean-up, an aliquot of the extract was evaporated at 50 °C under a stream of air or nitrogen to remove the acetonitrile and to concentrate the sample. The remaining aqueous extract was acidified with 1 M HCl and cleaned up by SPE. SYN545720 was eluted with 50/50 v/v methanol/ water and parent and SYN546039 were eluted with 50/50 v/v acetonitrile/water. The hydrolysis step to free the conjugated residues of SYN546039 was not included for the purpose of the study. Parent or SYN546039 (free) or SYN545720 were added before extraction as a single analyte per sample. SYN546720 was only added to soya bean matrices. Validation data were available for maize oil, soya bean flour, soya bean milk and soya bean oil at the fortification level used in the storage stability study. Average recoveries at 0.2 mg/kg of parent or SYN546039 (free) or SYN545720 were within 70–120% limits and RSDs were within 20% ($n=8$). Linearity of detector response (coefficient of correlation $r > 0.99$, $1/\times$ weighted regression) was observed in the range 0.02–1 ng/mL using seven single standards in solvent. No interfering peaks (> 0.02 ng/mL standard signal) were detected in any of the control extracts.

Modification C of HPLC-MS-MS method GRM042.04A was used for quantification of parent, SYN546039 and SYN545720 in a soya bean processing study [Ellis, 2012a, A17056D_10002]. Due to small sample sizes, volumes and weights for extraction were reduced. Soya bean oil was dissolved in n-hexane and partitioned into acetonitrile/water (80/20, v/v), as described in the original method. The extract was diluted with acetonitrile/water (25/75, v/v) prior to quantification of parent (soya bean oil). All other soya bean commodities were extracted with 50/50 acetonitrile/water as described in the original method for seeds. In these commodities, parent was analysed after iso-hexane liquid-liquid partition without SPE clean-up step. As in the original method validation, the free forms of SYN546039 and SYN545720 were added after the hydrolysis step to

verify the recovery. Matrix matched standards were used for quantification of all three analytes for all matrices. For soya bean meal, fat soy flour, pollard, refined oil, crude oil and aspirated grain fractions the secondary transition m/z 396 to 368 was used for quantification of parent, since the primary transition gave interferences. For pollard and fat soy flour the secondary transition of m/z 412 to 340 was used for quantification of SYN546039, since the primary transition gave interferences.

Modification C of HPLC-MS-MS method GRM042.04A was validated with very limited data [Ellis, 2012a, A17056D_10002]. Limited validation data were available in the range 0.01–1.0 mg/kg for soya bean seeds and aspirated grain fractions, 0.01–0.5 mg/kg for soya bean hulls, soy oil, soya bean meal, fat soy flour, pollard, okara, soy milk, tofu, soy sauce and miso. Fortifications of parent compound were performed before extraction and parent compound was quantified after the acetonitrile/water extraction stage for soya bean oil and after the iso-hexane liquid-liquid partition stage for all other soya bean commodities. Individual recoveries were between 72–116% for each matrix and analyte (range 0.01–1.0 mg/kg, $n=1-2$ per level, 3–4 levels per matrix). These limited method recoveries confirm the validity of the method under the modified conditions and for the processed soya bean commodities. Linearity of detector response (coefficient of correlation $r > 0.99$) was observed in the range 0.2–4 ng/mL using five single matrix matched standards. No interfering peaks (> 0.01 mg/kg) were detected in any of the control extracts.

The extraction and hydrolysis procedure used in method GRM042.04A was radio-validated using samples of soya bean hay and soya bean seed from the pyrazole labelled metabolism study [Oddy, 2012, SYN545192_10102]. An aliquot of the homogenised soya bean hay sample (5 g) was soaked in 25 mL water for 30 min and subsequently extracted with acetonitrile/water (80:20 v/v). An aliquot of the homogenised soya bean seed sample (10 g) was extracted twice with acetonitrile/water (1:1 v/v). Following centrifugation aliquots of the supernatants of each sample were analysed by LSC to determine the efficiency of extraction. A separate aliquot of the supernatants was evaporated to remove the acetonitrile and to concentrate the extract, acidified and partitioned (3 $\times$) with iso-hexane. The aqueous phase was adjusted to 0.5 M HCl and heated at 100 °C for 6 hrs. Aliquots of the hexane phase and the hydrolysate were analysed by LSC and TLC to determine levels of parent and the metabolites SYN546039 (free and conjugates) and SYN545720 (free and conjugates).

Results are shown in Table 23. Analysis of soya bean hay and soya bean seed extracts by LSC showed that at least 94% of the total radioactive residue could be extracted by method GRM042.04A. Good agreement was obtained between the levels of parent, SYN546039 (free including conjugates) and SYN546720 (free including conjugates) found after extraction (and hydrolysis) as performed in the metabolism study and as performed in method GRM042.04A. The slightly higher levels of parent and SYN546720 in soya bean hay and seeds obtained by method GRM042.04A could be the result of a different extraction and hydrolysis scheme used in the metabolism study.

Table 23 Radiovalidation of extraction procedures used in analytical method GRM042.04A

Commodity	Components	Metabolism Study		Method GRM042.04A		Trueness
		%TRR	Residue mg/kg eq	%TRR	Residue mg/kg eq	
Soya bean hay	TRR extracted	98 ^a	12	100 ^b	13	103%
	parent	67	8.4	68 ^b	8.5	99%
	SYN546039 incl conjugates	12 ^c	1.5	14 ^c	1.7	112%
Soya bean seed	TRR extracted	98 ^a	0.099	94 ^b	0.095	96%
	parent	15	0.015	18 ^b	0.018	124%
	SYN545720 incl conjugates	47 ^d	0.048	57 ^c	0.058	121%

^a In the metabolism study primary extraction of soya bean hay and seeds was by hexane (3 $\times$), diethyl ether (2 $\times$), acetonitrile (2 $\times$), acetonitrile/water 4:1 v/v (2 $\times$ –7 $\times$), acetonitrile/water 3:7 v/v (1 $\times$ –2 $\times$), water (1 $\times$), and acetonitrile (1 $\times$).

^b In method GRM042.04A primary extraction was by acetonitrile/water 4:1 v/v (1 $\times$) for hay and acetonitrile/water 1:1 v/v (2 $\times$) for seeds. After concentration and acidification of the extract, parent was partitioned into iso-hexane.

^c In the metabolism study for hay only the acetonitrile/water extracts (26.0% TRR) were subjected to 3 hydrolysis procedures, of which bovine rumen fluid (pH 7, 24 hrs at 39 °C) was the most effective.

^d In the metabolism study for seeds only the acetonitrile/water extracts (85.0% TRR) were subjected to hydrolysis by

bovine rumen fluid (pH 7, 24 hrs at 39 °C). The resulting hydrolysate was partitioned between diethyl ether and water. The resulting aqueous phase (29.8% TRR) was subjected to hydrolysis by 0.5 M HCl for 6 hrs at 100 °C.

^e In GRM042.04A the aqueous phase after liquid-liquid partition was subjected to 0.5 M HCl for 6 hrs at 100 °C.

Conclusion:

- Analytical method GRM042.04A and its modifications have three possible moments to analyse parent: just after acetonitrile/water extraction, just after iso-hexane partition or after SPE clean-up. Validation of the method therefore needs to mention the conditions for the parent analysis.
- Analytical method GRM042.04A and its modifications indicate that fortifications of SYN546039 and SYN545720 need to be conducted after the acid hydrolysis procedure. In this way, the full analytical procedure is not validated for the free forms of SYN546039 and SYN545720, because loss or degradation during extraction, liquid-liquid partition and hydrolysis remains unnoticed. It is recommended to include a validation for the whole procedure in case method compliance needs to be shown during actual sample analysis.
- Analytical method GRM042.04A and its modifications use a hydrolysis procedure to cleave the SYN546039 and SYN545720 conjugates. The extraction efficiency of the free forms and the conjugates, the efficacy of the hydrolysis procedure for the conjugates and the stability of the free forms during hydrolysis is validated by a separate radio-validation experiment in soya bean seeds and soya bean hay. The recovery of any SYN546039 or SYN545720 released after hydrolysis is validated by the fortifications of SYN546039 or SYN546720 after the acid hydrolysis procedure.
- The original HPLC-MS-MS method GRM042.04A is considered valid for the determination of parent, SYN546039 (free and conjugated) and SYN545720 (free and conjugated) in the range 0.01–0.1 mg/kg for soya bean seeds, soya bean oil, soya bean milk and 0.01–0.5 mg/kg for soya bean forage. The validity for the parent compound extends only to quantification after the acetonitrile/water extraction stage for soya bean oil, after iso-hexane partition for soya bean seeds and after SPE clean-up for soya bean milk and soya bean forage.
- HPLC-MS-MS method POPIT MET134 Rev 01 is considered valid for the determination of parent, SYN546039 (free and conjugated) and SYN545720 (free and conjugated) in the range 0.01–0.1 mg/kg for soya bean seed. The validity for the parent compound extends only to quantification after iso-hexane partition for soya bean seeds.
- Modification A of HPLC-MS-MS method GRM042.04A is considered valid for the determination of parent and SYN546039 (free) at the level of 0.2 mg/kg for dry soya beans and dry broad beans for the purpose of storage stability studies only.
- Modification B of HPLC-MS-MS method GRM042.04A is considered valid for the determination of parent and SYN546039 (free) at the level of 0.2 mg/kg for maize oil, soya bean flour, soya bean milk and soya bean oil for the purpose of storage stability studies only.
- Modification C of HPLC-MS-MS method GRM042.04A is considered valid for the determination of parent, SYN546039 (free and conjugated) and SYN545720 (free and conjugated) in the range 0.01–1.0 mg/kg for soya bean seeds and aspirated grain fractions, 0.01–0.5 mg/kg for soya bean hulls, soy oil, soya bean meal, fat soy flour, pollard, okara, soy milk, tofu, soy sauce and miso. The validity for the parent compound extends only to quantification after the acetonitrile/water extraction stage for soya bean oil and after the iso-hexane liquid-liquid partition stage for all other soya bean commodities.

HPLC-MS-MS method GRM042.08A

HPLC-MS-MS Method GRM042.08A, version 26 June 2012, [Braid, 2012, SYN545192_10216] is intended for use as pre-registration method for the determination of parent (free), SYN546039 (free

and conjugates) and SYN546206 (free) in plant commodities. The original method or its modification was used in field rotational crop studies and storage stability studies.

High water content crops (10 g) were extracted by homogenisation in 80/20 (v/v) acetonitrile/water. Dry sample matrices (5 g, e.g. grains, straw, hay) were pre-soaked with water (25 mL) for 30 min prior to homogenisation. For the determination of parent and SYN546206 (free), diluted aliquots of the filtered extracts were analysed directly by HPLC-MS-MS. For the determination of SYN546039, aliquots of the extracts were evaporated under a stream of air or nitrogen to remove the acetonitrile, acidified with 1 M HCl and partitioned with 75/25 (v/v) iso-hexane/diethyl ether to separate parent and SYN546206 off. The iso-hexane/diethyl ether fraction was back-partitioned with water to recover the small amount of conjugated SYN546039. The water fraction was then combined with the aqueous acidic fraction. The aqueous acidic fraction was heated at 100 °C for 6 hrs to hydrolyse conjugates of SYN546039. The hydrolysate was cleaned up by SPE and SYN546039 was eluted with 65/35 (v/v) acetonitrile/ water. Following dilution, samples were analysed by HPLC-MS-MS. The primary transition monitored for parent was m/z 396→91 with confirmatory transition m/z 396→368. For SYN546039 the primary transition monitored was m/z 412→91 with confirmatory transition m/z 412→340. The primary transition monitored for SYN546206 is m/z 382→342 with confirmatory transition m/z 382→362. Samples with expected residues > 0.1 mg/kg need to be diluted before analysis.

The analysis conditions as specified in the method description need to be followed carefully. Since parent compound degrades under the hydrolysis conditions used to hydrolyse conjugates of SYN546039 into their free form, parent is separated from the sample before hydrolysis. This step will also remove residues of SYN546206 as these are not conjugated. The metabolite SYN546039 is mainly conjugated in rotational crops and to release the free metabolite, an acid hydrolysis step is required. Change in hydrolysis conditions may result in either incomplete deconjugation or degradation of SYN546039 (free). Parent compound has been observed to adsorb to glass surfaces in solutions with < 50% organic solvent and therefore storage conditions need to be chosen carefully. These considerations have been dealt with in the described analytical method.

HPLC-MS-MS Method GRM042.08A was validated [Watson, 2012c, SYN545192_10203] according to the full validation scheme for spinach, carrot roots and wheat commodities (grain, straw, forage). The validation was performed for the quantification transition ions as well as for the confirmation transition ions. Samples were fortified with a mixture of SYN545192, SYN546039 and SYN546206 standard before extraction. The reported LOQ was 0.01 mg/kg for each commodity and each analyte. Average recoveries at 0.01 mg/kg and 0.1 mg/kg of parent or SYN546039 (free) or SYN546206 (free) were within 70–120% limits and RSDs were within 20%. For wheat straw and wheat forage recoveries at 0.01 mg/kg and 0.5 mg/kg were also within these ranges. Linearity of detector response (coefficient of determination $R^2 > 0.99$) was observed in the range 0.1–4 ng/mL using six single standards. This range is equivalent to 0.25–10× LOQ in the samples. Samples which were fortified at 10× LOQ were diluted by a factor of two and samples which were fortified at 50× LOQ were diluted by a factor of 10 to fall within the linear range. The magnitude of the matrix effect was considered to be significant ($\geq 20\%$ suppression or enhancement). Matrix matched standards were used for each matrix/analyte combination. No interfering peaks > 0.3LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

Additional validation data for the determination of SYN546206 were available for spinach, wheat grain, wheat straw and potato at the fortification level used in the storage stability study [Watson, 2013, SYN545192_10137]. SYN546206 was added before extraction as a single analyte per sample. Average recoveries at 0.2 mg/kg of SYN546206 were within 70–120% limits and RSDs were within 20% (n=12). Linearity of detector response (coefficient of correlation $r > 0.999$) was observed in the range 0.02–10 ng/mL using six single matrix matched standards. No interfering peaks > 0.3LOQ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

Reduced validation data were available for the determination of parent, SYN546206 (free) and SYN546039 (free) in carrot (roots and tops) [Ellis, 2012b/c, A17056B_10004, A17056B_10005]. Average recoveries at 0.01 mg/kg (n=3), 0.05 mg/kg (n=2) and 0.1 mg/kg (n=1) were within 70–

120% limits and RSDs were within 20% at 0.01 mg/kg. Linearity of detector response (coefficient of correlation $r > 0.999$) was observed in the range 0.02–4 ng/mL using five single matrix matched standards. No interfering peaks $> 0.3\text{LOQ}$ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

Modification A of HPLC-MS-MS method GRM042.08A was used in the US field rotational crop studies [Mayer, 2012, A17056B_50013]. Parent and SYN546206 were analysed after liquid-liquid partition and SPE clean-up. An aliquot of the acetonitrile/water extracts was evaporated under a stream of nitrogen to remove the acetonitrile. The remaining aqueous extract was acidified with 1 M HCl and partitioned with 75:25 iso-hexane/diethyl ether to separate parent and SYN546206 (organic phase) from SYN546039 (acidic aqueous phase). The iso-hexane/diethyl ether fraction was back-partitioned with water. The organic fraction was evaporated to dryness and taken up in 50/50 v/v acetonitrile/water. The aqueous fractions were combined, diluted to 0.5 M HCl, and heated at 100 °C for 6 hours to hydrolyse conjugates of SYN546039. The post-hydrolysis extract containing the SYN546039 residues was combined with the fraction containing the parent and SYN546206 residues and cleaned-up on SPE using acetonitrile/water (50/50, v/v) as eluent. The eluent was analysed by HPLC-MS-MS.

Only limited validation data were available for modification A for the determination of parent, SYN546206 (free) and SYN546039 (free) in lettuce, spinach, wheat commodities (forage, hay, straw and grain), turnip (roots, tops), radish (roots and tops) [Mayer, 2012, A17056B_50013]. The original method determines parent and SYN546206 directly in the initial extract, while the modification determines parent and SYN546206 after liquid-liquid partition and an SPE clean-up step, which may introduce losses of both analytes. Individual recoveries at 0.01 mg/kg ($n=1$) and 0.1 mg/kg ($n=1$) for each of the commodities were within 70–120% limits. Linearity of detector response (coefficient of correlation $r > 0.999$) was observed in the range 0.02–4 ng/mL using five single matrix matched standards. No interfering peaks > 0.005 mg/kg) were detected in any of the control extracts.

The extraction procedure used in method GRM042.08A was radio-validated using samples of wheat hay and straw from the pyrazole labelled confined rotational crop study [Roohi and Adams, 2012, SYN545192_10246]. An aliquot of the homogenised wheat hay and straw sample (5 g) was soaked in 25 mL water for 30 min and subsequently extracted with acetonitrile/water (80:20 v/v). Following centrifugation aliquots of the supernatants of each sample were analysed by LSC and TLC

Results are shown in Table 24. Analysis of wheat hay and wheat straw extracts showed that the efficiency of extraction for the residue analytical method was at least 71% for parent and 81% for SYN546206 (free). Efficiency of extraction of SYN546039 from wheat hay and wheat straw was not verified and efficiency of hydrolysis to extract the SYN546049 conjugates from wheat hay and wheat straw was not verified either.

Table 24 Radiovalidation of primary extraction procedures used in analytical method GRM042.08A

Commodity	Components	Confined rotational crop study ^a 90 day PBI		Method GRM042.08A ^b		Efficiency %TRR method: confined study

	SYN546206	15—total 14—free 1.3—conj	0.050—total 0.046—free 0.004—conj	— 14—free —	— 0.045—free —	— 99—free —

^a In the confined rotational crop study primary extraction of wheat hay and straw was by acetonitrile (1×), acetonitrile/water (4:1, v/v) (2–3×), acetonitrile/water (3:7, v/v) (1×), water (1×), acetonitrile (1×). Extracts were combined, concentrated, re-suspended in pH 2 water and partitioned with hexane/diethyl ether (1:3 v/v). The organic fraction contained the free metabolites. The aqueous fraction was subjected to hydrolysis by bovine rumen fluid (pH 7, 24 hrs at 39 °C, under nitrogen). This fraction contained the conjugates.

^b In method GRM042.08A primary extraction was by acetonitrile/water 4:1 v/v (1×).

Conclusion:

- Efficiency of extraction is at least 71% for parent and 81% for SYN546206 (free) as shown by a radio-validation study in wheat hay and wheat straw.
- Efficiency of extraction and hydrolysis for SYN546039 conjugates has been confirmed in a radio-validation study using method GRM042.04A, where the extraction and hydrolysis procedures are identical to those in method GRM042.08A.
- HPLC-MS-MS method GRM042.08A is considered valid for the determination of parent, SYN546039 (free/conjugated) and SYN546206 (free) in the range 0.01–0.1 mg/kg for spinach, carrot (roots, leaves) and wheat grain and 0.01–0.5 mg/kg for wheat straw and wheat forage.
- HPLC-MS-MS method GRM042.08A is considered valid for the determination of SYN546206 (free) at a single level of 0.2 mg/kg in spinach, wheat grain, wheat straw and potato tuber for the purpose of a storage stability study.
- Modification A of HPLC-MS-MS method GRM042.08A is considered valid for the determination of parent, SYN546206 (free) and SYN546039 (free/conjugated) in the range 0.01–0.1 mg/kg for spinach and wheat commodities (forage, hay, straw and grain), since it could be shown that extension of the original method with liquid-liquid partition and an SPE clean-up step did not introduce losses compared to the original method.
- Modification A of HPLC-MS-MS method GRM042.08A (or the original method) is considered insufficiently validated for the determination of parent, SYN546206 (free) and SYN546039 (free/conjugated) in lettuce, turnip (roots, tops) and radish (roots, tops) since only one recovery per level (0.01 and 0.1 mg/kg) is available for each commodity.

HPLC-MS-MS method GRM023.03A

HPLC-MS-MS method GRM023.03A, version 11 February 2010, [Hargreaves, 2010, SYN508210_10287] is intended for use as pre-registration method for the determination of SYN508272 (CSCC210616, free and conjugated) and SYN545720 (CSCD465008, free only) and seven other related chemicals in plant commodities. The original method or its modification was used in a storage stability study.

High water samples and grains (10 g) were extracted by homogenisation in 80/20 (v/v) acetonitrile/water. Straw and hay samples (5 g) were pre-soaked with 25 mL water for 30 min prior to homogenisation. Soya bean hay was extracted twice with 80/20 acetonitrile/water and extracts were combined. For the determination of SYN508272 (CSCC210616), separate aliquots of the initial extracts (equivalent to 0.2 g sample) were evaporated to remove the acetonitrile. The aliquots were

buffered to pH 5 with 0.2 M sodium acetate buffer and hydrolysed using driselase® at 37 °C (6–20 hrs) and cleaned-up through an SPE procedure using Oasis TM HLB cartridges. SYN508272 was eluted with acetonitrile. The acetonitrile was evaporated to dryness and the residue re-dissolved in water. For the determination of SYN545720 (CSCD465008), separate aliquots of the initial extracts (equivalent to 0.2 g) were evaporated to remove the acetonitrile and partitioned with iso-hexane. The aqueous phase was then acidified to pH 1 with 1 M HCl to ensure that SYN545720 is retained on the SPE cartridge and taken through an SPE clean-up procedure, using Oasis TM HLB cartridges. SYN545720 was eluted with 50/50 v/v water/acetonitrile. The eluate was evaporated to remove the acetonitrile and then diluted with water. SYN508272 and SYN545720 were analysed separately by HPLC-MS-MS using different solvent and ionisation systems. The primary transition monitored for SYN508272 was m/z 176→136 with confirmatory transition m/z 176→156. For SYN545720 the primary transition monitored was m/z 161→141 with confirmatory transition m/z 161→66. Samples with expected residues > 0.5 mg/kg need to be diluted before analysis.

The analysis conditions as specified in the method description need to be followed carefully. It is important that all the acetonitrile is removed from the sample prior to enzyme hydrolysis, since any remaining acetonitrile may adversely affect the efficiency of the hydrolysis. Change in enzyme hydrolysis conditions may result in either incomplete deconjugation or degradation of free metabolites. These considerations have been dealt with in the described analytical method.

HPLC-MS-MS Method GRM023.03A was validated [Klimmek and Gizler, 2009, SYN524464_11238] according to the full validation scheme for SYN508272 (CSCC210616) in wheat (grain, straw, whole plant), carrot roots, spinach, potatoes, whole oranges, oilseed rape seeds, dry lentils, tomatoes and maize kernels, using the driselase hydrolysis step as indicated the analytical method. Further the method was validated according to the full validation scheme for SYN545720 (CSCD465008) in whole oranges and dry soya bean seeds without addition of a pectinase hydrolysis step and for SYN545720 (CSCD465008) in potatoes, whole oranges, oil seed rape seeds, lentils, tomatoes, maize kernels and dry soya bean seeds with addition of a pectinase hydrolysis step (see note below). The validation was performed for the quantification transition ions as well as for the confirmation transition ions. Samples were fortified with a mixture of SYN508272 and SYN545720 (and seven other related chemicals) before extraction. The reported LOQ was 0.01 mg/kg for each commodity and each analyte. Average recoveries at 0.01 mg/kg and 0.1 mg/kg of SYN508272 and SYN545720 were within 70–120% limits and RSDs were within 20%. Linearity of detector response (determination coefficient $R^2 > 0.99$) was observed in the range 0.05–20 ng/mL using 6–8 single standards. This range is equivalent to 0.25–12× LOQ in the samples. Significant enhancement or suppression ($> \pm 10\%$) of detector response was observed for some of the matrices tested. Matrix matched standards were used to compensate for these effects observed in method validation. For the determination of SYN508272 (CSCC210616), matrix matched standards were used for wheat grain, wheat straw, orange, oilseed rape seed, lentils, tomatoes, maize kernels and soya bean seeds. For the determination of SYN545720 (CSCD465008), matrix matched standards were used in orange, oilseed rape seed, lentils, tomatoes, maize kernels and soya bean seeds. No interfering peaks $> 0.3\text{LOQ}$ (i.e. 0.003 mg/kg) were detected in any of the control extracts. The viability of individual batches of driselase® to cleave sugar conjugates was investigated by hydrolysing 2-Nitrophenyl β -D-glucopyranoside into 2-nitrophenol, causing a colour change from colourless to yellow/green.

Note: SYN545720 (CSCD465008) residues in crops may be present as conjugates and therefore a pectinase hydrolysis step was included during validation of the analytical method. For the analysis of SYN545720 (free + conjugated) aliquots (equivalent to 0.2 g) were evaporated to remove acetonitrile then buffered to pH 5 with sodium acetate buffer then hydrolysed using pectinase at 37 °C (16-20 hrs). Thereafter, the solution was partitioned with hexane and the aqueous phase was acidified to pH 1 with 1 M HCl and taken through a SPE clean-up procedure using Oasis TM HLB cartridges. SYN545720 was eluted with 50:50 v/v water:acetonitrile. The column eluates were evaporated to remove the acetonitrile and then diluted with water. During this method validation it was demonstrated in oranges and soya bean seed matrix, that the removal/addition of the pectinase hydrolysis step had no adverse effect on the recovery of free SYN545720. The analytical method as used in the storage stability studies did not include the pectinase step.

Additional validation data are available for the determination of SYN508272 and SYN545720 in whole oranges, dry soya bean seeds and dry broad beans [Klimmek *et al*, 2011, SYN524464_11446]. The analytical method included an enzyme hydrolysis step (driselase for SYN508272 and pectinase for SYN465008) as described in the validation report [Klimmek and Gizler, 2009, SYN524464_11238]. Samples were fortified separately with SYN508272 or SYN545720 before extraction. Average recoveries at 0.2 mg/kg of SYN508272 and SYN545720 were within 70–120% limits and RSDs were within 20%.

Conclusion:

- HPLC-MS-MS method GRM023.03A is considered valid for the determination of SYN508272 (free) in the range 0.01–0.1 mg/kg for wheat (grain, straw, whole plant), carrot roots, spinach, potatoes, whole oranges, oilseed rape seeds, dry lentils, tomatoes, maize kernels for the full analytical method including the driselase hydrolysis step.
- HPLC-MS-MS method GRM023.03A is considered valid for the determination of SYN545720 (free) in the range 0.01–0.1 mg/kg in potatoes, whole oranges, oil seed rape seeds, lentils, tomatoes, maize kernels and dry soya bean seeds. For whole oranges and dry soya bean seeds it has been shown that inclusion of a pectinase step does not have an effect on the recovery of the free SYN545720.
- HPLC-MS-MS method GRM023.03A is considered valid for the determination of SYN508272 (free) or SYN545720 (free) at the level of 0.2 mg/kg for whole oranges, dry soya beans and dry broad beans for the purpose of storage stability studies only.
- HPLC-MS-MS method GRM023.03A is considered not valid for the determination of conjugated SYN545720 and conjugated SYN508272, since the efficacy of the hydrolysis procedure has not been verified. However, since the method was only used in a storage stability study (free metabolites), this will have no impact on the results.

Analytical methods used in study reports in animal commodities

HPLC-MS-MS method GRM042.06A and Method 1887 version 2.0

HPLC-MS-MS Method GRM042.06A, version 27 January 2012, [Harris and Braid, 2012, SYN545192_10182] is identical to Method 1887 rev 2.0, version 22 September 2011, [Ward and Harris, 2011, SYN545192_10157]. The method is intended for use as pre-registration method for the determination of parent (free), SYN546039 (free and conjugates) and SYN546422 (free and conjugates) in animal commodities. A modification of the method was used in a cow feeding study.

Meat, liver, kidney, milk, and eggs (10 g) were homogenised with acetonitrile:water (80:20, v/v). Fat (10 g) was dissolved into n-hexane before liquid-liquid partitioning into acetonitrile:water (80:20, v/v). For the determination of parent, diluted aliquots of the extract were analysed directly by HPLC-MS-MS. For determination of SYN546039 and SYN546422, an aliquot of the extract was diluted with water prior to removal of the acetonitrile by evaporation. The remaining extract was then buffered with 0.4 M sodium acetate and conjugates of SYN546039 and SYN546422 were hydrolysed with β -glucuronidase by incubation at 37 °C and pH 5 for a minimum of 6 hours. After hydrolysis, the sample was diluted with acetonitrile:water (50:50, v/v), centrifuged and analysed by HPLC-MS-MS. The primary transition monitored for parent was m/z 396 $\rightarrow$ 91 with confirmatory transition m/z 396 $\rightarrow$ 368. For SYN546039 the primary transition monitored was m/z 412 $\rightarrow$ 91 with confirmatory transition m/z 412 $\rightarrow$ 340. The primary transition monitored for SYN546422 is m/z 430 $\rightarrow$ 364 with confirmatory transition m/z 430 $\rightarrow$ 394. Samples with expected residues > 0.1 mg/kg need to be diluted before analysis.

The analysis conditions as specified in the method description need to be followed carefully. To release the free metabolites of SYN546039 and SYN546422 a hydrolysis step is required. It is important that hydrolysis conditions are not changed to ensure efficient hydrolysis. The viability of the β -glucuronidase enzyme needs to be checked prior to use by hydrolysing phenolphthalein

glucuronide. Parent compound has been observed to adsorb to glass surfaces in solutions with < 50% organic solvent. These considerations have been dealt with in the described analytical method.

HPLC-MS-MS Analytical Method 1887 version 2.0 [Ward and Harris, 2011, SYN545192_10157] including the hydrolysis step was validated according to the full validation scheme for bovine meat, liver, kidney, fat, milk, and chicken eggs. The validation was performed for the quantification transition ions as well as for the confirmation transition ions. Samples were fortified with a mixture of SYN545192, SYN546039 and SYN546422 standard before extraction. The reported LOQ was 0.01 mg/kg for each commodity and each analyte. Average recoveries at 0.01 mg/kg and 0.1 mg/kg of parent or SYN546039 (free) or SYN546422 (free) were within 70–120% limits and RSDs were within 20%. Linearity of detector response (coefficient of determination $R^2 > 0.99$ for $1/\times$ weighted regression) was observed in the range of 0.15–10 ng/mL for parent and 0.06–4 ng/mL for SYN546039 and SYN546422 using six single standards. This range is equivalent to 0.3–20 $\times$ LOQ in the samples. The magnitude of the matrix effect was considered to be significant ($\geq 20\%$ suppression or enhancement) for parent, SYN546039 or SYN546422 in meat, liver, kidney or eggs. Matrix-matched calibration standards were used for all analytes in meat, liver and kidney and for SYN546039 and SYN546422 in eggs. Solvent standards were used for all analytes in fat and milk and for SYN545192 in eggs. No interfering peaks $> 0.3\text{LOQ}$ (i.e. 0.003 mg/kg) were detected in any of the control extracts. The viability of the β -glucuronidase enzyme was checked visually before use by observing a colour change from colourless to pink after hydrolysis of phenolphthalein glucuronide to phenolphthalein.

Modification A of HPLC-MS-MS method 1887 Version 2.0 was used in the cow feeding study and the storage stability study in animal commodities [Ward and Vance, 2012, SYN545192_10188]. During analysis of bovine tissues, a chromatographic peak was found that interfered with the analysis of SYN546039. The extraction and work-up procedure were unchanged; modifications were made to the HPLC-MS-MS system only. Samples were fortified with a mixture of parent, SYN546039 and SYN546422 standard before extraction. Additional validation data were available for eggs, whole milk, skimmed milk, cream, bovine muscle, liver, kidney and fat. Average recoveries at 0.01–0.2 mg/kg (milk, muscle and liver) or 0.01–0.1 mg/kg (skimmed milk, cream, kidney and fat) or 0.2 mg/kg (eggs) were within 70–120% limits and RSDs were within 20% ($n=2$ –16 per level). Linearity of detector response (coefficient of correlation $r > 0.99$, weighting factor $1/\times$) was observed in the range 0.15–10 ng/mL (parent) or 0.06–4.0 ng/mL (metabolites) using seven single solvent standards or matrix matched standards. No interfering peaks $> 0.3\text{LOQ}$ (i.e. 0.003 mg/kg) were detected in any of the control extracts.

The extraction and hydrolysis procedure used in method GRM042.06A was radio-validated using samples of milk, liver and muscle from the pyrazole labelled metabolism study in lactating goats [Green, 2012, SYN545192_10184] and samples of egg yolk from the pyrazole labelled metabolism study in laying hens [Lowrie and Kadow, 2012, SYN545192_10170]. An aliquot of milk (50 g), liver (25 g), muscle (25 g) and egg yolk (25 g) was extracted once with acetonitrile/water (80:20 v/v). An aliquot of the liver extract was evaporated to remove the acetonitrile. The remaining extract was then buffered with 0.4 M sodium acetate and conjugates were hydrolysed with β -glucuronidase by incubation at 37 °C and pH 5 for a minimum of 6 hours. After hydrolysis, the enzyme was denatured by addition of acetonitrile. Aliquots of the milk, liver, muscle and egg extracts and the liver hydrolysate were analysed by LSC and 2D-TLC.

Results are shown in Table 25. Good agreement was obtained between the levels of parent, SYN546039 (free including conjugates) and SYN546422 (free including conjugates) found after extraction (and hydrolysis) as performed in the metabolism study and as performed in method GRM042.06A.

^a In the metabolism study liver and muscle were primary extracted sequentially with acetonitrile (1×), acetonitrile/water 4:1 v/v (1–4×), acetonitrile/water 3:7 v/v (1–2×), water (1×) and acetonitrile (1×). Liver extracts were subject to β -glucuronidase (pH 5, 37 °C, 18 hrs) and subsequently partitioned with ethyl acetate. Milk was primary extracted with dichloromethane (3×), ethyl acetate (2×) and acetone (1×). Egg yolk was primary extracted with dichloromethane (1×), acetonitrile (1×), acetonitrile/water 4:1 v/v (2–3×), acetonitrile/water 3:7 v/v (1–4×), water (1×) and acetonitrile (1×).

^b In method GRM042.06A primary extraction was by acetonitrile/water 4:1 v/v (1×). Extracts were then subjected to β -glucuronidase (pH 5, 37 °C, 6 hrs). In this experiment only liver extracts were subjected to β -glucuronidase; in the actual method, all matrices were β -glucuronidase.

Conclusion:

- The efficacy of the extraction procedure of parent and SYN546039 (free) is confirmed by a separate radio-validation experiment in muscle, liver, milk and eggs, while the efficacy of the extraction procedure of SYN546422 (free) is confirmed in muscle, liver and milk.
- The efficacy of the extraction and hydrolysis procedure of SYN546039 conjugates or SYN546422 conjugates is confirmed by a separate radio-validation experiment in bovine liver.
- HPLC-MS-MS method GRM042.06A or Analytical Method 1887 version 2.0 is considered valid for the determination of parent (free), SYN546039 (free/conjugated) and SYN546422 (free/conjugated) in the range 0.01–0.1 mg/kg for meat, liver, kidney, fat, milk and eggs.
- Modification A of HPLC-MS-MS method GRM042.06A is considered valid for the determination of parent (free), SYN546039 (free/conjugated) and SYN546422 (free/conjugated) in the range 0.01–0.2 mg/kg (milk, muscle, liver) or 0.01–0.1 mg/kg (skimmed milk, cream, kidney and fat) or 0.2 mg/kg (eggs).

Analytical methods used in study reports in soil and water

The Meeting received analytical methods descriptions and validations for the determination of parent and its metabolites in soil and water. Since soil or water samples were not analysed in the field rotational crop studies, analytical methods for soil and water were not summarized.

Stability of pesticide residues in stored analytical samples

The Meeting received information on storage stability of parent, SYN546039, SYN546206 and SYN545720 in raw and processed plant commodities and of parent, SYN546039 and SYN546422 in animal commodities.

Study 1

Storage stability was investigated by spiking various homogenised plant commodities with 0.20 mg/kg parent or SYN546039 or SYN546206 (one analyte per sample) [Watson, 2013, SYN545192_10137]. Samples were stored for 22–24 months at –18 °C and were analysed in duplicate at various intervals. Modification A of HPLC-MS-MS method GRM042.03A was used for quantification of parent and SYN546039 in spinach, orange, wheat grain, wheat straw and potato. Modification A of HPLC-MS-MS method GRM042.04A was used for quantification of parent and SYN546039 in dry soya bean seeds and dry broad bean seeds. HPLC-MS-MS method GRM042.08A was used for quantification of SYN546206 in spinach, wheat grain, wheat straw and potato. Methods GRM042.03A, GRM04.04A and GRM042.08A are considered valid for the purpose of this study (commodity type and concentration level of the analytes). Average concurrent recoveries were within 70–120% for each analyte and matrix and control samples had residues < 0.3LOQ (i.e. < 0.003 mg/kg), showing adequate performance at the time of analysis of the samples.

Storage stability results (not corrected for concurrent recovery) and concurrent recoveries are shown in Table 26 and 27. Residues of parent and SYN546039 (free) are stable for at least 24 months in crop commodities representative of the high water (spinach), high acid (orange), high starch (wheat grain and potato), high protein (dry broad bean seed), high oil (soya bean seed) commodity groups as well as in wheat straw when stored at or below –18 °C. Residues of SYN546206 are stable for at least 22 months in crop commodities representative of the high water (spinach) and high starch (wheat grain, potato) commodity groups as well as in wheat straw when stored at or below -18 °C.

	671	0.21	110	106

^a The % remaining was set at 100% at time zero. If 0.16 mg/kg was found at time zero, instead of the expected 0.20 mg/kg, the 0.16 mg/kg was set at 100%, to see the development of this residue level in time.

Study 2

Storage stability was investigated by spiking various homogenised plant commodities with 0.20 mg/kg SYN508272 and SYN545720 [Klimmek *et al*, 2011, SYN524464_11446]. Samples were stored for 24 months at -18 °C and were analysed in duplicate at various intervals using HPLC-MS-MS method GRM023.03A. The analytical method included an enzyme hydrolysis step (driselase for SYN508272 and pectinase for SYN465008) as described in the validation report of the method [Klimmek and Gizler, 2009, SYN524464_11238]. Method GRM023.03A is considered valid for the purpose of this study (commodity type and concentration level of the analytes). Average concurrent recoveries were within 70–120% for each analyte and matrix and control samples had residues < 0.3LOQ (i.e. < 0.003 mg/kg), showing adequate performance at the time of analysis of the samples.

Storage stability results (not corrected for concurrent recovery) and concurrent recoveries are shown in Table 28. Residues of SYN508272 (free) and SYN545720 (free) are stable for at least 24 months in crop commodities representative of the high oil (soya bean seeds), high acid (orange) and high protein (dry broad bean seeds) commodity groups when stored at or below -18 °C.

Note: The study report describes storage stability for a set of seven related chemicals. SYN508272 (CSCC210616) and SYN545720 (CSCD465008) were added as a single compound to separate samples. The other related chemicals were added to other samples. Addition of these chemicals did therefore not affect the storage stability results of SYN508272 or SYN545720.

Table 28 Storage stability of 0.20 mg/kg SYN545720 or SYN508272 in crop commodities stored frozen at -18 °C

	539	0.16	101	101	0.18	97	86
	734	0.18	112	88	0.21	115	109

^a The % remaining was set at 100% at time zero. If 0.16 mg/kg was found at time zero, instead of the expected 0.20 mg/kg, the 0.16 mg/kg was set at 100%, to see the development of this residue level in time.

Study 3

Storage stability was investigated by spiking homogenised processed plant commodities with 0.20 mg/kg parent or SYN546039 or SYN545720 (one analyte per sample) [Hagan and Bertrand, 2012/2013, SYN545192_50177, SYN545192_50544]. The SYN545720 compound was only added to processed soya bean commodities. Samples were stored for 24 months at –10 °C and were analysed in duplicate at various intervals. Modification B of HPLC-MS-MS method GRM042.03A was used for the quantification of parent and SYN546039 in maize flour and maize meal, raisins, dried apple and apple juice. Modification B of HPLC-MS-MS method GRM042.04A was used for the quantification of parent, SYN546039 and SYN545720 in maize oil, soya bean flour, soya bean milk and soya bean oil. Methods GRM042.03 and GRM042.04A are considered valid for the purpose of this study (commodity type and concentration level of the analytes). Average concurrent recoveries were within 70–120% for each analyte and matrix. Levels in control samples were < 0.04 mg/kg, but since the fortification levels are 0.2 mg/kg, this is considered to have no impact on the study results. Therefore, performance is considered adequate at the time of analysis of the samples.

Storage stability results (not corrected for concurrent recovery) and concurrent recoveries are shown in Tables 29 and 30. Residues of parent, SYN546039 (free) and SYN545720 (free) are stable for at least 24 months in crop commodities various processed crop commodities (flour, meal, oil, soymilk, dried fruit, fruit juice) when stored at or below –10 °C.

Study 4

Storage stability was investigated by spiking various animal commodities with 0.20 mg/kg parent, SYN546039 or SYN546422 (one analyte per sample) [Ward and Vance, 2012, SYN545192_10188]. Samples for concurrent recoveries were spiked with a mixture of these three analytes. Samples were stored for 56–78 days at –20 °C and were analysed in duplicate using modification A of HPLC-MS-MS method 1887 (see method GRM042.06). The modification of Method 1887 is considered valid for the purpose of this study (commodity type and concentration level of the analytes). Average concurrent recoveries were within 70–120% for each analyte and matrix and control samples had residues < 0.3LOQ (i.e. < 0.003 mg/kg), showing adequate performance at the time of analysis of the samples.

Storage stability results (not corrected for concurrent recovery) and concurrent recoveries are shown in Table 31. Residues of SYN545192, SYN546039 and SYN546422 are stable in milk stored frozen for at least 62 days, in eggs for at least 56 days, in liver for at least 78 days and in muscle for at least 76 days. According to OECD Guideline 506 storage stability in kidney and fat may be extrapolated from the other animal tissues.

Table 31 Storage stability of 0.20 mg/kg parent, SYN546039 and SYN546422 in animal commodities stored at –20 °C

Analyte	Matrix	Storage period (days)	Mean residue (mg/kg)	Mean % remaining	Mean concurrent recovery (%)
parent	milk	0	0.18	100 ^a	89
		62	0.21	119	94

		56	0.17	85	98
		78	0.16	80	94

^a The % remaining was set at 100% at time zero. If 0.16 mg/kg was found at time zero, instead of the expected 0.20 mg/kg, the 0.16 mg/kg was set at 100%, to see the development of this residue level in time.

USE PATTERN

Benzovindiflupyr is a broad-spectrum fungicide belonging to the chemical class of pyrazole carboxamides (like bixafen, fluxapyroxad, furametpyr, isopyrazam, penflufen, penthiopyrad, sedaxane). Benzovindiflupyr acts as an inhibitor of the fungal complex II respiratory chain, where it inhibits the succinate dehydrogenase enzyme (succinate dehydrogenase inhibitor, SDHI fungicide) by blocking the ubiquinone-binding sites in the mitochondrial complex. Benzovindiflupyr is a broad-spectrum fungicide, especially used for its effect against rust. [Label information and Mayer, 2012, A17056B_50013].

Benzovindiflupyr is a registered fungicide in soya beans only and only in Paraguay (Table 32). The original registered labels were submitted in the original language as well as in its English translation.

Benzovindiflupyr registrations are intended in the USA in 2014 for pome fruit, blueberries, grapes, fruiting vegetables (including cucurbits and sweet corn), root and tuber vegetables, pulses (dry beans, dry peas and soya beans), cereals (barley, maize and wheat), oilseeds (cottonseed; peanuts and rapeseed), sugarcane and coffee beans. At the time of this evaluation, the respective labels were not authorised and consequently the residue trials were not submitted.

Table 32 Registered pre-harvest uses of benzovindiflupyr

Crop	Country	Form (g ai/kg)	Application				PHI, days
			Method	Rate kg ai/ha	Spray volume	Number (interval in days)	
Soya bean	Paraguay	WG 150 ^{a, b}	Foliar spray	3 × 0.045	100–200 L/ha	3 (14)	21

^a water dispersible granule containing 150 g/kg benzovindiflupyr and 300 g/kg azoxystrobin.

^b The product must be used with a paraffinic mineral oil, used as an adjuvant. The recommendation is to add the adjuvant to the water volume together with the formulated product for benzovindiflupyr [Syngenta, 2014b].

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received information on supervised residue trials of benzovindiflupyr for soya beans only. Application rates and spray concentrations have been rounded to two significant figures; residues at around the LOQ or 0.01 mg/kg have been rounded to one figure. Residue data are recorded unadjusted for percentage recoveries or for residue values in control samples unless otherwise stated. Unquantifiable residues are shown as below the reported LOQ (e.g. < 0.01 mg/kg). Where multiple samples were taken from a single plot or where multiple analyses were conducted on a single sample, the average value is reported. Where results from separate plots with distinguishing characteristics such as different formulations, crop varieties or treatment schedules were reported, results are listed

separately for each plot, but only one value is selected for MRL derivation. Residues from the trials conducted according to critical GAP have been used for the estimation of maximum residue levels, STMR and HR values. Those results are underlined.

Soya beans

Supervised residue field trials were conducted on soya beans in the 2010–2011 season in Brazil [Casallanova, 2011a/b/c, A17961A_10022; A17056F_10022; A18126B_10032]. Soy plants were treated with an EC formulation containing 150 g ai/L benzovindiflupyr alone (report M11063) or 50 g ai/L benzovindiflupyr in combination with 100 g ai/L azoxystrobin (report M11075) or with a WG formulation containing 150 g ai/kg benzovindiflupyr in combination with 300 g ai/kg azoxystrobin (report M11086). Small plots of soya beans (60–90 m²) were treated as indicated in Table 33 using boom sprayers with a spray volume of 200 L/ha. All treatments included Nimbus adjuvant at 600 mL/ha.

Soya bean plants were harvested at maturity at three time points after the final application with growth stages BBCH 85–97, 86–97 and 87–97. Soya bean plants were threshed immediately to separate the seeds and the rest of plant. Samples were collected from at least 12 different points along the plot reaching at least 2 kg of soya bean seeds after threshing. Sample sizes were in accordance with appendix V of the FAO manual. All samples were stored frozen for 15–73 days at –20 °C. This storage period is covered by the storage stability studies on parent, SYN546039 and SYN545720 in commodities with high oil content.

Samples were analysed for parent and its metabolites SYN546039 and SYN545720 using HPLC-MS-MS method POPIT MET.134 (see GRM042.04A). The analytical method is considered valid in the range 0.01–0.1 mg/kg for the determination of parent, free and/or conjugated SYN546039 and free and/or conjugated SYN545720 in dry soya bean seed. Average concurrent recoveries were within 70–120% for each analyte and control samples had residues < LOQ (i.e. < 0.01 mg/kg), showing adequate performance at the time of analysis of the samples.

Residues of benzovindiflupyr and its metabolites SYN546039 and SYN545720 from the trials are summarised in Table 33.

Table 33 Residues in soya bean seeds after foliar spray applications in the field

^a 600 mL/ha of Nimbus adjuvant added to the spray solution. Nimbus is a paraffinic mineral oil, used as an adjuvant [Syngenta, 2014b]

^b The formulation also contained azoxystrobin. The treatment of 0.030/0.045/0.050 kg ai/ha for benzovindiflupyr resulted in 0.060/0.090/0.100 kg ai/ha for azoxystrobin. All benzovindiflupyr treatments were preceded by a single treatment with azoxystrobin at 0.050 kg ai/ha.

^c Rainfall within 24 hrs after the last application: 16 mm in in Holambra, 10 mm in Rio Verde and 0.4 mm in Rondonopolis. Given the high residues found in Holambra, trials can be selected for MRL derivation.

FATE OF RESIDUES IN STORAGE AND PROCESSING

In storage

No data submitted.

In processing

The Meeting received information on the nature of residues under conditions simulating pasteurisation, baking/brewing/boiling and sterilisation. In addition the Meeting received processing studies on soya beans.

Study 1

The behaviour of benzovindiflupyr was studied under conditions simulating pasteurisation, baking/brewing/boiling and sterilisation [Simmonds, 2011, SYN545192_10162]. Duplicate solutions of 1.00–1.01 mg/L [pyrazole-5-¹⁴C]-benzovindiflupyr were prepared in 0.1 M sterile citrate buffers at pH 4, 5 and 6 in glass tubes. The buffer solutions were incubated in the dark for 20 minutes at 88–90 °C (pH 4), 60 minutes at 98–100 °C (pH 5) or 20 minutes at 120–121 °C (pH 6) and 0.95–1.00 bar. Control samples from each pH group were incubated in the dark at room temperature. The buffer solution was then removed from each tube and the tubes rinsed with acetonitrile to recover the radioactivity adsorbed to the glassware. The buffer and rinse solutions were combined and analysed by LSC on the day of incubation. All samples were analysed by HPLC with radio-detection and representative samples were also analysed by TLC with radio-detection to confirm the identity of benzovindiflupyr parent. Parent was used as reference standard for both analyses.

The pH of the solutions did not change throughout the course of each experiment. The mean recovery of radioactivity applied to the test systems ranged from 98.4 to 100.7% for hydrolysed samples and from 97.7 to 101.8% for control sample. Table 34 shows radioactivity in the treated samples and control samples comprised only parent (no hydrolysis products were observed).

Table 34 Recovery and identification of radioactivity in 1 mg/L [¹⁴C]benzovindiflupyr solutions under pasteurisation, baking/brewing/boiling and sterilisation simulating conditions

Conditions	post incubation (%TAR)	parent (%TRR)
pH 4 (90 °C, 20 min) (pasteurisation)	99/101	100/100
pH 5 (100 °C, 60 min) (baking/brewing/boiling)	99/100	100/100
pH 6 (120 °C, 20 min) (sterilisation)	99/98	100/100

Study 2

Two supervised residue field trials with soya beans were conducted in Greece in 2010 [Ellis, 2012a, A17056D_10002]. Small plots of soya beans (360 m²) were treated with an EC formulation containing 150 g ai/L benzovindiflupyr alone. Four foliar applications were made, the first two at 0.074–0.075 kg ai/ha and the second two at an exaggerated rate of 0.369–0.372 kg ai/ha, each with a spray interval of 7 days. The applications were made with a backpack sprayer at a spray volume of 591–598 L/ha (no adjuvant). The last application was made at growth stage BBCH 82 (19–20 October 2010). Soya bean plants were harvested at normal commercial harvest (BBCH 89), 14 days after the last application. Plants were harvested and threshed using a combine and then separated further using an air stream to remove lighter parts and heavy parts were removed by hand. The seeds (50 kg per trial) were transported to the processing facility (Melissohori, Greece) at ambient temperature (< 5 hrs). The soya bean seeds were processed into refined oil, fat soy flour, tofu and soy sauce using standardised procedures designed to simulate relevant industrial processes. All weight fractions have been calculated for the initial weight of sub-sample processed in the relevant step for trial 01 and 02 respectively.

Refined oil processing

Soya bean seeds (26.140/25.460 kg) were cleaned by air cleaning, resulting in cleaned soya bean seeds (25.907/25.267 kg) and aspirated grain fractions (0.233/0.193 kg). The cleaned soya bean seeds were then dried until the optimal moisture content was reached. Afterwards the conditioned soya bean seeds were ground and sieved, resulting in soya bean hulls (2.393/2.300 kg) and dehulled soya bean seeds (22.054/20.626 kg). Subsequently the dehulled soya bean seeds were conditioned and flaked. The flakes were then extracted in two steps. Firstly n-hexane was added, heated up to around 60 °C and circulated for about 2 hours and then the solvent-oil mixture was distilled to separate oil and solvent. A rotary evaporator was used to remove any remaining solvent from the oil. The resulting fractions were crude oil (5.109/4.941 kg) and wet soya bean meal (17.936/17.168 kg). The wet soya bean meal was toasted at 120 °C to inactivate trypsin inhibitors. The toasted soya bean meal was conditioned to obtain an optimal moisture content of 15%. After conditioning the meal was milled, resulting in milled conditioned soya bean meal (20.033/19.216 kg). The crude oil was refined in several steps. For hydration, the crude oil was heated up to 60–70 °C and 10% of water was added. The mixture was continuously stirred for 45 min at 85–90 °C. After that the mixture was left for phase separation and the watery phase was removed. The remaining oily phase was heated up to 85 °C and 1% of phosphorus acid was added. The mixture was continuously stirred for 45 min at 85 °C. After that, 10% water was added and the mixture was left at 85 °C for phase separation. The watery phase was removed. For neutralisation the oily phase was heated up to 90 °C while continuously stirred. After that sodium hydroxide was added and the mixture was left for about 20 min. Then 10% of water was added and after 5 min the stirrer was switched off. After separation of phases the soapstock was removed. For washing, the remaining oily phase was heated up to 90 °C while stirred. After that, 10% of water was added and the mixture was left for 20 min for phase separation. The watery phase was removed. For drying, the remaining oily phase was heated up to 95 °C while stirred and citric acid was added. Drying was done using a vacuum until no more water remained in the oil. For bleaching, the oil was heated up to 95 °C while stirred. The oil was bleached for 35 min after addition of 1% of podsol. After that, the oil was filtered to remove the podsol. For deodorisation the oil was heated up and steam was transferred through the oil when it reached 160 °C. The oil was heated up further, until it reached 240 °C and then stayed at this temperature for about 20 min. The steam supply was stopped after cooling down to 160 °C. Drying of the oil was performed until a temperature ≤ 80 °C was reached. The resulting fraction is the refined oil (2.606/2.452 kg).

Fat soy flour processing

Soya bean seeds (5.000/5.000 kg) were cleaned by air cleaning, resulting in cleaned soya bean seeds (4.945/4.967 kg) and aspirated grain fractions (0.055/0.033 kg). Afterwards the soya bean seeds were milled, resulting in pollard (1.058/1.174 kg) and dehulled soya bean seeds (3.875/3.769 kg). Dehulled soya bean seeds were milled to get fat soy flour (3.440/3.385 kg).

Tofu processing

Soya bean seeds (5.000/5.000 kg) were cleaned by air cleaning, resulting in cleaned soya bean seeds (4.934/4.955 kg) and aspirated grain fractions (0.066/0.045 kg). The cleaned soya bean seeds were mixed with 2.5 fold rate of water for 12 hours swelling time. Afterwards mixture was separated to steep water and swelled soya bean seeds. The swelled soya bean seeds were mixed with 5 fold tap water and cooked for 10 min with continuous stirring. After cooking, the suspension was squeezed to get okara (9.792/9.627 kg) and soy milk (48.384/48.445 kg). The soy milk was heated up and at 85 °C calcium sulfate was added. The mixture was pressed to get raw tofu. The raw tofu was pasteurised at 82–87 °C for 5 min. After cooling down the resulting product was pasteurised tofu (3.664/3.497 kg).

Soy sauce processing

Soya bean seeds (5.000/5.000 kg) were cleaned by air cleaning, resulting in cleaned soya bean seeds (4.946/4.967 kg) and aspirated grain fractions (0.054/0.033 kg). The cleaned soya bean seeds were mixed with 6.25 fold water for 12 hours swelling time. Afterwards soya bean seeds were cooked for 85 min until they were soft. The cooked soya bean seeds were mixed with wheat flour (type 405), wheat pollards, *Aspergillus oryzae* and water. All the ingredients were kneaded to a loaf and matured for 5 days to get koji. Mixed salt and water (brine) was added to koji and a mash (moromi) was created. After one day a pH value of 4.5–5.0 was reached with lactic acid. One day later *Saccharomyces rouxii* was added to the mash. The moromi underwent a fermentation process which took around 3 months at 33 °C. After the maturing process, the moromi was pressed, resulting in raw soy sauce (12.730/12.030 kg) and miso (9.355/10.636 kg). The raw soy sauce was filtered and pasteurised to get pasteurized soy sauce (12.730/12.030 kg).

Soya bean seeds and processed fractions were stored at –18 °C for a maximum of 12 months prior to analysis. The storage period of 12 months is covered by the storage stability studies on parent, SYN546039 and SYN545720 in commodities with high oil content, soya bean flour, soya bean milk and soya bean crude oil.

Samples were analysed for parent, SYN546039 and SYN545720 using modification C of HPLC-MS-MS method GRM042.04A using matrix matched standards. Modification C of HPLC-MS-MS method GRM042.04A is considered valid for the determination of parent, free and/or conjugated SYN546039 and free and/or conjugated SYN545720 in the range 0.01–1.0 mg/kg for soya bean seeds and aspirated grain fractions, 0.01–0.5 mg/kg for soya bean hulls, soy oil, soya bean meal, fat soy flour, pollard, okara, soy milk, tofu, soy sauce and miso. Soya bean seeds were analysed immediately before processing. Results were not corrected for control levels (< 0.01 mg/kg for each analyte and matrix). Results were not corrected for individual concurrent method recoveries (72–116% for each analyte and matrix). Residue results and processing factors are shown in Table 35.

Processing studies summary

Calculated processing factors for soya beans are summarized in Table 36.

Table 36 Overview of processing factors

Soya bean commodities	PF parent	PF median or best estimate
Soya bean seeds (RAC)	–	
aspirated grain fractions	7.4, 7.6, 7.7, 7.9, 8.3, 9.6, 11, 14	8.1
soya bean hulls	10, 11	10
soy oil, crude	0.77, 0.96	0.86
soy oil, refined	0.65, 0.68	0.66
soya bean meal, dried	< 0.38, < 0.40	< 0.4
soy fat flour	< 0.34, < 0.44	< 0.4
pollard	3.6, 4.8	4.2
okara	< 0.32, < 0.44	< 0.4
soy milk	< 0.32, < 0.44	< 0.4
tofu, pasteurised	0.52, 0.58	0.55
soy sauce, pasteurised	< 0.34, < 0.36	< 0.4
miso, pasteurised	< 0.34, < 0.36	< 0.4

Residues in the edible portion of food commodities

No data submitted.

Residues in animal commodities

Direct animal treatments

Not applicable.

Farm animal feeding studies

The Meeting received information on feeding studies in dairy cows.

A residue feeding study in lactating Holstein/Friesian dairy cows was conducted in the UK in 2011 [Ward and Vance, 2012, SYN545192_10188]. Benzovindiflupyr was administered orally in gelatine capsules once daily to three groups of three cows for 28 consecutive days. Two control cows received gelatine dosing capsules containing no active substance. Experimental conditions are indicated in Table 37. Milk samples were collected twice daily throughout acclimation and feeding periods (days –1, 1, 2, 3, 5, 7, 10, 14, 17, 21, 24 and 28) and PM and AM milk was combined to produce a 24 hr bulk milk sample. Average daily milk yields ranged from 7.5–16 kg/animal. Skimmed milk and cream were produced from milk collected at day 21 and 28 using a centrifugal cream separator. Animal 4 (1× dose group) was killed on welfare grounds on day 14 due to an underlying health condition unrelated to on-study procedures. All remaining treated cows and one cow from the control group were killed approximately 22–24 hours following the final dose. Samples of liver, kidney, muscle (diaphragm, loin and hind leg) and fat (perirenal, mesenteric and subcutaneous) were collected from all animals. Milk and tissue samples were stored at –20 °C until analysed. The maximum frozen storage intervals prior to analysis were 18 days for milk, 15 days for skimmed milk, 24 days for cream, 20 days for liver, 23 days for kidney, 34 days for muscle and 57 days for fat.

Samples were analysed for parent, SYN546039 (including conjugates) and SYN546422 (including conjugates) using modification A of HPLC-MS-MS method 1887 (see method GRM042.06) and using matrix-matched standards. Method 1886 version 2.0 is considered valid for the purpose of this study (commodity type and concentration level of the analytes). Residues of parent, SYN546039 or SYN546422 were not found in any of the control samples (each < 0.01 mg/kg). Mean concurrent recoveries for all analytes and all tissues were within 70–120%, showing adequate performance at the time of sample analysis.

Analytical results in tissue samples are shown in Table 38. Samples from the 1× and 5× dose groups were only analysed when residues in one or more samples from the next highest dose rate contained residues ≥ 0.01 mg/kg (LOQ). Residues of parent and SYN546039 (free plus conjugated) were highest in liver. Residues in other tissues decreased in the order kidney > fat > muscle for both parent and SYN546039. Residues of SYN546422 (free plus conjugated) were not found (< 0.01 mg/kg) in any of the tissues.

No residues (< 0.01 mg/kg, each analyte) were found in whole milk at any of the treatment days (10× dose rate samples analysed only). No residues (< 0.01 mg/kg, each analyte) were found in skimmed milk in the day 21 and day 28 samples (10× dose rate samples analysed only). Residues in cream for the 21 and 28 day samples are shown in Table 39.

Table 37 Experimental conditions of the cow feeding study

Cow number	Mean individual and group bodyweight over the feeding period (kg)	Mean daily dry feed intake (kg feed/animal)	Actual mean dose (ppm ai in feed)	Actual mean dose (mg ai/animal/day)	Actual mean dose (mg/kg bw/day)
1, 2	676, 648 (group 662)	14	0 0× dose group	0	0
3, 4, 5	734, 596, 613 (group 648)	15	3.5 1× dose group	53	0.082

National Residue Definition

No information available.

APPRAISAL

Benzovindiflupyr was scheduled for residue evaluation as a new compound by the 2014 JMPR at the 45th session of the CCPR (2013). The toxicological review was conducted in 2013, which established an ADI of 0–0.05 mg/kg bw and an ARfD of 0.1 mg/kg bw. Additional toxicological data were provided for the metabolites SYN546039 and SYN545720. Benzovindiflupyr was defined by the WHO panel as the only toxicologically significant compound in animals, plants and the environment.

Benzovindiflupyr is a broad-spectrum fungicide belonging to the chemical class of pyrazole carboxamides. Benzovindiflupyr acts as an inhibitor of the fungal complex II respiratory chain, where it inhibits the succinate dehydrogenase enzyme (succinate dehydrogenase inhibitor, SDHI) by blocking the ubiquinone-binding sites in the mitochondrial complex.

The Meeting received information from the manufacturer on identity, metabolism, storage stability, residue analysis, use pattern, residues resulting from supervised trials on soya beans, fate of residue during processing, and livestock feeding studies.

Chemical name:

Benzovindiflupyr: N-[(1R,4S)-9-(dichloromethylene)-1,2,3,4-tetrahydro-1,4-methanonaphthalen-5-yl]-3-(difluoromethyl)-1-methylpyrazole-4-carboxamide (IUPAC).

Structural formula:

Benzovindiflupyr contains chiral centres at both the bridgehead carbon atoms potentially resulting in four stereoisomeric forms. However, the bicyclic ring is a rigid structure, and therefore only two stereoisomers exist (an enantiomeric pair). Technical benzovindiflupyr consists of a racemic mixture of two enantiomers SYN546526 and SYN546527, at a ratio of 50:50. SYN546526 represents N-[(1R,4S)-9-(dichloromethylene)-1,2,3,4-tetrahydro-1,4-methanonaphthalen-5-yl]-3-(difluoromethyl)-1-methylpyrazole-4-carboxamide. SYN546527 represents N-[(1S,4R)-9-(dichloromethylene)-1,2,3,4-tetrahydro-1,4-methanonaphthalen-5-yl]-3-(difluoromethyl)-1-methylpyrazole-4-carboxamide. The enantiomers were unresolved using the chromatographic solvent systems in the reports. Both enantiomers were measured within the same single chromatographic peak and they were collectively reported as one concentration. Both enantiomers are fungicidally active. No toxicological studies were performed on the individual enantiomers.

Metabolites referred to in the appraisal by codes:

SYN546206 (N-demethyl-BVFP)	 N-demethyl-benzovindiflupyr

SYN546039 (BVFP-OH)	 hydroxy-benzovindiflupyr
SYN546041 (N-demethyl-BVFP-OH)	 N-demethyl-hydroxy-benzovindiflupyr
SYN546042 (N-demethyl-BVFP-OH)	 N-demethyl-hydroxy-benzovindiflupyr
SYN546422	 N- [(1SR,3RS)-2-(dichloromethylene)-1-hydroxy-3-(2-hydroxy-ethyl)-indan-4-yl]-3-(difluoromethyl)-1-methyl-1H-pyrazole-4-carboxamide
SYN508272	 3-difluoromethyl-1-methyl-1H-pyrazole-4-carboxylic acid amide

NOA449410	 3-difluoromethyl-1-methyl-1H-pyrazole-4-carboxylic acid
SYN545720	 3-difluoromethyl-1H-pyrazole-4-carboxylic acid

Animal metabolism

The Meeting received results of metabolism studies in laboratory animals, lactating goats and laying hens.

Metabolism in laboratory animals was summarized and evaluated by the WHO panel of the JMPR in 2013. In absorption, distribution, metabolism and excretion (ADME) studies, overnight-fasted animals showed clinical signs at doses that were non-toxic to fed animals. Therefore, most of the ADME studies were performed in fed animals. Absorption of benzovindiflupyr was approximately 80% at the low dose (1 mg/kg bw) and showed saturation at the higher dose (approximately 60% absorption at 40 mg/kg bw). In low-dose bile duct cannulated animals, 4% of the administered dose was found in urine, 17% in faeces and 69–76% in bile; in high-dose animals, 9% of the administered dose was found in urine, 32% in faeces and 47–57% in bile. At both dose levels, 86–97% of the administered dose was excreted within 48 hours after administration. The major route of excretion was by bile. For tissues, the elimination half-lives were in the range of 40–316 hours. Highest residues were identified in the liver, kidney, adrenals, thyroid and heart. After repeated daily dosing, levels of radioactivity in tissues appeared to have reached steady-state concentrations after 14 days. The predominant metabolic pathway for benzovindiflupyr is N-demethylation, phenyl and/or bicyclo hydroxylation and opening of the bicyclo system. Additionally, subsequent formation of glucuronic acid or sulfate conjugates was observed. The amide bond of benzovindiflupyr is preserved.

One lactating goat per radiolabel was dosed orally once daily for 7 consecutive days with a gelatin capsule containing [¹⁴C-phenyl]-benzovindiflupyr or [¹⁴C-pyrazole]-benzovindiflupyr. The equivalent actual mean daily doses in the dry feed were 41 or 32 ppm for the phenyl or pyrazole label, respectively. Goats were sacrificed 12 hours after the last dose. Total recovered radioactivity amounted to 90% and 86% of the administered dose for the phenyl and pyrazole radiolabelled forms, respectively. The majority of the radioactivity was recovered in faeces (79%/73%, phenyl/pyrazole). The remainder of the dose was recovered in urine (4.5%/5.2%, phenyl/pyrazole) and GI tract contents (6.8%/7.2%), while only low levels were found in milk and tissues (<0.5% in total).

The highest radioactivity concentrations were found in liver (1.3/0.70 mg/kg eq) and kidney (0.28/0.18 mg/kg eq), followed by fat (0.098/0.070 mg/kg eq) and muscle (0.070/0.032 mg/kg eq). Total radioactive residues in milk reached a plateau concentration of approximately 0.046 mg/kg eq following 96 hours dosing for the phenyl label and 0.035 mg/kg eq following 72 hours dosing for the pyrazole label..

Following solvent extraction, residue extractabilities were 78–89% TRR for liver and ≥ 94% TRR for milk and all other tissues. Liver and kidney extracts were treated with β-glucuronidase to cleave glucuronide and sulphate conjugates.

Parent was identified in milk and all goat tissues at levels of 5.5–13% TRR in milk, kidney and liver, 24–25% in muscle and 41–44% TRR in fat. Conjugated metabolites formed a significant

part of the extracted residue in liver and kidney. The most significant metabolites (including conjugates) identified in all tissues and milk were the mono-hydroxylated metabolite SYN546039 (22–50% TRR) and metabolite SYN546422 (16–25% TRR in milk and kidney, 1.5–8.9% TRR in other tissues). Levels of SYN546039 in milk and tissues (except fat) or levels of SYN546422 in milk and kidney were higher than those of the parent compound. Other metabolites (including conjugates) were found at levels below 10% TRR. Post-extraction solids from liver (11–22% TRR) were shown to be associated with protein. Protease treatment of the post-extraction solids resulted in a mixture of highly polar metabolites.

Five laying hens per radiolabel were dosed orally once daily for 14 consecutive days with a gelatin capsule containing [¹⁴C-phenyl]-benzovindiflupyr or [¹⁴C-pyrazole]-benzovindiflupyr. The equivalent actual mean daily doses in the dry feed were 16–20 or 17–20 ppm for the phenyl or pyrazole label, respectively. Hens were sacrificed 12 hours after the last dose. Total recovered radioactivity amounted to 88% and 93% of the administered dose for the phenyl and pyrazole radiolabelled forms, respectively. The majority of the radioactivity was recovered in excreta (88%/92%, phenyl/pyrazole), while only low levels were found in eggs and tissues (<0.2% in total).

The highest radioactivity concentrations were found in liver (0.19/0.25 mg/kg eq), followed by fat (0.033/0.045 mg/kg eq) and muscle (0.025/0.036 mg/kg eq). Total radioactive residues in egg yolks achieved a plateau concentration of 0.17–0.18 mg/kg eq after 168–240 hrs of dosing. Total radioactive residues in egg whites achieved a plateau concentration of 0.03–0.04 mg/kg eq after 120–168 hrs of dosing.

Following solvent extraction, residue extractabilities were ≥83% TRR for egg yolk and egg white, 68–73% TRR for skin with fat, 48–49% TRR for liver and 24–37% TRR for muscle. Liver extracts were treated with β-glucuronidase to cleave glucuronide and sulphate conjugates.

Parent was identified at levels of 0.2–3.3% TRR in liver and muscle, 11–14% in eggs and 38–42% TRR in skin with fat. Benzovindiflupyr was extensively metabolised, resulting in low levels of various metabolites in tissues (<6.0% TRR each). The most significant metabolites in eggs were the mono-hydroxylated metabolites SYN546039 (12–22% TRR in eggs, 1.3–5.1% TRR in tissues) and the mono-hydroxylated demethylated metabolites SYN546041 (10.6–12.5% TRR) and SYN546042 (6.6–12.2% TRR). Levels of SYN546039, SYN546041 and SYN546042 in eggs were in the same order of magnitude as those of the parent compound. Post-extraction solids from liver (51–52% TRR) and muscle (63–76% TRR) were shown to be associated with protein. Protease treatment of the post-extraction solids resulted in a mixture of highly polar metabolites.

In summary, metabolism observed in lactating goats and laying hens arose via hydroxylation on the alicyclic ring to form SYN546039 (all tissues, milk, eggs). In hens metabolism proceeded through N-demethylation to form SYN546041 and SYN546042 isomers (mainly in eggs), while in ruminants metabolism proceeded through an alternative pathway consisting of oxidative opening of the alicyclic ring to form SYN546422 (mainly in milk, kidney). Several other minor metabolites arose in livestock by cleavage between the pyrazole and phenyl rings and/or conjugation as glucuronide or sulphate compounds. Further metabolism involves association with proteins.

The major compounds identified in goat, hen tissues, milk or eggs are: parent, SYN546039, SYN546422, SYN546041 and SYN546042 and their conjugates. Parent and SYN546039 and its conjugates comprise a significant part of residue in tissues, milk and eggs. Significant additional contributions are found for metabolites SYN546041 and SYN546042 in eggs and SYN546422 and its conjugates in milk and goat kidney.

In general, metabolism between goat, hen and rat is similar, with a few exceptions. Formation of SYN546422 is only found in goat. Opening of the bicyclo system as such is found in rat and metabolite SYN546422 is postulated as a plausible rat intermediate between the open bicyclo rat metabolites SYN546634 and SYN546707 (the demethylated form of SYN546422). Cleavage between the pyrazole and phenyl rings to form SYN508272 is found in the pyrazole labelled studies in hens and goats, while in the rat studies this bond is preserved.

Plant metabolism

The Meeting received plant metabolism studies for benzovindiflupyr after foliar application on fruits (tomatoes), cereals (wheat) and pulses/oilseeds (soya beans).

The metabolism of ^{14}C -phenyl-benzovindiflupyr or ^{14}C -pyrazole-benzovindiflupyr in indoor grown tomatoes was studied following four foliar applications at 0.13–0.14 kg ai/ha at weekly intervals. Total radioactive residues (TRR) in mature tomato fruits at DAT = 1 and 14 were 0.047 and 0.092 mg/kg eq for the phenyl label and 0.18 and 0.15 mg/kg eq for the pyrazole label, respectively. A high proportion of the residue remained on the surface of the fruit (65–79% TRR). The residues in or on the fruit could be extracted by acetonitrile/water (> 99% TRR). The principal component of the residue was the parent compound (91–95% TRR). A number of metabolites were detected, none reaching >0.5% TRR.

The metabolism of ^{14}C -phenyl-benzovindiflupyr or ^{14}C -pyrazole-benzovindiflupyr in indoor grown wheat was studied following two foliar applications at 0.14 kg ai/ha at a 35 day interval. Residue levels in wheat forage harvested 9 days after the first application and residue levels in wheat hay, wheat straw and wheat grains harvested 10, 40 and 41 days after the second application were 3.0, 4.9, 8.1, 0.12 mg/kg eq for the phenyl label and 2.1, 6.4, 9.0, 0.092 mg/kg eq for the pyrazole label, respectively. The major part of the residues (> 97% TRR) could be extracted with acetonitrile/water. The principal component of the residue was the parent compound: 84–87% TRR in grain, 81–84% TRR in straw and 89–103% in wheat forage and hay. A number of metabolites were detected, none reaching >5.0% TRR. Several of these metabolites were present in the free and conjugated form.

The metabolism of ^{14}C -phenyl-benzovindiflupyr or ^{14}C -pyrazole-benzovindiflupyr in indoor grown soya beans was studied following two foliar applications at 0.12–0.13 kg ai/ha at a 22 day interval. Residue levels in soya bean forage harvested 11 days after the first application and soya bean hay and soya bean seeds harvested at 13 and 30 days after the second application were 3.4, 14 and 0.029 mg/kg eq for the phenyl label and 4.1, 13 and 0.10 mg/kg eq for the pyrazole label, respectively. The major part of the residues (> 89% TRR) could be extracted with solvents. Parent was identified at levels of 15–31% TRR in soya bean seeds, 67–72% TRR in soya bean hay and 83–85% TRR in soya bean forage. The most significant metabolite in soya bean seeds was the cleavage product SYN545720 (47% TRR). The major part of the SYN545720 metabolite was present in the conjugated form (30% TRR), particularly as an aspartic acid conjugate or monosaccharide conjugate. The most significant metabolite in soya bean forage and hay was the mono-hydroxylated metabolite SYN546039 (9.2–12% TRR). The major part of the SYN546039 metabolite was present in the conjugated form (8.5–12% TRR), particularly as a malonyl glycoside or glycoside conjugate. A number of other metabolites were detected, none reaching >14% TRR. One of these metabolites was NOA449410, a plant specific metabolite, which was not detected in rat. NOA449410 was present at very low levels: < 1.2% TRR or 0.012 mg/kg eq) in soya forage, 0.039 mg/kg eq in soya hay or 0.0012 mg/kg eq in soya seeds.

In summary, the degree of metabolism in crops after foliar application varied. In fruits and cereals parent compound represented the principal part of the residue in tomato fruits, wheat grain, wheat straw and wheat forage and hay. Metabolism proceeded further in pulses/oilseeds with parent representing 15–31% TRR in soya bean seeds, 67–72% TRR in soya bean hay and 83–85% TRR in soya bean forage. Metabolism observed in pulses/oilseeds arose via hydroxylation on the alicyclic ring to form SYN546039). Metabolism proceeded through N-demethylation and cleavage between the pyrazole and phenyl rings to form SYN545720.

In general, metabolism between plants and rat is similar, except for the cleavage between the pyrazole and phenyl rings. In rat this bond is preserved. The cleavage product SYN508272 is found in the pyrazole labelled studies in hens and goats. Cleavage products NOA449410 and SYN545720 are not found in rat nor in livestock.

Environmental fate in soil

The Meeting received information on photolysis in water and on soil and information on rotational crops.

All plant metabolism studies have been conducted indoors. Since the interval between the first application and harvest for the investigated commodities is long (29–111 days) and the residue is a surface residue, photolysis may form a major route of degradation. Since indoor grown plants are not subjected to the full spectrum of sunlight, degradation on field grown plants may show a different behaviour. Photolysis studies in water or on soil show a DT₅₀ of 44 or 144–244 days, respectively, confirming the potential for photolysis. Photolysis in water after 15 days and on soil after 30 days demonstrated the formation of low levels of SYN546039, SYN508272, NOA449410, and SYN545720 (0.6–8.5% TAR), indicating the absence of an alternative degradation pathway under outdoor conditions. In addition, preliminary experimental work on photolysis on leaf surfaces grown under greenhouse, under artificial sunlight and outdoor conditions for 7 days, demonstrated very minor degradation in all three test conditions while the resulting minor degradates were qualitatively similar. The Meeting concluded that the indoor plant metabolism studies are considered acceptable for deriving a residue definition for plant commodities.

Metabolism of ¹⁴C-phenyl-benzovindiflupyr or ¹⁴C-pyrazole-benzovindiflupyr was investigated in confined rotational crops following a single bare soil treatment. A sandy loam soil was treated at a rate of 0.53–0.54 kg ai/ha under indoor conditions. Rotational crops (lettuce, wheat and turnip) were sown at 30, 90 and 300 day plant back intervals (PBI). Total radioactivity in rotational crops ranged from 0.003–0.77 mg/kg eq at 30 day PBI, 0.002–0.34 mg/kg eq at 90 day PBI and 0.007–0.29 mg/kg eq at 300 day PBI. Total radioactivity levels above 0.05 mg/kg eq were found in wheat forage, hay and straw at all plant back intervals.

Wheat grain had very low residues (< 0.01–0.014 mg/kg eq) and most extracts were not amenable to chromatographic examination. In turnip roots, parent was the principal component and ranged from 81–90% TRR at the 30 day plant back interval, 69–72% TRR at the 90 day plant back interval and 64–71% at the 300 day plant back interval. In the leafy parts of crops (lettuce, turnip leaves, wheat forage, hay, straw) parent compound was the principal component of the residue at the 30 day PBI. Parent ranged from 14–37% TRR at the 30 day PBI, 13–35% TRR at the 90 day PBI and 6.5–29% TRR at the 300 day PBI. At the 90 and 300 day PBI, significant metabolites were the cleavage products NOA449410 and SYN545720, together accounting for 53–73% TRR, 34–46% TRR and 24–26% TRR in immature lettuce, mature lettuce and wheat forage respectively. NOA449410 was mainly present in the conjugated form whereas SYN545720 was present in the free and conjugated form. Other metabolites were generally present at low levels (each < 10% TRR). In wheat forage, wheat hay and wheat straw, SYN546206 and SYN546039 were more significant, frequently occurring at > 10% TRR and occasionally approaching 20% TRR each (including conjugates). SYN546206 was mainly present in the free form; SYN546039 was mainly present in the conjugated form.

From these data the Meeting concluded that benzovindiflupyr can be taken up from the soil under confined conditions even after long plant back intervals (300–366 days). Metabolites found in confined rotational crops (SYN546206, SYN546039, NOA449410 and SYN545720) are identical to those observed in primary crops and may have arisen from photolysis, degradation in and uptake from soil as well as from metabolism within the crop itself.

In two field rotational crop studies at four different locations in the EU benzovindiflupyr was applied onto bare soil at a single application of 0.20 kg ai/ha. Rotational crops (spinach, wheat, carrots) were sown 28–32, 60–69 or 355–366 days after application.

In another field rotational crop study at four different locations in the USA benzovindiflupyr was applied as foliar application to soya beans or peanuts at 3x 0.10 kg ai/ha with 14 day intervals. The last application was at BBCH 71–89 of the target crops. The soya bean and peanut target crops were harvested and removed from the field. Rotational crops (spinach or lettuce, radish or turnip, wheat) were sown 30 or 180 days after application.

No residues > 0.01 mg/kg of parent benzovindiflupyr or metabolites SYN546206 or SYN546039 (including conjugates) were found in any of the harvested commodities at any of the rotations, except in wheat forage and wheat straw from the 28–30 or 60 day plant back intervals. Parent and SYN546039 (including conjugates) were found in wheat forage and wheat straw at levels up to 0.012–0.022 mg/kg. Metabolites NOA449410 and SYN545720 were not analysed.

The dose rates as used in the field rotational crop studies (1x0.20 kg ai/ha or 3x0.10 kg ai/ha) are higher than those used in the actual supervised residue trials submitted (3x 0.045 kg ai/ha for soya beans). Based on the current uses, the Meeting concluded that no residues are expected in rotational crops. Should additional uses be developed in future, rotational crop studies may need to be re-evaluated.

Methods of Analysis

The Meeting received description and validation data for analytical methods for the determination of benzovindiflupyr related residues in plant and animal commodities.

The existing multi-residue method QuEChERS was submitted as enforcement/monitoring method for the determination of parent compound in plant and animal commodities. Plant commodities were extracted with acetonitrile/water (1:1, v/v), Samples were cleaned-up by SPE prior to quantification by HPLC-MS/MS. The Meeting considers validation sufficient for plant commodities with high acid content, high water content, high starch content, high oil content and all animal commodities (meat, liver, kidney, fat, milk and eggs). The LOQ was 0.01 mg/kg for parent compound in each matrix.

Several other HPLC-MS/MS methods were submitted for the determination of parent and its metabolites SYN546206 (free), SYN545720 (including conjugates) and/or SYN546039 (including conjugates) in plant material. Crop commodities were extracted with acetonitrile/water (80/20). Parent and SYN546206 were separated off by liquid-liquid partition and the remaining extract was treated with acid at pH 2 for 6 hrs at 100 °C to cleave the SYN545720 and/or SYN546039 conjugates. Extraction efficiency for acetonitrile/water was at least 71% for parent and 81% for SYN546206 (free) as shown by a radio-validation study in wheat hay and wheat straw. Efficiency of extraction and hydrolysis was >100% for SYN546039 (including conjugates) and SYN545720 (including conjugates) as shown by a radio-validation study in soya bean hay and soya bean seed. Most analytical methods were considered fit for purpose with LOQs of 0.01 mg/kg for individual analytes.

Another HPLC-MS/MS method was submitted for the determination of parent and its metabolites SYN546039 (including conjugates) and SYN546422 (including conjugates) in milk, eggs or animal tissues. Animal commodities were extracted with acetonitrile/water (80/20). Parent was determined directly in the primary extract, while the remaining extract was treated with beta-glucuronidase at pH 5 for 6 hrs at 37 °C to cleave the SYN546039 and/or SYN546422 conjugates. Extraction efficiency for acetonitrile/water was >100 % for parent, free SYN546039 and free SYN546422 as shown by a radio-validation study in milk, muscle, and egg yolk. Efficiency of extraction and hydrolysis was >100% for SYN546039 (including conjugates) and at least 67% for SYN546422 (including conjugates) as shown by a radio-validation study in liver. The analytical method was considered fit for purpose with LOQs of 0.01 mg/kg for individual analytes.

Stability of pesticide residues in stored analytical samples

The Meeting received information on the storage stability of parent, SYN546039, SYN546206 and SYN545720 in raw and processed plant commodities and of parent, SYN546039 and SYN546422 in animal commodities.

Storage stability studies showed that benzovindiflupyr and metabolite SYN546039 (free) were stable for at least 24 months at -18°C in crop commodities representative of the high water, high acid, high starch, high protein and high oil commodity groups as well as in wheat straw. Metabolite SYN546206 (free) was stable for at least 22 months at -18 °C in crop commodities representative of the high water and high starch commodity groups as well as in wheat straw. Metabolites SYN545720

(free) and SYN508272 (free) were stable for at least 24 months at -18 °C in crop commodities representative of the high oil, high acid and high protein commodity groups.

Benzovindiflupyr and metabolites SYN546039 (free) and SYN545720 (free) were stable for at least 24 months at -10 °C in various processed commodities: flour (maize, soya), meal (maize), oil (maize, soya), soymilk, dried fruits (grape, apple) and fruit juice (apple).

Benzovindiflupyr and metabolites SYN546039 (free) and SYN546422 (free) were stable at -20 °C for at least 56–62 days in milk and eggs and at least 76–78 days in liver and muscle. According to OECD Guideline 506 storage stability in kidney and fat may be extrapolated from the other animal tissues, so The Meeting concluded that residues in kidney and fat are likely to be stable for at least 76 days.

Definition of the residue

The major compounds identified in goat, hen tissues, milk or eggs are: parent, SYN546039, SYN546422, SYN546041 and SYN546042 and their conjugates. Parent was identified at levels of 38–44% TRR (0.012–0.040 mg/kg) in goat fat and hen skin with fat, 24–25% (0.008–0.017 mg/kg) in goat muscle and 0.2–14% TRR (<0.001–0.14 mg/kg) in milk, eggs, and all other tissues. The mono-hydroxylated metabolite SYN546039 and its conjugates was identified at levels of 22–50% TRR (0.008–0.64 mg/kg eq) in milk and goat tissues, 12–22% TRR (0.008–0.022 mg/kg eq) in eggs and <6.0% TRR in hen tissues. Metabolite SYN546422 and its conjugates was only found in goat and was identified at levels of 16–25% TRR (0.010–0.052 mg/kg eq) in milk and goat kidney and 1.5–8.9% TRR (0.001–0.056 mg/kg eq) in other goat tissues. The mono-hydroxylated demethylated metabolite isomers SYN546041 and SYN546042 were identified at levels of 11–12% TRR (0.003–0.020 mg/kg eq) and 6.6–12% TRR (0.002–0.020 mg/kg eq) in eggs, respectively, <5.0% TRR in hen tissues and <10% TRR in goat tissues and milk.

Benzovindiflupyr parent is found in every animal commodity, although the levels in milk, eggs, edible offal and hen muscle are low. To be able to detect benzovindiflupyr related residues, metabolites SYN546039, SYN546422 (goat only), SYN546041 (eggs only) and SYN546042 (eggs only) could be included in the residue definition for enforcement/monitoring. Since a significant part of these metabolites is present as conjugates, a hydrolysis procedure is required to be able to measure these metabolites. Including the metabolites in the residue definition means the residue is unlikely to be measured by a multi-residue method. Since benzovindiflupyr itself can be measured by a multi-residue method and use of a multi-residue method is encouraged, the Meeting decided to define the residue for enforcement/monitoring as parent only.

The log K_{ow} for benzovindiflupyr is 4.3. The goat metabolism study and the goat feeding study did not show a clear partition of the parent compound into the fat tissues, although in the high dose cow feeding study, parent was found in cream and not in the corresponding whole milk. In a hen metabolism study, the partitioning of the parent compound into the fatty tissues is more pronounced: highest levels of benzovindiflupyr are found in egg yolks (0.022–0.024 mg/kg) and skin with fat (0.012–0.019 mg/kg). Since benzovindiflupyr has a preference for fat in the poultry tissues as well as in high dose milk, the Meeting considers the residue fat soluble.

Apart from benzovindiflupyr, metabolites found at significant levels in livestock commodities were: SYN546039, SYN546041, SYN546042, SYN546422 and their conjugates. The toxicity of SYN546039, SYN546041, SYN546042 and SYN546422 is considered to be covered by toxicity studies on benzovindiflupyr since each of the free metabolites was actually found or agreed to be a possible intermediate in the rat. N-demethylation is regarded as neutral for toxicological potency while hydroxylation generally lowers toxicity. The JMPR 2013 received additional toxicological data for the mono-hydroxylated metabolite SYN546039, showing that this compound is at least 10 fold less toxic than parent. For metabolites SYN546041, SYN546042 and SYN546422 a read across to SYN546039 toxicity studies seems justified based on the close structural similarity and this suggests that they are also at least 10 fold less toxic than the parent.. Therefore none of these metabolites is considered relevant for the residue definition for dietary risk assessment. The Meeting decided to define the residue for dietary risk assessment as parent only.

In primary crops, parent compound represented the principal part of the residue in most crop commodities: 91–95% TRR (0.004–0.16 mg/kg) in tomato fruits, 84–87% TRR (0.077–0.10 mg/kg) in wheat grain, 81–84% TRR (6.6–7.6 mg/kg) in wheat straw and 89–103% (2.1–5.9 mg/kg) in wheat forage and hay, 67–72% TRR (8.7–10 mg/kg) in soya bean hay and 83–85% TRR (2.8–3.5 mg/kg) in soya bean forage. Metabolism proceeded further in pulses/oilseeds with parent representing 15–31% TRR (0.009–0.015 mg/kg) in soya bean seeds. A significant metabolite in soya bean seeds was SYN545720 (47% TRR (0.047 mg/kg eq) including conjugates). A significant metabolite in soya forage and hay was SYN546039 (9.2–12% TRR (0.38–1.6 mg/kg eq) including conjugates).

In rotational crops parent was the principal component in root commodities (64–90% TRR, 0.008–0.023 mg/kg) and a significant component (6.5–37% TRR, 0.001–0.085 mg/kg) in the leafy parts of crops (lettuce, turnip leaves, wheat forage, hay, straw). Significant metabolites were the cleavage products NOA449410 and SYN545720, together accounting for 34–73% TRR (0.009–0.014 mg/kg eq) and 24–26% TRR (0.023–0.026 mg/kg eq) in lettuce and wheat forage, respectively. In wheat forage, wheat hay and wheat straw, SYN546206 and SYN546039 were frequently occurring at > 10% TRR each, and occasionally approaching 20% TRR each (0.006–0.12 mg/kg eq, including conjugates).

Benzovindiflupyr is found in every primary crop commodity, although the levels in soya bean seeds are low. Benzovindiflupyr is found in every rotational crop commodity, except cereal grains, although levels in leafy crop parts vary. To be able to detect benzovindiflupyr related residues metabolites SYN545720 and NOA449410 could be included in the residue definition for enforcement/monitoring. Since a significant part of these metabolites is present as conjugates, a hydrolysis procedure is required to be able to measure them. Including the metabolites in the residue definition means the residue is unlikely to be measured by a multi-residue method. Furthermore, SYN545720 and NOA449410 can also arise in plant commodities as a result of treatment with other pyrazole fungicides like bixafen, fluxapyroxad, isopyrazam and sedaxane. Since SYN545720 and NOA449410 cannot be seen as a marker for benzovindiflupyr, the Meeting decided to define the residue for enforcement/monitoring as parent only.

Apart from benzovindiflupyr, metabolites found at significant levels in plant commodities were: SYN546206, SYN546039, NOA449410, SYN545720 and their conjugates. The toxicity of SYN546206 and SYN546039 is considered to be covered by toxicity studies on benzovindiflupyr since each of the free metabolites was actually found in the rat. The cleavage products NOA449410 and SYN545720 are not found in rat. N-demethylation is regarded as neutral for toxicological potency, while hydroxylation generally lowers toxicity. The JMPR 2013 received additional toxicological data for the mono-hydroxylated metabolite SYN546039, showing that this compound is at least 10 fold less toxic than parent. Toxicity studies for NOA449410 (from sedaxane studies) and SYN545720 (from isopyrazam and sedaxane studies) showed that the toxicity of these metabolites is probably 100–1000 fold less toxic than parent. SYN546206 is the only compound which might be relevant for the residue definition for dietary risk assessment, since the toxicological potency might be similar to the parent. Metabolite SYN546206 is only found in feed commodities (wheat forage, wheat hay, wheat straw) in the confined rotational crop studies and its presence could not be confirmed in the field rotational crops studies. The Meeting decided to define the residue for dietary risk assessment as parent only.

The Meeting recommended the following residue definition for benzovindiflupyr:

Definition of the residue for compliance with the MRL and for dietary risk assessment for plant and animal commodities: *benzovindiflupyr*.

The Meeting considers the residue fat soluble.

Results of supervised residue trials on crops

Soya beans (dry)

Field trials involving soya beans were performed in Brazil.

Critical GAP for soya beans in Paraguay is for three foliar applications without adjuvant at 0.045 kg ai/ha at 14 day intervals with a PHI of 21 days. Trials from Brazil (3x 0.045 kg ai/ha, interval 19–59 and 14 days, PHI 21–28 days, adjuvant added) matched this GAP. For each plot location, replicate trials were conducted with two-three different formulations. Only the highest residue was selected from these trials. For trials, where residues at longer PHIs (28 – 35 days) were higher than residues at PHI 21 days, the highest residue was selected. Benzovindiflupyr residues were: <0.01, <0.01, <0.01, <0.01, 0.01, 0.03 mg/kg (n=6).

The Meeting estimated a maximum residue level of 0.05 mg/kg on soya beans (dry). The Meeting estimated an STMR of 0.01 mg/kg.

Fate of residues during processing

Information on the fate of residues during processing showed that benzovindiflupyr is stable (100% recovery) under standard conditions simulating pasteurisation, baking/brewing/boiling and sterilisation.

Processing studies were undertaken for soya beans. Processing factors based on the residue for parent only are listed in the table below. Using the STMR_{RAC} obtained from benzovindiflupyr use, the Meeting estimated STMR-Ps for processed commodities to be used in the livestock dietary burden calculations and/or dietary intake calculations.

Commodity	Processing factors Residue: parent only	Processing factor (PF) (median or best estimate)	STMR-P = STMR _{RAC} x PF (mg/kg)
soya aspirated grain fractions	7.4, 7.6, 7.7, <u>7.9</u> , <u>8.3</u> , 9.6, 11, 14	8.1	0.081
soya bean hulls	<u>10</u> , <u>11</u>	10	0.10
soya oil, crude	<u>0.77</u> , <u>0.96</u>	0.86	0.0086
soya oil, refined	<u>0.65</u> , <u>0.68</u>	0.66	0.0066
soya meal, dried	<0.38, <0.40	<0.4	0.004
soya fat flour	<0.34, <0.44	<0.4	0.004
soya pollard	<u>3.6</u> , <u>4.8</u>	4.2	0.042
soya okara	<0.32, <0.44	<0.4	0.004
soya milk	<0.32, <0.44	<0.4	0.004
soya tofu, pasteurised	<u>0.52</u> , <u>0.58</u>	0.55	0.0055
soya sauce, pasteurised	<0.34, <0.36	<0.4	0.004
soya miso, pasteurised	<0.34, <0.36	<0.4	0.004

Residues in animal commodities

The Meeting estimated the dietary burden of benzovindiflupyr residues on the basis of the livestock diets listed in the FAO manual appendix IX (OECD feedstuff table). For bulk commodities like soya beans, calculation from STMR provides the levels in feed suitable for estimating maximum residue levels as well as STMR values for animal commodities. Commodities used in the dietary burden calculation are soya beans and soya bean processed commodities. Supervised residue trials on soya bean forage and fodder were not available, whereby the dietary burden for livestock might be underestimated.

Dietary burden calculations for beef cattle, dairy cattle, broilers and laying poultry are provided in Annex 6. A mean and maximum dietary burden for livestock, based on benzovindiflupyr use, is shown in the table below.

Livestock dietary burden for benzovindiflupyr residues, expressed as ppm of dry matter diet

	US	EU	AU	JP	overall	
	Max and mean	Max and mean	Max and mean	Max and mean	Max and mean	
beef cattle	0.017	0.013	0.0022	0.011	0.017	^a
dairy cattle	0.0016	0.013	0.0029	0.0069	0.013	^b

	US	EU	AU	JP	overall	
	Max and mean	Max and mean	Max and mean	Max and mean	Max and mean	
poultry broiler	0.0033	0.015	0.0081	0.0015	0.015	^c
poultry layer	0.0033	0.0081	0.0081	0.0013	0.0081	^d

^a Highest mean and maximum dietary burden suitable for maximum residue level and STMR estimates for mammalian meat

^b Highest mean and maximum dietary burden suitable for maximum residue level and STMR estimates for milk

^c Highest mean and maximum dietary burden suitable for maximum residue level and STMR estimates for poultry meat

^d Highest mean and maximum dietary burden suitable for maximum residue level and STMR estimates for eggs

The Meeting received a feeding study on lactating cows.

Three groups of three lactating Holstein cows were dosed once daily via capsules at levels of 3.5, 16 and 32 ppm parent compound in dry weight feed for 28 consecutive days. Two control cows received a placebo. Milk was collected throughout the study and tissues were collected on day 28 within 22–24 hrs after the last dose. No parent residues >0.01 mg/kg were found in whole milk, cream, muscle, liver, kidney or fat at the 3.5 ppm dose level.

The dietary burden for beef and dairy cattle of 0.017 and 0.013 ppm, respectively, is 200 times lower than the lowest dose administered in the cow feeding study (3.5 ppm). Therefore, no parent residues > 0.01 mg/kg are expected in milk, cream and cattle tissues.

No feeding study is available for poultry. In a metabolism study laying hens were dosed at 16–20 ppm parent compound in the dry feed for 14 consecutive days. Parent residues were: 0.024 mg/kg in egg yolks, 0.0037 mg/kg in egg whites, 0.019 mg/kg in fat, in 0.00050 mg/kg in liver and 0.0012 mg/kg in muscle. The dietary burden for broiler and layer poultry of 0.015 and 0.0081 ppm, respectively, is 1000 times lower than the dose administered in the hen metabolism study (16–20 ppm). Therefore, no parent residues > 0.01 mg/kg are expected in eggs, egg yolks and hen tissues.

The Meeting estimated maximum residue levels of 0.01* mg/kg in milk, eggs and all animal commodities. The Meetings estimated an STMR and HR of 0 mg/kg in milk, eggs and all animal commodities. The residue in animal commodities is considered fat soluble.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits

Definition of the residue for compliance with the MRL and for dietary risk assessment for plant and animal commodities: *benzovindiflupyr*.

The Meeting considers the residue fat soluble.

Summary of recommendations

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Daily Intakes (IEDI) for benzovindiflupyr was calculated from recommendations for STMRs for raw and processed commodities in combination with consumption data for corresponding food commodities. The results are shown in Annex 3.

The IEDI of the 17 GEMS/Food cluster diets, based on the estimated STMRs represented 0% of the maximum ADI of 0.05 mg/kg bw, expressed as benzovindiflupyr.

The Meeting concluded that the long-term intake of residues of benzovindiflupyr from uses considered by the Meeting is unlikely to present a public health concern.

Short-term intake

The International Estimated Short Term Intake (IESTI) for benzovindiflupyr was calculated from recommendations for STMRs for raw and processed commodities in combination with consumption data for corresponding food commodities. The results are shown in Annex 4.

The IESTI for the diets submitted to the JMPR represented 0% of the ARfD (0.1 mg/kg bw, expressed as benzovindiflupyr). The Meeting concluded that the short-term intake of residues of benzovindiflupyr from uses considered by the Meeting is unlikely to present a public health concern.

BUPROFEZIN (173)

*First draft prepared by Dr Yukiko Yamada, Ministry of Agriculture, Forestry and Fisheries,
Tokyo, Japan*

APPRAISAL

Buprofezin was evaluated by JMPR in 1991 for the first time and then in 1995 and 1999. It was also reviewed under the Periodic Re-evaluation Programme in 2008 for toxicity and residues followed by residue evaluations in 2009 and 2012; and for consideration of a concern form from the USA in 2013¹.

The 2012 Meeting received information on supervised trials on coffee conducted in Brazil and the USA as well as coffee processing. These trials were conducted in accordance with GAP in the USA for coffee while employed different processing methods for producing green beans from coffee berries: wet method in Hawaii, USA; and dry method in Brazil. Due to the apparent difference in residues from different processing methods and the lack of information on processing practices for coffee berries used in the USA, the 2013 Meeting could not estimate a maximum residue level.

The current Meeting received another concern form from the USA stating that since the processing of coffee berries to green coffee followed the local practices of countries where the trials were conducted, a maximum residue levels should be estimated for coffee beans and roasted coffee beans.

During the current Meeting, new information became available about the processing practices in Hawaii, USA. According to the information, both the wet and dry methods are used for processing coffee berries to green beans. At the present time, mostly the wet method is used while the dry method is used in the small farms and some recently established large coffee farms. Based on the information, the Meeting concluded that the trials in the USA and Brazil complied with GAP in the use of pesticides for coffee and the processing practices used in the USA.

The Meeting reviewed the data provided to the 2012 Meeting. GAP in the USA for coffee allows four foliar applications (minimum interval of 14 days) at a rate of 1.12 kg ai/hL with a PHI of 0 days. The previous Meeting selected the following residue concentrations from the trials matching the above GAP:

From the trials in the USA (4): 0.08, 0.12, 0.155 and 0.24 mg/kg; and

From the trials in Brazil (3): 0.055 and 0.075 (2) mg/kg.

The combined residues were: 0.055, 0.075, 0.075, 0.08, 0.12, 0.155 and 0.24 mg/kg.

The Meeting estimated a maximum residue level and an STMR of 0.4 mg/kg and 0.08 mg/kg, respectively, for coffee beans.

Based on the STMR for coffee beans and the processing factor of 0.32 from coffee beans to roasted coffee beans and < 0.2 to freeze-dried coffee calculated in 2012 (2012 Evaluation), the Meeting estimated STMR-Ps of 0.0256 mg/kg and 0.016 mg/kg, respectively, for roasted coffee beans and freeze-dried coffee.

RECOMMENDATIONS

On the basis of the data from supervised trials, the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of the residue for compliance with MRLs and for estimation of dietary intake (Plant commodities and animal commodities): *buprofezin*

¹ 2012 Report and Evaluation; and 2013 Report (FAO)

Commodity		Recommended MRL, mg/kg		STMR/STMR-P	HR/HR-P
CCN	Name	New	Previous	mg/kg	mg/kg
SB 0716	Coffee beans	0.4	-	0.08	-
SM 0716	Coffee beans, roasted			0.0256	-
	Freeze-dried coffee			0.016	-

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Dietary Intakes (IEDIs) of buprofezin were calculated for the 17 GEMS/Food cluster diets using STMRs and STMRPs estimated by the 2008, 2009, 2012 and current Meetings (Annex 3). The ADI is 0-0.009 mg/kg bw and the calculated IEDIs were 3–40% of the maximum ADI. The Meeting concluded that the long-term intake of residues of buprofezin resulting from the uses considered by the 2008, 2009, 2012 and current JMPR is unlikely to present a public health concern.

Short-term intake

The International Estimated Short-Term Intakes (IESTI) of buprofezin were calculated for coffee beans and their processed products commodities using STMRs/STMR-Ps estimated by the current Meeting (see Annex 4). The ARfD is 0.5 mg/kg and the calculated IESTIs were 0–0 % of the ARfD for the general population and for children. The Meeting concluded that the short-term intake of residues of buprofezin, when used in ways that have been considered by the JMPR, is unlikely to present a public health concern.

CHLORANTRANILIPROLE (230)

First draft was prepared by Dr Paul Humphrey, Australian Pesticides and Veterinary Medicines Authority, Canberra, Australia

EXPLANATION

Chlorantraniliprole is a novel insecticide belonging to the class of selective ryanodine receptor agonists and was evaluated for the first time by JMPR in 2008 (T, R). It was also evaluated in 2010 and 2013 for additional MRLs. At the Forty-fifth Session of the CCPR (2013), chlorantraniliprole was listed for residue evaluation for additional maximum residue levels by the 2014 JMPR.

The Meeting received information on registered use patterns, supervised residue trials and fate of residues in processing.

The 2008 JMPR established an ADI and AfRD for chlorantraniliprole of 0–2 mg/kg bw/day and “not required” respectively. A residue definition of *chlorantraniliprole* was established for both compliance and dietary risk assessment in both plant and animal commodities.

USE PATTERN

Information on registered uses made available to this meeting is shown in Table 1.

Table 1 Registered uses of chlorantraniliprole on citrus fruit, green bulb vegetables, pulses (mung beans, chickpeas and soya beans), cereal grains, peanuts and herbs

^e Use a non-ionic surfactant/ wetting agent at 125 g active/ 100 L.

RESIDUES RESULTING FROM SUPERVISED TRIALS

The Meeting received information on supervised trials for the uses of chlorantraniliprole on citrus fruits (oranges and mandarins), bulb vegetables (green onions), pulses (chickpeas, mung beans and soya beans), cereals (barley, sorghum and wheat) and oilseeds (peanuts).

Trials were well documented with laboratory and field reports. The former included method validation including recoveries with spiking at residue levels similar to those occurring in samples from the supervised trials. Dates of analyses or duration of sample storage were also provided. Concurrent storage stability data was provided for the green onion trials, confirming sample stability over the trial storage period (24 months). Sufficient storage stability data for a range of crop matrices has also been evaluated by previous Meetings. Applications were generally made using backpack sprayers although occasionally tractor mounted sprayers were used. Samples were collected and stored frozen immediately or soon after sampling. Although trials included control plots, no control data are recorded in the Tables because, unless noted, no residues in control samples exceeded the LOQ. When residues were observed in the control samples they are shown as *c* followed by the residues observed in the control sample. Residues are unadjusted for recoveries. In some trials, samples were taken just before the final application and then again on the same day after the spray had dried. In the data tables the notation for these sampling times is '–0' and '0' respectively.

Residues from the trials conducted according to maximum GAP have been used for the estimation of maximum residue levels and dietary intake assessment. If a higher residue level was observed at a longer PHI than the GAP, the higher value has been used in MRL setting and dietary intake assessment. For replicate samples (from the same plot), the mean value (calculated on unrounded individual values) was used for maximum residue level estimation and dietary intake assessment. For two or more analyses of the same sample, the mean value was used for maximum residue level estimation and dietary intake assessment, with the individual results given in brackets. For multiple trials on a crop from the same location, the result from the trial yielding the highest residue was utilised for maximum residue level estimation and dietary intake assessment. In this case the trials are separated by a dotted line.

The results of these supervised trials are shown in the following tables:

Citrus fruits

Supervised trials were carried out on citrus fruit [eight trials (four orange, four mandarins)—Table 2] in the Republic of South Africa (RSA) during the 2010 growing season (van Zyl 2010, 2418/D924). Two foliar applications of a 200 g ai/L SC formulation were made with ground equipment at 3.5 g ai/100 L in 4200–13100 L/ha, resulting in applications of 147–459 g ai/ha. The second application was made 29–31 days after the first and 21 days before harvest. Two field sample replicates were harvested. Residues of chlorantraniliprole in peel and flesh were quantitated by GC-ECD method DuPont 13291. Acceptable concurrent recovery data were obtained.

Note: The RSA citrus data from the 2010 JMPR Meeting have also been tabulated below.

Bulb Vegetables

Supervised trials were carried out on green onions (five trials—Table 3) in Canada and the USA during the 2009–2010 growing seasons (Dorschner 2012b, A10204). Two foliar applications of a 200 g ai/L SC formulation were made at 110–118 g ai/ha. Applications were made to plots using spray volumes of 215–421 L/ha with ground equipment. Two field sample replicates were harvested from each plot for fresh green onions and also for dried green onions (i.e., four samples from each plot). Residues of chlorantraniliprole in fresh and dried whole plant were quantitated using a method similar to LC-MS/MS method DuPont 13294. Acceptable concurrent recovery data were obtained.

Pulses

Supervised trials were carried out on chickpeas (three trials—Table 4) in Australia during the 2011 growing season (Litzow 2013, DuPont-33763). Two foliar applications of a 350 g ai/kg formulation were made at 24.5–24.9 or 48.7–49.7 g ai/ha. A non-ionic surfactant was added. Applications were made to plots using spray volumes of 77–93 L/ha with ground equipment. Residues of chlorantraniliprole were quantitated by LC-MS/MS using Method DuPont 13294. Acceptable concurrent recovery data were obtained.

Residues in chickpea trash and forage are shown in Table 12.

Supervised trials were carried out on soya beans (four trials—Table 7) in Australia during the 2012 growing season (Litzow 2013, DuPont-33763). Two foliar applications of a 350 g ai/kg formulation were made at 24.2–24.5 or 49–49.4 g ai/ha. A non-ionic surfactant was added. Applications were made to plots using spray volumes of 82–106 L/ha with ground equipment. In two trials application was made once at BBCH 51/55 or 71/75 and forage samples were taken. Residues of chlorantraniliprole were quantitated by LC-MS/MS using Method DuPont 13294. Acceptable concurrent recovery data were obtained.

Residues in soya bean trash and forage are shown in Table 15.

Cereal grains

Supervised trials were carried out on barley (three trials—Table 8) in the USA during the 2009 growing season (Dorschner 2012a, IR-4 10204, also submitted to JMPR 2013). Two foliar applications of a 200 g ai/L SC formulation were made 7 days apart at 112–117 g ai/ha. Applications were made to plots using spray volumes of 115–210 L/ha with ground equipment. Replicate samples were taken from each plot. Residues of chlorantraniliprole were quantitated by LC-MS/MS using a method based on DuPont 13294. Acceptable concurrent recovery data were obtained.

Residues in barley hay and straw are shown in Table 16.

Supervised trials were carried out on sorghum (three trials-Table 9) in the USA during the 2009 growing season (Dorschner 2012a, IR-4 10204, also submitted to JMPR 2013). Two foliar applications of a 200 g ai/L SC formulation were made 7 or 30 days apart at 111–114 g ai/ha. Applications were made to plots using spray volumes of 139–255 L/ha with ground equipment. Replicate samples were taken from each plot. Residues of chlorantraniliprole were quantitated by LC-MS/MS using a method based on DuPont 13294. Acceptable concurrent recovery data were obtained.

Residues in sorghum forage and stover are shown in Table 17.

Supervised trials were carried out on peanuts (six trials—Table 11) in the USA during the 2011 growing season. Two foliar applications of a 200 g ai/L SC formulation were made at 111–115 g ai/ha with an adjuvant added. Applications were made to plots using spray volumes of 117–234 L/ha with ground equipment. Peanut samples (one replicate per untreated plot and two replicates per treated plot) were collected at maturity, 1 day after the second application.

FATE OF RESIDUES IN STORAGE AND PROCESSING

Residues after processing

Processing studies are necessary according to the uses and the residues of chlorantraniliprole on raw agricultural commodities. The fate of chlorantraniliprole residues during processing of raw agricultural commodities was investigated in wheat.

As a measure for the transfer of residues into processed products, a processing factor (PF) was used, defined as:

$$\text{PF} = \frac{\text{Residue in processed products (mg/kg)}}{\text{Residue in raw agricultural commodity (mg/kg)}}$$

Wheat

The effect of processing (laboratory scale) on residues of chlorantraniliprole in wheat was investigated in a trial conducted in the USA in the 2009 growing season (Dorschner 2012a, IR-4 10204). Wheat with incurred residues was obtained where plants were sprayed twice at 114 and 112 g ai/ha. Applications were made in 122 or 124 L/ha using ground equipment. Wheat bulk RAC samples were harvested 1 day after the second application.

Bulk wheat grain samples were processed according to simulated commercial procedures into the following samples: aspirated grain fractions, germ, middlings, flour, shorts and bran.

The moisture content of grain was determined and the grain dried in an oven set at 43–57 °C until the moisture content was 10–13%. The grain was transferred to the dust generation room and moved through the conveyor system for 120 minutes to remove the grain dust with an aspirator. Aspirated grain was cleaned with different sized screens to remove broken grain and foreign material. Cleaning yielded grain dust, screenings and cleaned grain. The aspirated grain fraction (grain dust) sample was collected and placed in frozen storage.

Cleaned grain was further processed into germ, middlings, flour, shorts and bran. For wheat germ, a portion of the cleaned grain was conditioned with water for 1 to 1.5 hours to adjust the moisture content to approximately 16%. The conditioned grain was passed through a mill and sifted with three different sized sieves. Material passing through all three sieves was aspirated to remove bran from the germ. The germ with endosperm was passed through a reduction mill and sifted to separate the germ from the endosperm. The germ was aspirated again to remove remaining bran and milled and sieved again to remove remaining endosperm. The germ fraction sample was collected and placed in frozen storage.

The remaining cleaned grain was mixed with water for at least 15 minutes and moisture conditioned according to the physical property of the wheat. The conditioned grain was passed through a mill, broken with three break rolls and sifted through two different sized screens. Break flour passed through the smaller screen and middlings passed through the larger screen. Coarse bran did not pass through either screen. A middlings fraction sample was collected and placed in frozen storage.

The remaining middlings were poured into the reductions system, passed through two reduction rolls and sifted. Reduction flour passed through the sifter, while shorts did not. The break flour and reduction flour were poured into an agitator and mixed for 15 minutes. The recombined flour fraction sample was collected and placed in frozen storage. The coarse bran was placed in a bran finisher and conveyed over a screen. Shorts passed through the screen and bran passed over the screen. The shorts from the bran finisher were added to the shorts from the reduction system to produce the shorts fraction sample, which was placed in frozen storage. The bran fraction sample was collected and placed in frozen storage.

Residues of chlorantraniliprole in wheat RAC and processed commodities were determined by LC/MS/MS using Method 13294. Acceptable concurrent recovery data were obtained for all wheat commodities.

Table 19 Residues of chlorantraniliprole in wheat and processed commodities

DAT = Days After Treatment

APPRAISAL

Chlorantraniliprole was first evaluated for residues and toxicological aspects by the 2008 JMPR. The 2008 JMPR established an ADI for chlorantraniliprole of 0-2 mg/kg bw and concluded that an ARfD was unnecessary. It was also evaluated in 2010 and 2013 for additional maximum residue levels. At the Forty-fifth Session of the CCPR (2013), chlorantraniliprole was listed for consideration of further additional maximum residue levels by the 2014 JMPR.

The Meeting received information on registered use patterns, supervised residue trials and fate of residues in processing. Product labels were available from Australia, Canada, India, the Republic of South Africa and the United States of America.

The residue definition for compliance with MRL and for dietary intake for plant and animal commodities is chlorantraniliprole. The residue is considered fat soluble.

Methods of analysis

Residue trial samples were analysed using LC-MS/MS methods based on those previously evaluated by the JMPR in 2008.

Stability of pesticide residues in stored analytical samples

Samples from the submitted studies were stored for periods less than the period of stability demonstrated in studies provided to the 2008 Meeting. Since the storage stability data from the 2008 JMPR cover a diverse range of crops and demonstrated stability of chlorantraniliprole for up to 2 years, it is considered that these data should be sufficient to cover the storage stability of all commodities in this submission.

The Meeting noted that concurrent storage stability data provided with the green onion residue trials also demonstrated stability of chlorantraniliprole residues over 24 months (the period for which the samples were stored) in fresh and dried green onions.

Results of supervised residue trials on crops

The Meeting received supervised trial data for application of chlorantraniliprole on oranges, mandarins, green onions (fresh and dried), chickpeas, mung beans and soya beans, barley, grain sorghum, wheat and peanuts.

Citrus Fruits

Residue trials were conducted in citrus fruits in the Republic of South Africa (RSA) in 2010 according to the critical GAP in the RSA (up to 2 applications at 3.5 g ai/ 100L, and a 7 day PHI).

Four trials were conducted in oranges and four trials in mandarins. In one orange trial the rate of the second application was not known, so data from this trial were not considered for estimation of a maximum residue level and STMR.

The Meeting noted that the RSA GAP is for the citrus fruit group and that a group maximum residue level of 0.5 mg/kg for chlorantraniliprole in citrus fruits was estimated at the 2010 JMPR Meeting based on 2009 South African trials in oranges (4) and mandarins/ tangelos (4). An STMR of 0.07 mg/kg was estimated.

The new citrus data were combined with the 2009 data to give a larger data set on which to base an estimation of the maximum residue level and STMR.

The ranked order of residues in oranges (whole fruit) from supervised trials in the RSA in 2009 and 2010 according to GAP was: **0.14**, 0.15, **0.15**, 0.22, 0.22, **0.24** and 0.27 mg/kg (*new data in bold italics*).

The ranked order of residues in mandarins and tangelos (whole fruit) from supervised trials in the RSA in 2009 and 2010 according to GAP was: **0.11**, 0.14, **0.15**, 0.18, 0.22, 0.25, **0.30** and 0.35 mg/kg (*new data in bold italics*).

The Meeting noted that the RSA GAP is for the citrus group and considered a group maximum residue level. To consider a group maximum residue level, residues across individual crops should not differ by more than 5×median. The Meeting noted that the median of the oranges and mandarins/ tangelos differed by less than 5-fold (only a 1.1-fold difference).

In deciding whether to combine the datasets for oranges and mandarins/ tangelos for use in the statistical calculator or to only utilise the data from the commodity with the highest residues, the Meeting recognised the similarity of the datasets (Mann-Whitney U-Test). Therefore the Meeting decided to combine the data from oranges and mandarins/ tangelos in order to estimate a maximum residue level for citrus fruit.

The ranked order of residues in oranges and mandarins/ tangelos (whole fruit) from supervised trials in the RSA in 2009 and 2010 according to GAP was: 0.11, 0.14 (2), 0.15 (3), 0.18, 0.22 (3), 0.24, 0.25, 0.27, 0.30 and 0.35 mg/kg.

The ranked order of residues in oranges and mandarins/ tangelos (edible portion - flesh) from supervised trials in the RSA in 2009 and 2010 according to GAP was: 0.02, 0.04, 0.05 (4), 0.06 (3), 0.07 (2), 0.08 (2), 0.09 and 0.11 mg/kg.

The Meeting estimated a maximum residue level of 0.7 mg/kg for residues of chlorantraniliprole in citrus fruits, together with an STMR of 0.06 mg/kg (based on the edible portion data). The Meeting estimated a median residue for whole citrus fruit of 0.22 mg/kg for use in processing calculations.

The Meeting withdrew its previous recommendation of 0.5 mg/kg for chlorantraniliprole in citrus fruits.

Bulb Vegetables – green onion

The GAP for bulb vegetables in the USA is for up to 4 applications at a maximum rate of 73 g ai/ha, or a maximum of 224 g ai/ ha, with a 7 day retreatment interval and a PHI of 1 day.

Residue trials were conducted in green onions in the USA (3 trials) and Canada (2 trials) in which two applications of chlorantraniliprole were made at 110 – 118 g ai/ ha (223-228 g ai/ ha per crop) with a 3 day retreatment interval and a PHI of 1 day.

The Meeting did not estimate a maximum residue level as the trials were not in accordance with the GAP.

Pulses – chickpeas

The critical GAP in India is 2 applications at 25 g ai/ ha and an 11-day PHI.

Four residue trials were conducted in chickpea (Bengal gram) in India in which two foliar applications of chlorantraniliprole were made at 25 or 50 g ai/ha. The PHI was 11 - 23 days.

Only one trial matches the Indian GAP. The observed residues were < 0.03 mg/kg.

The Meeting determined that a single trial was insufficient for estimation of a maximum residue level.

Three residue trials were conducted in chickpeas in Australia according to the GAP in Australia (2 applications at 24.5 g ai/ ha, 7 day retreatment interval and a 14 day PHI).

The ranked order of residues from supervised trials in Australia according to GAP was:

< 0.01, 0.015 and 0.025 mg/kg.

The Meeting decided that the number of trials available was not adequate to estimate a maximum residue level for chickpeas (dry).

Pulses – mung beans

Residue trials were conducted in mung beans in Australia according to the critical GAP in Australia (2 applications at 24.5 g ai/ ha, 7 day retreatment interval and a 14 day PHI).

The ranked order of residues from supervised trials in Australia according to GAP was: 0.092, 0.17 and 0.26 mg/kg.

The Meeting concluded that the number of trials available was not adequate to estimate a maximum residue level for mung beans (dry).

Pulses – soya beans

The GAP for soya beans in Australia is 2 applications at 24.5 g ai/ ha, 7-day retreatment interval, and a 14 day PHI.

Residue trials were conducted in soya beans in Australia.

The ranked order of residues from supervised trials in Australia according to GAP was:

≤ 0.01 (3) and 0.029 mg/kg.

Residue trials conducted in soya beans in Japan which were considered at the time of the 2010 JMPR showed that residues in dry soya beans were < 0.01 (2) mg/kg after 3 applications at 25 g ai/ ha at 7 day intervals and with a 14 day PHI. These trials match the Australian GAP, with the exception of three rather than two applications being made. However, the Meeting noted that the additional application had no effect on the residues in the Japanese trials, which were below the LOQ.

The Australian and Japanese soya bean data were combined and the ranked order of residues from supervised trials in Australia and Japan according to Australian GAP was:

≤ 0.01 (5) and 0.029 mg/kg.

The Meeting estimated a maximum residue level and an STMR value of 0.05 and 0.01 mg/kg respectively for chlorantraniliprole in soya beans.

Cereals

The Codex MRL for chlorantraniliprole in cereal grains is 0.02 mg/kg following the recommendation of the 2008 JMPR based on rotational crop data. An STMR of 0.01 mg/kg was estimated.

A study conducted on cereals in the USA in 2009 - 2010 (three trials in barley and sorghum and five in wheat) was submitted to the 2013 JMPR. As the compound was not registered in the USA for these crops, no estimations of maximum residue levels or STMRs were made. The study has been resubmitted, with relevant registered label use patterns in the USA and Canada for cereal grains except corn and wild rice, and is evaluated here against the critical Canadian GAP.

The GAP for cereals in Canada is 3×75 g ai/ha applications, with a 7-day retreatment interval and a 1-day PHI.

However, the submitted cereal trials were conducted with 2×111 -117 g ai/ha applications (RTI 7 days, PHI 1 day). The Meeting therefore did not estimate maximum residue levels for cereal grains as the trials were not conducted in accordance with the GAP.

Oilseeds – peanuts

The GAP in the USA is up to 4 applications at a rate of 73g ai/ha (or a maximum of 224 g ai/ha/ year) with a 3 day retreatment interval and a PHI of 1 day.

Six residues trials were conducted in peanuts in the USA in which two applications of chlorantraniliprole were made at 111–115 g ai/ ha (total application rate of 224–228 g ai/ha) with a 5-6 day retreatment interval and a PHI of 1 day.

A maximum residue level and STMR were not estimated as the trials were not conducted in accordance with the GAP.

Animal feeds

The Meeting received supervised trials data for chickpea, mung bean and soya bean forage, barley hay and straw, grain sorghum forage and stover and wheat forage, hay and straw.

Pulse forage

The GAP in Australia for chickpea, mung bean and soya bean is 2×24.5 g ai/ha applications with a 14-day grazing PHI.

Data for mung bean, chickpea and soya bean forage is available from the Australian trials, but does not match GAP as only one application was made, while in the chickpea trials, forage was not sampled at the correct PHI. The Meeting therefore did not estimate median and highest residues for pulse forages.

Cereals forages and fodders

Residue data for sorghum and wheat forage, barley and wheat hay, wheat straw and sorghum stover were received. The Meeting determined that the trials did not match the Canadian GAP, and maximum residue levels and median and highest residues were not estimated.

Fate of residues during processing

The Meeting received a processing study for wheat. STMR-P values were estimated for wheat grain processed commodities using the cereal grains STMR value of 0.01 mg/kg estimated by the 2008 Meeting based on rotational crop data (see table below).

A processing study for orange processing into juice was considering by the 2010 Meeting (see table below).

Processing Factors for Chlorantraniliprole from the Processing of Raw Agricultural Commodities (RACs)

RAC	Processed Commodity	Best Estimate Processing Factor	RAC MRL	RAC STMR	Processed Commodity STMR-P/median residue
Wheat	Aspirated Grain Fractions	33	0.02	0.01	0.34
	Bran	1.04			0.011
	Flour	0.38			0.004
	Middlings	0.28			0.003
	Shorts	0.7			0.007
	Germ	1.13			0.011
Oranges	Juice	0.17	0.7	0.22	0.037

Animal commodities

The Meeting recalculated the livestock dietary based on the uses considered by the current Meeting and by the 2008, 2010 and 2013 Meetings on the basis of diets listed in the FAO Manual Appendix IX (OECD Feedstuff Table).

The maximum dietary burdens are 36.1 ppm for beef cattle and 29.0 ppm for dairy cattle, while the mean dietary burdens are 17.4 ppm for beef cattle and 13.6 ppm for dairy cattle. These values have changed only marginally from those calculated by the 2013 Meeting (beef cattle maximum/mean of 31.7/15.7 ppm, and dairy cattle maximum/mean of 26.8/13.1 ppm). The maximum and mean dietary burdens for poultry were unchanged from those previously calculated.

The Meeting confirmed its previous recommendations for maximum residue levels and STMR values for meat from mammals other than marine mammals, milks, edible offal (mammalian), poultry meat, poultry, edible offal of, and eggs.

The Meeting noted that maximum residue levels have not previously been estimated for mammalian fats and poultry fats.

The Meeting noted that the 2010 Meeting estimated a maximum residue level of 0.2 mg/kg for meat (from mammals other than marine mammals) of 0.2 mg/kg (fat), together with STMR values of 0.049 mg/kg in fat and 0.009 mg/kg in muscle. The dietary burden has not changed significantly since. The Meeting estimated a maximum residue level of 0.2 mg/kg for mammalian fats (except milk fats), together with an STMR of 0.049 mg/kg.

The Meeting noted that the 2013 Meeting estimated a maximum residue level of 0.01* mg/kg (fat) and an STMR of 0 for poultry meat. The dietary burden has not changed significantly. The Meeting estimated a maximum residue level of 0.01* mg/kg for poultry fats, together with an STMR of 0.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI assessment.

Definition of the residue (for compliance with the MRL and for estimation of dietary intake) for plant and animal commodities: *chlorantraniliprole*

The residue is fat soluble

The Meeting estimated the maximum residue levels and STMR values shown below.

Commodity		MRL, mg/kg		STMR or STMR-P, mg/kg
CCN	Name	New	Previous	
FC 0001	Citrus Fruits	0.7	0.5	0.06
	Citrus fruit juice	-	-	0.037
MF 0100	Mammalian fats (except milk fats)	0.2	-	0.049
PF 0111	Poultry fats	0.01*	-	0
VD0541	Soya bean (dry)	0.05	-	0.01
CF 0654	Wheat bran, processed	-	-	0.011
CF 1211	Wheat flour	-	-	0.004
CF 1210	Wheat germ	-	-	0.012

Commodity		MRL, mg/kg	Highest residue, mg/kg	Median residue, mg/kg	Comments
CCN	Name				
-	Wheat aspirated grain fractions	-	-	0.34	Feedstuff
-	Wheat middlings	-	-	0.003	Feedstuff
-	Wheat shorts	-	-	0.007	Feedstuff

DIETARY RISK ASSESSMENT

Long-term intake

The evaluation of chlorantraniliprole has resulted in recommendations for MRLs and STMRs for raw and processed commodities. The International Estimated Daily Intakes for the 17 GEMS/Food cluster diets, based on STMRs estimated by this Meeting and the 2008, 2010 and 2013 Meetings were in the range 0-1 % of the maximum ADI of 2 mg/kg bw (Annex 3).

The Meeting concluded that the long-term intake of residues of chlorantraniliprole from uses that have been considered by the JMPR is unlikely to present a public health concern.

Short-term intake

The 2008 JMPR decided that an ARfD was unnecessary and concluded that the short-term intake of residues of chlorantraniliprole is unlikely to present a public health concern.

CLOTHIANIDIN (238)

First draft prepared by Ms T. van der Velde-Koerts, Centre for Nutrition, Prevention and Health Services (VPZ), National Institute for Public Health and the Environment (RIVM), The Netherlands

APPRAISAL

Clothianidin is reconsidered by the Meeting because new data for thiamethoxam became available and clothianidin is a metabolite (sometimes referred to as CGA322704) of thiamethoxam.

Clothianidin was evaluated for toxicology and residues as a new compound in 2010, resulting in a number of MRL recommendations. Additional residue data were evaluated in 2011 and 2012. The residue definition for clothianidin in plant commodities for enforcement and dietary risk assessment is clothianidin.

The 2010 Meeting established an acceptable daily intake (ADI) of 0–0.1 mg/kg bw per day and established the acute reference dose (ARfD) as 0.6 mg/kg bw for clothianidin. Clothianidin residues can also arise from thiamethoxam use (metabolite CGA322704). Therefore, both compounds need to be considered if residue data in support of new uses are submitted. The residue definition in plant commodities for enforcement is thiamethoxam, while the residue definition for dietary risk assessment is thiamethoxam and the metabolite CGA322704 (clothianidin), considered separately.

At the 2014 JMPR Meeting residue data were submitted to support the use of thiamethoxam on use avocado, mango, beans, mint, hops, and persimmon.

The Meeting received analytical methods and supervised trials data for the use of thiamethoxam on avocado, mango, beans, mint, hops and persimmon as well as processing data on mango and mint. The resulting CGA322704 data relevant for maximum residue level recommendations of clothianidin are summarized below.

Combination of residues from clothianidin use and thiamethoxam use

Clothianidin residues may arise from use of clothianidin as well as from use of thiamethoxam (metabolite CGA322704).

The Meeting considered it unlikely that both pesticides are used on the same crop and therefore the maximum estimated residue levels, the maximum STMR, and the maximum HR of each use is taken as recommendation.

Summary of residue data of clothianidin following use of thiamethoxam in relation to clothianidin use reviewed by the 2014 Meeting.

CCN	Commodity name	Origin of use	MRL mg/kg	STMR or STMR-P mg/kg	HR or HR-P mg/kg
FI 0326	Avocado	thiamethoxam	0.03 T	0.01 T	0.02 T
FI 0345	Mango	thiamethoxam	0.04 T	0.02 T	0.02 T
DH 1100	Hops	thiamethoxam	0.07 T	0.026 T	0.028 T
HH 0738 ^e	Mints	thiamethoxam	0.3 T	0.11 T	0.12 T
VP 0061	Beans with pods	thiamethoxam	0.2 T	0.07 T	0.10 T
	Bean forage	thiamethoxam		0.075 T	0.11 T

T = Thiamethoxam use

Fate of residues during processing

Processing studies were undertaken for the use of thiamethoxam on mango and mint (no known use of clothianidin). Processing factors based on the residue for the metabolite clothianidin are listed in the table below. Using the STMR_{RAC} obtained from the thiamethoxam use, the Meeting estimated STMR-Ps for processed commodities to be used in dietary intake calculations.

Commodity	PFs	PF (median or best estimate)	STMR-P = STMR _{RAC} x PF (mg/kg)	HR-P = HR _{RAC} x PF (mg/kg)
	Metabolite CGA322704 (clothianidin) (STMR _{pulp+peel} = 0.02 mg/kg, HR _{pulp+peel} = 0.02 mg/kg)			
Mango, dried flesh	5.67, 8.40, 7.00, 4.00	6.3	0.13	0.13
Mint, oil	< 0.22, < 0.19	< 0.20	n.a.	n.a.

Livestock dietary burden

The additional data on residue levels of clothianidin in bean forage from thiamethoxam use (JMPR 2014) warranted new dietary burden calculations for clothianidin.

The Meeting estimated the dietary burden of clothianidin on the basis of the livestock diets listed in the FAO manual appendix IX (OECD feedstuff table) using the OECD_Feed_Calculator_V1_4. Calculation from highest residue, STMR (some bulk commodities) and STMR-P values provides the levels in feed suitable for estimating MRLs, while calculation from STMR and STMR-P values from feed is suitable for estimating STMR values for animal commodities. The 2014 JMPR Meeting recalculated the livestock dietary burden of clothianidin through clothianidin and thiamethoxam use based on the uses presented by the 2010 Meeting and including the residue values for fresh bean forage from the 2014 JMPR Meeting on thiamethoxam.

The new dietary burdens calculations of clothianidin for beef cattle, dairy cattle, broilers and laying poultry are provided in Annex 6. The calculations were made according to the livestock diets from US/CAN, EU, Australia and Japan in the OECD Feed Table 2009.

Livestock dietary burden, clothianidin, ppm of dry matter

	US	EU	AU	JP	overall	
	Max	Max	Max	Max	max	
Beef cattle	0.30	0.80	1.1	0.027	1.1	^a
Dairy cattle	0.28	0.61	0.87	0.051	0.87	^b
Poultry – broiler	0.050	0.21	0.094	0.022	0.21	
Poultry – layer	0.050	0.26	0.094	0.018	0.26	^c
	Mean	Mean	Mean	Mean	Mean	
Beef cattle	0.088	0.17	0.75	0.024	0.75	^a
Dairy cattle	0.12	0.17	0.61	0.033	0.61	^b

^a Highest mean and maximum beef or dairy cattle dietary burden suitable for maximum residue level and STMR estimates for mammalian meat.

^b Highest mean and maximum dairy cattle dietary burden suitable for maximum residue level and STMR estimates for milk.

^c Highest mean and maximum poultry dietary burden suitable for maximum residue level and STMR estimates for poultry meat and eggs.

Animal commodities maximum residue level estimation

Clothianidin residues in animal commodities from both thiamethoxam (metabolite CGA322704) and clothianidin use are considered below.

Cattle-clothianidin residues from thiamethoxam use

The residues of clothianidin were evaluated in the same way as described for thiamethoxam (see appraisal 2010) for maximum residue level estimation, the highest residue in the tissues and milk were calculated by interpolating the maximum dietary burden (6.1 ppm) between the relevant feeding levels (6-20 ppm) from the dairy cow feeding study and using the highest tissue concentrations based on the residue definition for enforcement from individual animals within those feeding groups and using the mean milk concentration from those feeding groups (see table below).

The STMR values for the tissues and milk were calculated by interpolating the mean dietary burden (2.4 ppm) between the relevant feeding levels (2-6 ppm) from the dairy cow feeding study and using the mean tissue and milk concentrations based on the residue definition for dietary risk assessment from those feeding groups (see table below).

	Feed level (ppm) for milk residues	Total residues in milk (mg/kg)	Feed level (ppm) for tissue residues	Total residue (mg/kg) in			
				muscle	Liver	kidney	fat
Maximum residue level – beef or dairy cattle							
Feeding study	6, 20	0.013, 0.043	6, 20	< 0.01, < 0.01	0.14, 0.38	< 0.01, 0.04	< 0.01, < 0.01
Dietary burden and residue estimate	6.1	0.013	6.1	< 0.01	0.14	< 0.01	< 0.01
STMR – beef or dairy cattle							
Feeding study	2, 6	0.005, 0.013 ^a	2, 6	< 0.01, < 0.01	0.049, 0.14	< 0.01, < 0.01	< 0.01, < 0.01
Dietary burden and residue estimate	2.4	0.0060	2.4	< 0.01	0.058	< 0.01	< 0.01

^a Calculated mean (day 3-26), data retrieved from JMPR 2010 evaluation

Cattle-clothianidin residues from clothianidin use

In a feeding study where lactating cows were dosed with clothianidin at up to 2.6 ppm dry feed, no clothianidin was found in tissues (< 0.02 mg/kg). Therefore, no residues are to be expected in tissues at the mean and maximum calculated dietary burden of 0.75 and 1.1 ppm based on the new clothianidin dietary burden calculation.

For milk MRL estimation, the highest residues in the milk resulting from dietary burden based on clothianidin were calculated by interpolating the maximum dietary burden for dairy cattle (0.87 ppm) between the relevant feeding levels (0.8 and 2.6 ppm) from the dairy cow feeding study and using the mean milk concentration from those feeding groups.

For milk STMR estimation, the median residues in the milk resulting from dietary burden were calculated by interpolating the mean dietary burden for dairy cattle (0.61 ppm) between the relevant feeding levels (0.27 and 0.80 ppm) from the dairy cow feeding study and using the mean milk concentration from those feeding groups.

	Feed level (ppm) for milk residues	Total residues in milk (mg/kg)
Maximum residue level – dairy cattle		
Feeding study	0.80, 2.6	0.0020, 0.012
Dietary burden and residue estimate	0.87	0.002
STMR – dairy cattle		
Feeding study	0.27, 0.80	< 0.0020, < 0.0020
Dietary burden and residue estimate	0.61	< 0.0020

Cattle- data combined from clothianidin and thiamethoxam use

Based on the combined data, the clothianidin data from the thiamethoxam cattle feeding studies were used to support the estimation of maximum residue levels, STMR and HR values for mammalian meat and milk.

The Meeting confirmed the previous maximum residue level recommendations for clothianidin in milk, liver, muscle, fat and edible offal (except liver). The Meeting also confirmed the previous recommended STMR and HR values for meat, muscle, fat, and edible offal (except liver).

The Meeting estimated a new STMR for clothianidin in milk of 0.006 mg/kg and recommended to withdraw the previous recommendation of 0.002 mg/kg. The Meeting estimated a new STMR and HR value for clothianidin in liver of 0.058 and 0.14 mg/kg, respectively and recommended to withdraw the previous recommendations of 0.034 and 0.10 mg/kg, respectively.

Poultry-clothianidin

The new maximum and mean dietary burdens of clothianidin through clothianidin and thiamethoxam use for poultry are marginally lower or unchanged. No new estimations are required. The Meeting agreed that the previous recommendations were confirmed.

RECOMMENDATIONS

The 2011 Meeting recommended the following residue definition for clothianidin (through thiamethoxam and clothianidin use):

Definition of the residue for compliance with the MRL and for estimation of dietary intake for plant and animal commodities: *clothianidin*.

The residue is not fat soluble.

CCN	Commodity Name	CLOTHIANIDIN Maximum residue level recommendations (mg/kg)		STMR or STMR-P (mg/kg)		HR or HR-P (mg/kg)	
		New	previous	New	previous	new	previous

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Daily Intakes (IEDI) of for clothianidin was calculated from recommendations for STMRS for raw and processed commodities in combination with consumption data for corresponding food commodities. The results are shown in Annex 3.

The IEDI of clothianidin in the 17 food cluster diets, based on the estimated STMRS was in the range 1–3% of the maximum ADI of 0.1 mg/kg bw. The Meeting concluded that the long-term intake of residues of clothianidin arising from uses of thiamethoxam and clothianidin considered by the 2010, 2011, 2012 and the present Meeting is unlikely to present a public health concern.

Short-term intake

The International Estimated Short Term Intake (IESTI) for clothianidin was calculated from recommendations for STMRS and HRs for raw and processed commodities in combination with consumption data for corresponding food commodities. The results are shown in Annex 4.

The IESTI for the general population represented 0% of the ARfD (0.6 mg/kg bw) and the IESTI for children represented 0–0% of the ARfD. The Meeting concluded that the short-term intake of residues of clothianidin, from uses of thiamethoxam considered by the present Meeting, is unlikely to present a public health concern.

CYFLUMETOFEN (273)

*First draft prepared by Dr Yukiko Yamada, Ministry of Agriculture, Forestry and Fisheries,
Tokyo, Japan*

EXPLANATION

Cyflumetofen (consisting of isomers) is a bridged diphenyl acaricide (miticide) for control of *Tetranychus* sp. (Two spotted spider mite, Kanzawa spider mite, Desert spider mite) and influences the mitochondrial electron transport chain by inhibiting the complex II substance in the cell. Cyflumetofen does not have translaminar or systemic activity.

Cyflumetofen was first registered in Japan in 2007. Henceforth, cyflumetofen has been registered in a number of countries. It is used in a variety of crops, including citrus fruits, pome fruits, stone fruits, berry fruits, vegetables, dried herbs, and teas. It was included in the Codex Priority List in 2013 by the 45th CCPR as a new compound for evaluation by the current JMPR.

The Meeting received information on physical and chemical properties, animal and plant metabolism, environmental fate, analytical methods, storage stability, use patterns, supervised trials, and processing. Cyflumetofen is reviewed by the JMPR for the first time.

IDENTITY

ISO common name: Cyflumetofen
 Chemical name
 IUPAC: 2-methoxyethyl (RS)-2-(4-*tert*-butylphenyl)-2-cyano-3-oxo-3-(α,α,α -trifluoro-*o*-tolyl)propionate
 CAS: 2-methoxyethyl α -cyano- α -[4-(1,1-dimethylethyl)phenyl]- β -oxo-2-(trifluoromethyl)benzenepropanoate

CAS Registry No.: 400882-07-7

CIPAC No.: 821

Structural formula:

Molecular formula: C₂₄H₂₄F₃NO₄

Molecular weight: 447.45

The metabolism and distribution of cyflumetofen in animals and plants and the fate of cyflumetofen in the environment were investigated using the following ^{14}C -radiolabelled compounds.

[*t*-butylphenyl-ring- $\text{U-}^{14}\text{C}$]-cyflumetofen
("butylphenyl-label")

[benzoyl-ring- $\text{U-}^{14}\text{C}$]-cyflumetofen
("benzoyl-label")

Animal metabolism

The Meeting received information on the results of studies on lactating goats which were fed radio-labelled cyflumetofen.

Metabolism studies on laboratory animals including rats were reviewed in the framework of toxicological evaluation by the current JMPR and the relevant information is summarized below.

Rat

Highest residues were found in the liver followed by the kidney regardless of sex, dose and label position and time point of measurement. Cyflumetofen was extensively metabolized: in total 18 metabolites were identified. B-1, 2-trifluoromethylbenzoic acid was a major metabolite in the rat metabolism (occurring up to 28% of the applied dose). The predominant metabolic pathway for cyflumetofen involves cleavage of the *tert*-butylphenyl and trifluorotolyl moieties. Major reactions on the *tert*-butylphenyl ring are cleavage of the methoxyethyl group, hydroxylation at the butyl group, decarboxylation and glucuronidation at the butyl group. Major reactions on the trifluorotolyl-ring are glutathione conjugation at the carboxyl group and further changes of the glutathione group to mercapturic acid or thiolactic acid. In addition, hydroxylation and

oxidation reactions at the butyl group and cleavage of the carboxylic ester moiety is observed on the parent structure.

Lactating goats (Sowka, et al, 2011a; and Fabian & Landsiedel, 2011a)

Two lactating goats were given orally by gavage radio-labelled cyflumetofen for 12 (benzoyl-label) or 10 (butylphenyl-label) consecutive days. The mean actual dose of benzoyl-label for each of the two goats (Goat 1 and 2) was 0.27 and 0.30 mg/kg bw corresponding to 14.9 and 12.1 ppm in feed. The mean actual dose of butylphenyl-label for each of the two goats (Goat 3 and 4) was 0.43 and 0.48 mg/kg bw corresponding to 12.8 and 11.8 ppm in feed. Milk samples were collected twice daily. The goats were sacrificed 18–24 h after the last dose and tissue/organ samples were collected.

The radioactivity in urine, faeces, blood, stomach content, gut content, gut/stomach, individual milk samples (two samples per day), cage wash, cream and skim milk was determined by liquid scintillation counting (LSC). After transport of the samples to the test facility, subsamples of urine, faeces, and milk of both animals dosed with the benzoyl-label and both animals dosed with the butylphenyl-label were combined to generate label-specific pooled samples. The tissues/organs of both animals (benzoyl- and butylphenyl-label separately) were combined and homogenized. Bile was also pooled. The pooled samples and homogenized tissues were measured with LSC (solid samples after oxidative combustion of small aliquots). All samples were stored at -18 °C or below.

No extraction was necessary for urine and bile prior to HPLC analysis. Subsamples of the pooled milk and faeces samples, and homogenized tissue samples were extracted with acetonitrile and water, or only acetonitrile. The results of the solvent extractions (LSC of the combined extracts) are referred to as extracted radioactive residues (ERR). The residual radioactive residues after solvent extraction (RRR) were determined by combustion analysis. The solvent extracts with sufficient concentrations of radioactive residues were analysed by reversed-phase HPLC with gradient elution and radio-detection, generally using two chromatographic methods.

Identification of metabolites was mainly based on fractionation of urine of both labels and bile of the butylphenyl-label, followed by HPLC-MS, GC-MS and/or NMR analysis of the isolated fractions. Thereafter, the MS samples were used as reference items for co-chromatography experiments to achieve peak assignment.

The residues after solvent extraction of liver (benzoyl- and butylphenyl-label) and kidney (benzoyl-label) were further incubated with protease, whereby significant portions of radioactivity were released. The protease solubilizates of liver (both labels) were analysed by HPLC.

During the study period, no behavioural or physical abnormalities were observed. At sacrifice, macroscopic examinations revealed no abnormalities.

Daily samples of milk, urine, and faeces obtained for twelve and ten consecutive days were measured for total radioactive residues for each animal. The results in Table 2 indicate that the radioactive residue was rapidly and extensively excreted.

Until sacrifice, the radioactive residues excreted via urine amounted to 29.9% and 33.6% (Goat 1 and 2 of the benzoyl-label) and 38.4% and 45.3% (Goat 3 and 4 of the butylphenyl-label) of the total radioactivity administered. The residues excreted via faeces accounted for 49.0% and 43.9% (Goat 1 and 2) and 50.3% and 42.6% (Goat 3 and 4) of the dose. The recovered radioactivity from urine and faeces together with from cage wash accounted for 79.4 and 78.5% of the total administered radioactivity for Goat 1 and Goat 2, respectively. Similarly, the recovered radioactivity from urine and faeces together with from cage wash accounted for 89.6, and 89.1% of the total administered radioactivity for Goat 3 and 4, respectively.

In milk, only low proportions of the administered dose were found, 0.10% and 0.14% (benzoyl-label, Goat 1 and 2) and 0.04% and 0.03% (butylphenyl-label, Goat 3 and Goat 4).

For both labels, only low portions of the administered dose were retained in edible tissues and organs. The total radioactive residues of the benzoyl- and butylphenyl-label in edible tissues/organs and milk were as follows: 0.019 mg/kg and 0.008 mg/kg in milk; 0.404 mg/kg and 0.287 mg/kg in liver, 0.191 mg/kg and 0.167 mg/kg in kidney, 0.010 mg/kg and 0.005 mg/kg in leg muscle, 0.010 mg/kg and 0.004 mg/kg in back muscle, 0.014 mg/kg and 0.018 mg/kg in abdominal fat and 0.014 mg/kg and 0.015 mg/kg in renal fat. In milk, muscle and fat tissues, only low residue levels were found. The rate of extracted radioactivity was high, above 78% TRR, except for milk from goats dosed with the benzoyl-label (51% TRR) and liver

($\geq 65\%$ TRR). In milk; however, the radioactive residues after solvent extraction were below 0.010 mg/kg, and from liver additional radioactivity was released upon protease treatment.

For further analysis, samples from Goat 1 and Goat 2 were pooled (benzoyl-label) and Goat 3 and Goat 4 (butylphenyl-label) were pooled to generate pooled samples for milk (Days 5-12 and Days 1-10), urine (Days 1-12 and Days 1-10), and homogenized faeces (Days 1-12 and Days 1-10). Similarly for each label, samples of liver, bile, kidney, muscle tissues and fat tissues were used to generate one pooled sample per matrix and label. These samples were LSC measured, resulting in the TRR. Additionally, milk and tissue samples were extracted and the TRR was calculated as the sum of the ERR and the residue after solvent extraction (TRR calculated). The TRR calculated was used for all further calculations.

The total radioactive residues in goat milk, tissue, urine and faeces are provided in Table 2.

Table 2a Material balance after repeated oral dose of radiolabelled cyflumetofen to goats, including distribution of residues, and total radioactive residues (TRRs) in milk, tissues, urine and faeces

^f Abdominal fat referred as subcutaneous fat in the in-life report, back muscle referred as flank muscle

Recovered radioactivity from goat matrices were characterized and the results are shown in Tables 3 (benzoyl-label) and 4 (butylphenyl-label).

In urine of the goats given benzoyl-label, the main component B-1 accounted for 1.92 mg/kg or 47.0% TRR. Metabolite M9210I021 was the second most abundant component (0.61 mg/kg or 15.0% TRR). Metabolites M9210I029, M9210I030 and AB-1 were less abundant and accounted for up to 8.9% TRR.

In urine of the goats dosed with butylphenyl-label, metabolite M9210I014 was the main component and accounted for 1.26 mg/kg or 20.7% TRR. Metabolites M9210I021 and M9210I040 were the second most abundant components and accounted for 0.644 mg/kg or 11.0% TRR and 0.612 mg/kg and 10.1% TRR, respectively. Other identified metabolites were M9210I019, M9210I023, M9210I032, M9210I029, M9210I033, M9210I030, A-12, A-2 and AB-1 (each below or equal to 0.316 mg/kg or 5.2% TRR).

The extracted radioactive residues (ERR) in pooled samples of faeces of the goat administered with benzoyl-label (Days 1-12) and butylphenyl-label (Days 1-10) amounted to 78.7% and 95.5% of the TRR, respectively. In the faeces acetonitrile extract of the benzoyl-label metabolite B-1 was the main component

with 0.801 mg/kg or 63.9% TRR. The parent compound BAS 9210 I was also identified, although at significantly lower amounts, and accounted for 0.092 mg/kg or 7.4% TRR. In the faeces acetonitrile extract of the butylphenyl-label, the unchanged parent compound was the only component identified accounting for 0.588 mg/kg or 45.6% TRR.

The ERR in pooled samples of milk from the goats dosed with the benzoyl-label (Days 5-12) and butylphenyl-label (Days 5-10) amounted to 0.009 mg/kg or 51.0% TRR and 0.007 mg/kg or 93.5% TRR, respectively. In the acetonitrile extract of milk from the benzoyl-label dose, metabolite B-1 was the only component identified and accounted for 0.001 mg/kg or 4.5% TRR. In the solvent-extracted residues of milk from the butylphenyl-label dose, metabolite M9210I033 was the main component and accounted for 0.002 mg/kg or 30.0% TRR. The other identified metabolites, M9210I023, M9210I029 and M9210I030, were significantly less abundant and accounted for up to 7.8% of the TRR, less than 10% TRR.

In bile from the both experiments, the label-unspecific metabolites M9210I042, M9210I044 and M9210I043 were identified from 12.1% to 22.3% of the TRR. In bile from the benzoyl-label dose, B-1 was additionally identified accounting for 0.319 mg/kg or 22.4% TRR.

The ERR in pooled sample of liver from the benzoyl- and butylphenyl-label doses amounted to 0.276 mg/kg or 70.8% TRR and 0.182 mg/kg or 64.6% TRR. The residues after solvent extraction of liver (from benzoyl-label and butylphenyl-label) were further incubated with protease, whereby 14.0% and 17.4% of the TRR were released additionally. In the solvent extracted residues of liver from the benzoyl-label dose, metabolite B-1 was the main component accounting for 0.125 mg/kg or 32.0% of the TRR. M9210I042 accounted for 6.7% of the TRR. All components characterized in the ERR from the benzoyl-label dose by HPLC were below or equal to 3.3% TRR. Metabolite B-1 was also identified in the protease solubilize (0.010 mg/kg or 2.5% TRR). In the solvent extracted residues of liver from the butylphenyl-label dose, M9210I042 accounted for 0.023 mg/kg or 8.3% TRR and M9210I043 for 0.014 mg/kg and 5.1% TRR. All components characterized in the ERR of the butylphenyl-label dose by HPLC were below or equal to 3.1% TRR. The characterized components in the protease solubilize of the butylphenyl-label dose were each below or equal to 4.6% TRR.

The ERR in samples of kidney from the benzoyl- and butylphenyl-label doses amounted to 0.161 mg/kg or 85.1% TRR and 0.155 mg/kg or 95.5% TRR. The residue after solvent extraction of kidney (benzoyl-label) was further incubated with protease, whereby 9.4% of the TRR were released additionally. In the solvent extracted residues of kidney of the benzoyl-label dose, metabolite B-1 was the most abundant component with 0.102 mg/kg or 53.9% TRR. All components characterized in the ERR of the benzoyl-label dose by HPLC were below or equal to 5.3% TRR. In the acetonitrile extract of kidney of the butylphenyl-label dose, metabolite M9210I023 accounted for 0.017 mg/kg or 10.2% TRR. Other metabolites identified were M9210I032, M9210I033, M9210I030, M9210I014 and A-2, which were present at up to 6.7% of the TRR. All components characterized in the ERR of the butylphenyl-label by HPLC were below or equal to 8.0% TRR.

The ERR in samples of leg muscle from the benzoyl- and butylphenyl-label dose amounted to 0.008 mg/kg or 84.3% TRR and 0.004 mg/kg or 92.6% TRR. In samples of back muscle the ERR was 0.007 mg/kg or 78.4% and 0.003 mg/kg or 90.4%, respectively. In the acetonitrile extracts of leg muscle and back muscle of the benzoyl-label dose, metabolite B-1 was the main component accounting for 0.005 mg/kg or 50.5% TRR and 0.004 mg/kg or 46.5% TRR, respectively. Due to low residue levels, the muscle tissue extracts of the butylphenyl-label were not analysed by HPLC.

The ERR in samples of abdominal fat of the benzoyl- and butylphenyl-label dose amounted to 0.014 mg/kg or 93.2% TRR and 0.019 mg/kg or 96.3% TRR. In samples of kidney fat (benzoyl-label) the ERR was 0.014 mg/kg or 93.0%. In the acetonitrile extracts of abdominal and kidney fat of the benzoyl-label dose, metabolite B-1 was also the main component (0.006 mg/kg or 40.2% TRR and 0.006 mg/kg or 41.0% TRR), but additionally the parent compound was identified (0.003 mg/kg or 19.6% TRR and 0.003 mg/kg or 21.0% TRR). In the acetonitrile extract of abdominal fat of the butylphenyl-label dose, metabolite A-2 was the main component accounting for 0.008 mg/kg or 40.2% TRR.

The results of the above metabolism studies indicate that residue levels of Cyflumetofen and its metabolites were relatively low in edible tissues and milk except liver and kidney.

After repeated oral doses of benzoyl-label, metabolite B-1 was the predominant radioactive residue present in all of edible tissues tested and milk as well as excreta. It is the only metabolite present above 0.01 mg eq/kg and > 10% TRR in edible tissues or milk: in liver (0.125 mg eq/kg, 32.0% TRR) and kidney

(0.102 mg eq/kg, 53.9% TRR). M9210I042 was found at 0.026 mg eq/kg but 6.7% TRR. Cyflumetofen was found only in fat, among edible tissues, at 0.003 mg eq/kg, around 20%TRR. There were no identified metabolites in edible tissues or milk.

After repeated oral dose of butylphenyl-label, only M9210I023 was identified above 0.01 mg eq/kg and > 10% TRR in kidney (0.017 mg eq/kg, 10.2% TRR). M9210I043 and M9210I042 were found in liver at 0.014 mg eq/kg (5.1% TRR) and 0.023 mg eq/kg (8.3% TRR) respectively. M9210I033 was present in kidney at 0.011 mg eq/kg but 6.7% TRR. There were some other minor metabolites identified in edible tissues and milk but all were < 0.01 mg eq/kg. Cyflumetofen was not found in any edible tissues or milk.

From the metabolism studies, the metabolic pathway of cyflumetofen in lactating goats is speculated as:

- hydrolysis of the formic acid ester followed by hydrolytic cleavage of the trifluoromethylbenzoyl moiety resulting in metabolite B-1 (2-trifluoromethylbenzoic acid) and the labile metabolite M9210I014
- decarboxylation of metabolite M9210I014 resulting in metabolite A-2
- hydrolysis of the formic acid ester followed by decarboxylation yielding metabolite AB-1
- hydrolytic cleavage of the trifluoromethylbenzoyl moiety of metabolite AB-1 also leads to metabolite A-2
- glucuronidation of AB-1 to form M9210I042 and M9210I044
- hydroxylation yields M9210I043.

Oxidation, decarboxylation and hydroxylation of the t-butyl side chain seem to occur. Loss of nitrile from A-2 or its further metabolites also occur. Some conjugation of the carboxyl group of metabolites with the amino acid glycine, yielding conjugated metabolites also may occur.

Figure 1 Proposed metabolic pathway of cyflumetofen in goats

Plant metabolism

The Meeting received information on the fate of cyflumetofen in Satsuma mandarin, apple and eggplant.

Satsuma mandarin (Hayashi, 2004a)

Two individual Satsuma mandarin trees were sprayed with formulated butylphenyl-label or benzoyl-label at an equivalent application rate of 0.600 kg ai/ha. The concentration of the application solutions was 16 mg cyflumetofen in 0.080 L blank formulation. The concentration of the blank formulation was 159 mg formulation in 0.199 L of water. The amount of spray solution per tree was 0.0369 L. The growth stage of the Satsuma mandarin fruit was just before fruit maturation. Satsuma mandarin trees, each tree separately, were kept in climate controlled greenhouses. The trees were irrigated and fertilizer (N-P-K-Mg) was added as needed. No other pesticides were used. The achieved application rate was 89.2 to 92.9% of the target.

For both treatments with the two radio-labelled cyflumetofen, fruit samples were taken at 1, 7 and 30 DAT and leaf samples at 1, 7 and 14 DAT. Four fruits were sampled at random per sampling point and pooled per two fruits. Twenty leaves were randomly sampled per sampling points and pooled per 10 leaves. Untreated fruit and leaf samples were taken at the final harvest point. Fruit and leaf samples were immediately surface rinsed with acetonitrile.

Total radioactivity in the rinse was determined by LSC. The surface rinse was concentrated by evaporation to dryness, and then redissolved prior to analysis by HPLC. The rinsed fruit was separated into peel and pulp fractions. Surface washed leaf, peel and pulp samples were homogenized with dry ice. Homogenates were extracted twice with acetonitrile:water (8:2 v/v). The extracts, after filtration, were combined and radioactivity was determined by LSC. Extracts were further concentrated (volume reduction by rotary-evaporation) prior to analysis by HPLC. Solid residues were dried and radioactivity was determined by combustion/LSC. Total radioactivity was determined as the sum of surface rinse, extracts and solid residues.

Identification was achieved by HPLC and TLC, and comparison with reference standards. Confirmation was also achieved by LC-MS/MS analysis of isolated fractions. HPLC recoveries were determined and were always > 86%. The procedural recovery of the extraction method was 96% for cyflumetofen and 100.4% for total radioactivity, demonstrating the applicability of the employed methods. Storage stability was demonstrated over the experimental period.

The results for distribution and identification of radioactivity in Satsuma mandarin fruit and leaves are presented in the following tables.

Total radioactive residues (TRR) in fruit were 0.58–0.62 mg eq/kg on 1 DAT and 0.57–0.57 mg eq/kg on 30 DAT. Distribution of radioactivity for butylphenyl- or benzoyl-label applications were similar. The majority of the radioactivity was found in the surface rinse: 95–96% of the TRR on 1 DAT and 88–89% of the TRR on 30 DAT. In peel, 4.3–4.8% of the TRR was recovered on 1 DAT, increasing to 10.8–11.5% of the TRR on 30 DAT (9.1–10.1% of the TRR extracted from peel on 30 DAT). Radioactive residues in flesh were very low ($\leq 0.6\%$ of the TRR).

TRR in leaves were 33–35 mg eq/kg on 1 DAT and 28–38 mg eq/kg on 14 DAT. Distribution of radioactivity for butylphenyl- or benzoyl-label applications was similar. The majority of the radioactivity was found in the surface rinse: 95–97% of the TRR on 1 DAT and 87–94% of the TRR on 30 DAT. Leaf residues were 3.4–4.9% of the TRR on 1 DAT, increasing to 5.6–12.9% of the TRR on 30 DAT (4.9–12.4% of the TRR extracted from leaves on 14 DAT).

Cyflumetofen was by far the predominant identified fraction in fruit (sum of rinse and peel extracts): 88–90% of the TRR on 1 DAT decreasing to 44–54% of the TRR on 30 DAT. Other identified metabolites were AB-6, AB-7, A-12 and B-1 (all $\leq 1.6\%$ TRR on 1 DAT and maximum 8.6, 8.5, 4.4 and 11.2% of the TRR, respectively on 30 DAT). It is gradually metabolized over time to produce metabolites B-1, AB-6 and AB-7. However, even 30 DAT, the parent accounted for about 50% TRR.

Cyflumetofen was also the predominant identified fraction in leaves (sum of rinse and extracts): 89–90% of the TRR on 1 DAT decreasing to 73-81% of the TRR on 30 DAT. Other identified metabolites were AB-6, AB-7, A-12 and B-1 (all $\leq 4.8\%$ of the TRR on 1 DAT and maximum 4.2, 1.5, 3.6 and 9.1% of the TRR, respectively on 30 DAT).

Data are the mean of duplicate experiments.

Apple (Dohn, 2004a)

One apple tree grown within a commercial apple orchard in California, USA, was sprayed with formulated butylphenyl- or benzoyl-label at an equivalent application rate of 0.600 kg ai/ha.

Application took place in October 2002. The concentration of the application solutions was approximately 225 (butylphenyl-label) and 211 mg/L (benzoyl-label) cyflumetofen in blank formulation. The achieved application rate was 115 to 120% of the target. Storage stability was demonstrated over the experimental period. At the time of application, fruits were near maturity. The plots were (drip) irrigated and fertilizer (N-P-K and Ca) was added as needed. Other pesticides were used prior to application of cyflumetofen, which does not interfere with cyflumetofen. Fruit samples were taken at 1, 7 and 30 DAT (for both labels and untreated plot). Leaf samples were taken at 7 and 30 DAT (also for both labels and untreated plot).

Fruit and leaf samples were immediately surface rinsed two times with acetonitrile. Total radioactivity in the rinse was determined by LSC. The surface rinse was concentrated prior to analysis by HPLC/TLC. The rinsed fruit and leaves were homogenized with dry ice and liquid nitrogen. Homogenates were extracted twice with acetonitrile and twice with acetonitrile:water (1:1 v/v). The extracts after centrifugation were combined and radioactivity was determined by LSC. Extracts were further concentrated prior to analysis by HPLC/TLC. Solid residues were dried and radioactivity was determined by combustion/LSC. Total radioactivity was determined as the sum of surface rinse, extracts and solid residues.

Identification was achieved by HPLC and TLC, and comparison with reference standards. Some extracts were further characterized by reversed phase solid phase extraction and LSC/HPLC analysis of eluates.

Total radioactive residues (TRR) in apple fruit were 0.100–0.113 mg eq/kg on 1 DAT and 0.079–0.057 mg eq/kg on 30 DAT. Results for butylphenyl- and benzoyl-label were similar. For the butylphenyl- and benzoyl-label, the majority of the radioactivity was found in the surface rinse: 95 and 96% of the TRR, respectively on 1 DAT and 71 and 67% of the TRR, respectively on 30 DAT. Extracted radioactivity was not determined on 1 DAT due to low levels of radioactivity, and was 15 and 9.6% of the TRR on 7 DAT for butylphenyl- and benzoyl-label respectively and 22 and 28% of the TRR on 30 DAT, respectively. Unextracted radioactivity was low: 5.3–7.6% of the TRR on 30 DAT.

TRR in apple leaves were 6.1–7.3 mg eq/kg on 7 DAT and 4.9–9.5 mg eq/kg on 30 DAT. Surface rinse removed less radioactivity from leaves for the benzoyl-label compared to the butylphenyl-label. For the butylphenyl- and benzoyl-label, the majority of the radioactivity was found in the surface rinse: 91 and 87% of the TRR, respectively on 7 DAT and 82 and 72% of the TRR, respectively on 30 DAT. Extracted radioactivity was 13 and 21% of the TRR on 30 DAT for butylphenyl- and benzoyl-label respectively. Unextracted radioactivity was low: 4.9–6.7% of the TRR on 30 DAT.

Cyflumetofen was the predominant identified compound in apple fruit (sum of rinse and extracts): 89–95% of the TRR on 1 DAT decreasing to 53–65% of the TRR on 30 DAT. Other identified metabolites were AB-6, AB-7 and B-1 (all $\leq 5\%$ of the TRR on 1 DAT and maximum 5.3, 6.3 and 1.8% of the TRR, respectively on 30 DAT).

Cyflumetofen was also the predominant identified compound in apple leaves (sum of rinse and extracts): 77–85% of the TRR on 7 DAT and 44–60% of the TRR on 30 DAT. Other identified metabolites were AB-6, AB-7 and B-1 at maximum 8.6, 5.6 and 4.8% of the TRR, respectively on 30 DAT.

The results for apple fruit and leaves (distribution and identification of radioactivity for both labels) are presented in the following tables.

“Minor” refers to ¹⁴C peaks in the chromatogram with a concentration < 0.200 mg eq/kg in the extract. This refers to a

total of all minor components.

Eggplant (Dohn, 2004b)

Eggplants grown on two plots (1.1–1.5 m²) located in California and containing six to eight eggplants were sprayed with formulated butylphenyl- or benzoyl-label cyflumetofen at an equivalent application rate of 0.600 kg ai/ha. Application took place on August 2002. The concentration of the application solutions was approximately 140 (butylphenyl-label) and 220 mg/L (benzoyl-label) cyflumetofen in blank formulation. The achieved application rate was 98 to 114% of the target. Storage stability was demonstrated over the experimental period. The growth stage of the eggplant fruit was from just pollinated to mature. The eggplants were grown outdoors. The plots were (drip) irrigated and fertilizer (N-P-K-Ca-S) was added as needed. Other pesticides were used which do not interfere with cyflumetofen. Fruit samples were taken at 1, 7 and 14 DAT (for both labels and untreated plot). Leaf samples were taken at 14 DAT (also for both labels and untreated plot).

Fruit and leaf samples were immediately surface rinsed two times with acetonitrile. Total radioactivity in the rinse was determined by LSC. The surface rinse was concentrated, if necessary, prior to analysis by HPLC. The rinsed fruit and leaves were homogenized with dry ice. Homogenates were extracted twice with acetonitrile and twice with acetonitrile:water (1:1 v/v). The extracts, after centrifugation, were combined and radioactivity was determined by LSC. Extracts were further concentrated, if necessary by volume reduction by rotary-evaporation, prior to analysis by HPLC. Solid residues were dried and radioactivity was determined by combustion/LSC. Total radioactivity was determined as the sum of surface rinse, extracts and solid residues.

Identification was achieved by HPLC and 2D-TLC, and comparison with reference standards. Some degradates (U4) were identified by LC-MS/MS analysis of isolated fractions or were subjected to acid hydrolysis (U1 and U2) with 1 N HCl at 80 °C to release acid labile conjugates.

Total radioactive residues (TRR) in eggplant fruit were 0.323–0.488 mg eq/kg on 1 DAT and 0.315–0.413 mg eq/kg on 14 DAT. Surface rinse removed less radioactivity from fruit for the benzoyl-label compared to the butylphenyl-label. For the butylphenyl- and benzoyl-label, the majority of the radioactivity was found in the surface rinse: 92 and 86% of the RR, respectively on 1 DAT and 81 and 56% of the TRR, respectively on 14 DAT. Extracted radioactivity was 7.1 and 13% TRR on 1 DAT for butylphenyl- and benzoyl-label respectively and 15 and 41% TRR on 14 DAT, respectively. Unextracted radioactivity was low: 2.7–4.1% of the TRR on 14 DAT.

TRR in eggplant leaves were 17–23 mg eq/kg on 14 DAT. Surface rinse removed less radioactivity from leaves for the benzoyl-label compared to the butylphenyl-label. For the butylphenyl- and benzoyl-label, the majority of the radioactivity was found in the surface rinse: 83 and 69% of the TRR, respectively on 14 DAT. Extracted radioactivity was 14 and 27% of the TRR on 14 DAT for butylphenyl- and benzoyl-label respectively. Unextracted radioactivity was low: 2.6–4.7% of the TRR on 14 DAT.

Cyflumetofen was the predominant identified compound in eggplant fruit (sum of rinse and extracts): 91–95% of the TRR on 1 DAT decreasing to 42–62% of the TRR on 14 DAT. Other identified metabolites were AB-6, AB-7, B-1, U4 and U1 and U2 (acid labile conjugates of B-1) (all ≤ 2.5% TRR on 1 DAT and maximum 3.4, 3.6, 14.8, 1.2, 16.2 and 6.3% of the TRR, respectively on 14 DAT).

Cyflumetofen was also the predominant identified compound in eggplant leaves (sum of rinse and extracts): 47–58% of the TRR on 14 DAT. Other identified metabolites were AB-6, AB-7, B-1, U4 (structure proposed) and U1 (conjugate of B-1) and U2 (conjugate of B-1) at 8.1, 5.7, 4.6, 4.3, 4.1 and 1.4% of the TRR, respectively on 14 DAT).

The results for eggplant fruit and leaves (distribution and identification of radioactivity for both labels) are presented in the following tables.

Proposed metabolic pathway of cyflumetofen in plants

In the metabolism studies on Satsuma mandarin, apple and eggplant, radioactive residues after treatment were at significantly higher concentrations in surface rinse of the respective fruits than their extracts. In all plants, cyflumetofen was the predominant residue. Metabolite B-1 was found in the fruit extract of apple (30 DAT) and eggplant (14 DAT) at 11.2% and 14.8% of TRR corresponding to 0.064 and 0.061 mg eq/kg respectively. No other individual components accounted for > 10% TRR. At smaller amounts, metabolites AB-6 and AB-7 were often identified in fruits.

Considering the results of the plant metabolism studies, the metabolic pathway of cyflumetofen in plants was speculated as follows:

- Cyflumetofen is photodegraded to AB-7, hydrolysed to B-1, or its nitrile is hydrolysed to amide followed by acyl migration to produce AB-6.
- The side chain of AB-7 is hydrolysed and oxidized to produce U4 (identified only in eggplant).
- B-1 conjugates to produce U1 and U2 (found only in eggplant).
- B-1 may also be produced from AB-6 and AB-7. A-12 (found only in Satsuma mandarin) may be derived directly from cyflumetofen or through AB-6

Figure 2 Proposed metabolic pathway of cyflumetofen in plants

Environmental fate

The Meeting received extensive information on fate and behaviour in soil, hydrolysis in aquatic systems, and residues in succeeding crops. Since cyflumetofen is applied as foliar spray on trees (citrus fruits, pome fruits, grapes and tree nuts), strawberry, tomato and eggplant, studies on hydrolysis rate and products (some included in the Physical and Chemical Properties Section), photolysis on plant surface (conditional: No information was available) and rotational crops were relevant to the current review ("Submission and evaluation of pesticide residues data for the estimation of maximum residue levels in food and feed", FAO, 2009).

Aerobic soil metabolism

Studies on aerobic soil metabolism studies on cyflumetofen and its degradates were provided.

Study 1_(Knight, 2004a)

Butylphenyl- or benzoyl-label cyflumetofen was incubated for 181 days in a sandy loam soil in the dark at 25 °C under aerobic conditions at a concentration of 0.93 mg/kg dw. Moisture was maintained throughout the incubation period and volatile radioactivity was trapped (PUF, ethyl digol, KOH). Soil biomass was 3.08% at the start of the experiment and 0.6% after 181 days (study end), indicating sufficiently viable conditions (at least during the first 100 days, as is also indicated by the continuous increase of [¹⁴C]CO₂).

Single soil portions of each label treatment were sampled at 0, 1, 3, 6, 10, 14, 30, 59, 90, 121 and 181 days. Samples were extracted with 100 mL acetonitrile (2×), followed by extraction with 100 mL acetonitrile:water (3:1 v/v) (2×) and finally reflux for 6 hours in acetonitrile:water (3:1 v/v). Polyurethane foam plugs were extracted with acetonitrile. Post-extraction solids were fractionated into fulvic and humic acids and humin. Extracts were subjected to chromatographic analysis by HPLC-RAM and TLC. Metabolite identification was obtained by comparison with reference substances of metabolites.

Mass balances were between 89.6 and 102.6% of applied radioactivity (AR) for both labels. Unextracted radioactivity was at maximum 43.4% AR (14 d) and 37.8% AR on day 90. Volatile radioactivity consisted only of CO₂ and was 25.7 and 34.0% AR on day 90 for butylphenyl- and benzoyl-label, respectively (27.9 and 39.3% AR at study end).

Cyflumetofen degraded with a DT₅₀ of 2.76 days and a DT₉₀ of 9.16 days by linear regression analysis. Degradation could be described by first-order kinetics (r² 0.952). Significant metabolites (exceeding 10% AR or 2× 5% at two consecutive time points) were AB-1 (max 8.3% AR, day 59), B-1 (max 22.9% AR, day 6) and SHL9 (max 7.9%, day 10).

Study 2 (Willems, 2008a)

Basing on the above study results, DT_{50} and DT_{90} for the degradation of cyflumetofen in soil were calculated following FOCUS guidance of EU. Optimization was by the Marquardt method using ordinary least squares weighting.

Cyflumetofen degrades in Wolston sandy loam soil (at 25 °C) with a half-life of 1.81–2.29 days (mean 2.05 d, persistence endpoint). Degradation was described by DFOP kinetics. For modelling a mean $DegT_{50}$ of 2.38 days was calculated (correction for soil moisture not included).

Study 3 (Ta and Strobush, 2011a)

The metabolism of cyflumetofen in four US soils under aerobic conditions was investigated using benzoyl- and butylphenyl-label. Four soils of different textures (loamy sand and loam soils) collected from different locations representing various geographical regions in the USA were used. Cyflumetofen was applied at the rate of 0.8 mg ai/kg soil, equivalent to 200 g ai/ha.

Soil equivalent to 50 g of dry weight was weighed into 250 mL wide-mouth polypropylene centrifuge bottles. The soils were maintained aerobically by connecting to an air flow-through system in the dark at 20 ± 2 °C for 120 days. The soil moistures were adjusted to approximately 40–60% of the maximum water holding capacity (MWHC) prior to application of test material to the soil and maintained throughout the incubation period by adding HPLC water if necessary. Moisturized CO₂-free air was passed over the soil surface and air leaving the system was passed through 1 N NaOH solution to trap any CO₂ produced. Duplicate samples were analysed at 0, 1, 3, 7, 16, 29, 58, and 120 days after treatment (DAT). The soil samples were extracted once with acetonitrile, followed by 70% acetonitrile in water twice, and trifluoroacetic acid was added to bring the extract solution to a concentration of 0.1% acid to prevent any hydrolysis that may occur. The solvent extracts were pooled, concentrated and analysed by HPLC. Identification of parent and its transformation products was performed by retention matching with reference standards by HPLC and confirmation by LC/MS and/or NMR. The amounts of CO₂ and organic volatiles produced were determined at each sampling time (excluding 0 DAT). The traps were assayed directly by adding aliquots of the trapping solutions into liquid scintillation fluid and counting by liquid scintillation counting.

Table 18 Soil properties

Geographic Location	CA, USA	IN, USA	NJ, USA	WI, USA
Soil series	Corralitos	Crosby	Penn	Burkhardt

The average total recovery of the radiolabelled material was 95.5% of the total applied radioactivity (TAR) for all samples from four soils with two labels.

California soil:

The total radioactivity recovered from the benzoyl-label ranged from 97.1 to 103.3% of the total applied radioactivity (TAR) with an average of 99.4% TAR. Radioactive residues extracted by solvent decreased from approximately 99.7–100% TAR at 0 day after treatment (DAT) to approximately 67.6–77.4% TAR at 120 DAT. Unextracted radioactive residues increased from approximately 0.3% TAR at 0 DAT to 16–21.6% TAR at 120 DAT. The concentration of the parent compound decreased from approximately 98.1–98.2% TAR at 0 DAT to approximately 3–5% TAR at 120 DAT. There

were three major (> 10% TAR) transformation products identified as B1, B3, and AB1 + AB1 dimer 2. At 120 DAT, the total evolved $^{14}\text{CO}_2$ was 9.9% TAR.

Indiana soil:

The total radioactivity recovered from the benzoyl-label ranged from 87 to 100.6% TAR with an average of 94.3% TAR. Radioactive residues extracted by solvent decreased from approximately 99–100.2% TAR at 0 DAT to approximately 31.5–32.6% TAR at 120 DAT. Unextracted radioactive residues increased from approximately 0.4% TAR at 0 DAT to 37.8–38.0% TAR at 120 DAT. The concentration of the parent compound decreased from approximately 97.6–98.9% TAR at 0 DAT to approximately 1.2–1.9% TAR at 120 DAT. There were 3 major (> 10% TAR) transformation products identified as B1, AB1 + AB1 dimer 1, and AB1 + AB1 dimer 2. At 120 DAT, the total evolved $^{14}\text{CO}_2$ was 17.6% TAR.

New Jersey soil:

The total radioactivity recovered from the benzoyl-label ranged from 90.2 to 101.5% TAR with an average of 95.4% TAR. Radioactive residues extracted by solvent decreased from approximately 100.5–101% TAR at 0 DAT to approximately 37.6–38.7% TAR at 120 DAT. Unextracted radioactive residues increased from approximately 0.5% TAR at 0 DAT to 31.1–32.7% TAR at 120 DAT. The concentration of the parent compound decreased from approximately 98.8–99.3% TAR at 0 DAT to approximately 1.3–2.7% TAR at 120 DAT. There were 3 major (> 10% TAR) transformation products identified as B1, AB1 + AB1 dimer 1, and AB1 + AB1 dimer 2. At 120 DAT, the total evolved $^{14}\text{CO}_2$ was 24.1% TAR.

The total radioactivity recovered from the butylphenyl-label ranged from 90.3 to 100% TAR with an average of 93.7% TAR. Radioactive residues extracted by solvent decreased from approximately 97.6–99.5% TAR at 0 DAT to approximately 33.8–36.2% TAR at 120 DAT. Unextracted radioactive residues increased from approximately 0.5% TAR at 0 DAT to 41.2–43.1% TAR at 120 DAT. The concentration of the parent compound decreased from approximately 94.5–96.6% TAR at 0 DAT to approximately 2.5–2.6% TAR at 120 DAT. There was 1 major (> 10% TAR) transformation product identified as AB1. At 120 DAT, the total evolved $^{14}\text{CO}_2$ was 17.3% TAR.

Wisconsin soil:

The total radioactivity recovered from the benzoyl-label ranged from 88.3 to 100.1% TAR with an average of 95.2% TAR. Radioactive residues extracted by solvent decreased from approximately 98.1–99.9% TAR at 0 DAT to approximately 39.8% TAR at 120 DAT. Unextracted radioactive residues increased from approximately 0.3% TAR at 0 DAT to 31.5–31.6% TAR at 120 DAT. The concentration of the parent compound decreased from approximately 96.8–98.4% TAR at 0 DAT to approximately 2.8–3.2% TAR at 120 DAT. There were four major (> 10% TAR) transformation products identified as B1, AB1, AB1 + AB1 dimer 1, and AB1 + AB1 dimer 2. At 120 DAT, the total evolved $^{14}\text{CO}_2$ was 17.3% TAR.

Table 19 Summary of aerobic soil metabolism study 2 results

Soil	Mass balance (Total recovery)	Degradation of cyflumetofen in 120 days	Half-life/ Dissipation time
CA soil	97.1 to 103.3% TAR	93.2–95.1%	3.51 days ^a
IN soil	87.0 to 100.6% TAR	96.4–97.0%	2.28 days ^b
NJ soil	90.2 to 101.5% TAR	92.0–97.5	2.36 days ^b
WI soil	88.3 to 100.1% TAR	93.6–95.6%	3.41 days ^b

Study 4 (Brands, 2011a)

Benzoyl-label was incubated for 120 days in the dark in 100 g dw equivalent each of three soils (Speyer 2.2, loamy sand; Speyer 2.3, sandy loam; and Speyer 6S, clay), which were equilibrated for 20–21 days in the dark, at 20 ± 2 °C under aerobic conditions at a concentration of 0.383 mg/kg (~0.8% acetonitrile) on a dry weight basis. A humidified air stream was passed through the soil containers (2 x 30 minutes/day). The outgoing air was passed through a polyurethane foam plug, a trap containing 2-ethoxyethanol and two traps containing 2M NaOH to trap volatile substances and CO₂. Soil moisture was kept constant at 45% of the MWHC throughout the incubation period. Soil biomass was determined at the start and end of the incubation period by the fumigation/extraction method.

Speyer 2.2, 2.3 and 6S soils, after sieving (2 mm), were used within two months (storage at 4 °C) of field sampling. The properties of these soils are shown in the following Table.

Table 20 Properties of the three soils used in the study.

Property	Speyer 2.2	Speyer 2.3	Speyer 6S
Origin	Hanhofen, Rheinland-Pfalz, Germany	Offenbach, Rhein-land-Pfalz, Germany	Siebelingen, Rhein-land-Pfalz, Germany
Texture (USDA)	Loamy sand	Sandy loam	Clay
Sand (% , USDA)	79.1	61.0	21.9
Silt (% , USDA)	13.5	29.8	36.0
Clay (% , USDA)	7.9	9.2	42.0
pH-water	-	-	-
pH-KCl	-	-	-
pH-CaCl ₂	5.6	6.2	7.0
% OM	4.07	1.76	3.26
% OC	2.36	1.02	1.89
CEC (meq/100g)	11	9	20
MWHC (% , w/w)	48.0	34.9	42.3

Single soil portions and associated traps were sampled at 0, 1, 3, 6 (duplicate sample), 10, 14, 21, 35 (duplicate sample), 58, 90 and 120 days. Soil samples were extracted three times with 100 mL acetonitrile/sodium acetate buffer pH 4 (75:25, v/v). Samples of day 35 were also extracted by n-hexane and acetonitrile-Soxhlet extraction (3 hours). Polyurethane foam plugs were extracted with acetonitrile (2×). Radioactivity in extracts and liquid traps was determined by LSC and in post-extraction solids by combustion/LSC. Soil extracts were fractionated in an organic and aqueous phase. Relevant fractions were subjected to analyses by HPLC-RAM and TLC. Metabolites were identified by comparison with reference substances of metabolites and LC-MS/MS analysis. Radioactivity in the NaOH traps was confirmed as CO₂ by precipitation with Ba(OH)₂.

Soil biomass was 1.1–2.1% of OC at the start and 0.3–2.7% at the end of the experiment. In combination with significant mineralization at the end of the study, sufficiently viable conditions were indicated.

Mass balances were between 87.9 and 109.8% of applied radioactivity (AR). No specific trend was observed and all results were considered acceptable.

The amount of extractable residues decreased from 103.5–104.6% AR to 54.1 (Speyer 2.2), 26.9 (Speyer 2.3) and 62.2% AR (Speyer 6S) at study end (day 120). Unextractables were maximum 32.1 (Speyer 2.2, day 58), 40.1 (Speyer 2.3, day 120) and 38.4% AR (Speyer 6S, day 35). Additional extraction with n-hexane (day 35 sample) released 1.6–3.2% AR radioactivity and with Soxhlet 1.8–5.1% AR.

Volatile radioactivity consisted mostly of CO₂ and was 9.5 (Speyer 2.2), 20.7 (Speyer 2.3) and 1.7% AR (Speyer 6S) at day 120 (study end) (0.8, 16.2 and 1.8% AR, respectively at day 90).

Unextracted radioactivity was at a maximum of 32.1 (Speyer 2.2, day 58), 40.1 (Speyer 2.3, day 120) and 38.4% AR (Speyer 6S, day 35).

Cyflumetofen degraded to < 10% AR after 21 days in Speyer 2.1 soil, to < 10% AR after 10 days in Speyer 6S soil and to ~10% AR at day 120 in Speyer 2.3 soil under aerobic conditions in the dark at 20 °C.

Those metabolites exceeding 10% AR or 2× 5% at two consecutive time points were B-1 (max 63.0% AR, day 90, Speyer 2.2) and B-3 (max 23.0% AR, day 21, Speyer 2.2). No other metabolites exceeding 5% AR were observed in any soil.

Study 5 (Willems, 2008a)

The degradation of cyflumetofen in three soils (Speyer 2.2, 2.3 and 6S) was studied by Brands in 2008 (NOTOX report 478338; 7.2.1/01), in which benzoyl-label was spiked to these soils and incubated for 120 days at 20 °C in the dark. Using the degradation results, DT₅₀ and DT₉₀ were calculated for cyflumetofen in accordance with FOCUS guidance ((SANCO/10058/2005, vs 2.0, June 2006). Optimization was by the Marquardt method using ordinary least squares weighting.

Table 24 Cyflumetofen degradation in Speyer 2.2, 2.3 and 6S soils

Time d	Cyflumetofen (% of applied)		
	Speyer 2.2	Speyer 2.3	Speyer 6S

120	10.2	10.6	5.4

^a including 2.6% unextracted residues

^b including 0.9% unextracted residues

^c including 6.3% unextracted residues

According to FOCUS guidance, first, single first order (SFO) and first order multi-compartment (FOMC) kinetics were run. Time zero results for cyflumetofen were adjusted for unextracted residues but not for metabolites because the radioactivity present as metabolites was similar to the amount of impurities in the spike solutions. The possibility for elimination of data points or constraining of M₀ was investigated, and when FOMC still resulted in a better fit, also dual first order in parallel (DFOP) kinetics were fitted to the data. DegT₅₀ and DegT₉₀ values for persistence were taken from the best fit model. For modelling, the SFO fit was first evaluated and when not acceptable, FOMC or DFOP were also assessed. In case FOMC or DFOP was suited for modelling, the DegT₅₀ for modelling was calculated as DegT₉₀/3.32.

Persistence and modelling endpoints for the degradation of cyflumetofen in soil were calculated and are shown in the following Table.

Table 25 Persistence and modelling endpoints for degradation of OK-5101 in Speyer soils

Soil	Persistence			Modelling
	DT ₅₀ at 20 °C days	DT ₉₀ at 20 °C days	model	DT ₅₀ at 20 °C ^a Days
Speyer 2.2	4.33	23.10	DFOP	6.70
Speyer 2.3	3.13	134.10	DFOP	13.30
Speyer 6S	2.20	8.40	DFOP	2.95

^a not including moisture correction.

Study 6 (Brands & Corral, 2011b)

The degradation of B-1 in soil was investigated in three soils (the same soils as in Study 4). A 50 g (dw) portion each of three soils (Speyer 2.2, loamy sand; Speyer 2.3, sandy loam; and Speyer 6S, clay), which were sieved (2 mm), stored at 4 °C and used within 4 weeks of field sampling, was equilibrated for 4 days in the dark at a moisture content of ~40% of the MWHC at 20 °C. Following equilibration, soil portions were treated with B-1 in acetonitrile/water 1/9 (v/v) at a rate of 0.25 mg/kg dw (~0.16% acetonitrile). The test substance was gently mixed in the soil. Incubation took place in the dark at 20±2 °C under aerobic conditions for 120 days. Soil moisture was kept constant at ~40% of the MWHC throughout the incubation period.

Soil biomass was determined at the start and end of the incubation period by the fumigation/extraction method. Single soil portions were sampled at 0, 1, 4 (duplicate sample), 10, 28 (duplicate sample), 70 and 120 days. Soil samples were extracted with 250 mL acetonitrile/water (10/90 v/v) for 30 minutes. The samples were filtered over a 0.2 µm filter prior to analysis by UPLC-MS/MS.

Biomass was > 1% of OC throughout the study. Actual moisture contents (dw basis) throughout the study were 20% (Speyer 2.2), 14% (Speyer 2.3) and 16% (Speyer 6S), equivalent to ~39% of the MWHC.

DT₅₀ and DT₉₀ values for B-1 were obtained by fitting single first order (SFO) kinetics to the data. The results are given in the following Table. The FOMC model was also verified and gave similar results as the SFO model, but optimization errors were much larger compared to the SFO model. Because there was also no biphasic pattern visible, the SFO model was selected as best fit model.

Table 27 Half-lives for degradation of B-1 at 20 °C under aerobic conditions based on SFO kinetics ^a

Soil	M ₀ %	K day ⁻¹	DT ₅₀ days	DT ₉₀ Days	r ²	χ ² (err)
Speyer 2.2	104 ± 2.8	0.110 ± 0.008	6.3	21.0	0.993	4.6
Speyer 2.3	106 ± 2.7	0.041 ± 0.003	16.7	55.5	0.988	5.3
Speyer 6S	102 ± 3.7	0.019 ± 0.002	36.3	121	0.959	7.2

^a not corrected for moisture content.

B-1 degraded in three soils under aerobic conditions in the dark at 20 °C with half-lives of 6.3, 16.7 and 36.3 days and DT₉₀ values of 21.0, 55.5 and 121 days. These values are not normalized for moisture. Degradation was described by SFO kinetics.

Study 7 (Corral & Brands, 2010c)

AB-1 was studied by incubating for 120 days in three soils (Speyer 2.1, sand; Speyer 2.2, loamy sand; and Speyer 6S, clay) in the dark at 20 °C under aerobic conditions at a concentration of 0.04 mg/kg

dw. Portions of 50 g dw equivalent soil were equilibrated for 11 days in the dark at a moisture content of ~40% of the MWHC at 20 °C. Following equilibration, soil portions were treated with AB-1 in acetonitrile at a rate of 0.04 mg/kg dw. The test substance was gently mixed in the soil. Incubation took place in the dark at 20±2 °C under aerobic conditions for 120 days. Soil moisture was kept constant at ~40% of the MWHC throughout the incubation period. Soil biomass was determined at the start and end of the incubation period by the fumigation/extraction method.

Single soil portions were sampled at 0, 0.25 (duplicate sample), 1, 2 (duplicate sample), 4, 29, 72 and 120 days. Soil samples were extracted with 400 mL acetonitrile/water (50/50 v/v) containing 0.05 or 0.1% (v/v) ammonium solution for 30 minutes. The samples were filtered over a 0.2 µm filter prior to analysis by UPLC-MS/MS (fully validated, see OTSA-0368).

Biomass was >1% of OC throughout the study. Actual moisture contents (dw basis) throughout the study were 13% (Speyer 2.1), 20% (Speyer 2.2) and 16% (Speyer 6S), equivalent to 39-40% of the MWHC

DT₅₀ and DT₉₀ values for AB-1 were obtained by fitting single first order (SFO), first-order multi-compartment (FOMC), dual first order in parallel (DFOP) and hockey-stick (HS) kinetics to the data. As there was a clear bi-phasic pattern observed, the HS and DFOP models described the results the best (and equally good). According to FOCUS guidance, the HS model is not used for obtaining endpoints for persistence, therefore the DFOP model was selected for use in exposure assessment. The calculated results are shown in the following table.

AB-1 degraded in three soils under aerobic conditions in the dark at 20 °C with half-lives of 0.07, 0.08 and 0.11 days (not corrected for moisture). Degradation was described by DFOP kinetics.

Photodegradation on soil surface (van Noorloos, 2007a and 2007b)

Photodegradation of cyflymetofen on soil surface was investigated using butylphenyl- and benzoyl-label cyflumetofen.

Butylphenyl- or benzoyl-label was applied uniformly over the surface of thin soil layers at a rate of 401 g ai/ha or 391–395 g ai/ha, respectively. The soil layers were irradiated (300–400 nm: 66.5 Watt/m²) for 15 days (equivalent to 33–38 days natural sunlight at 40 °N, summer) at 18–23 °C or for 14 days (equivalent to 35–36 days natural sunlight at 40 °N, summer) at 19–22 °C, respectively, with artificial light (Xenon lamp) simulating the sunlight spectrum. Control samples were incubated in the dark at approximately 20 °C. Duplicate samples were taken after 0, 1, 4, 7, 11 and 15 days of irradiation/incubation. Soil layers were extracted with (75/25 (v/v)) acetonitrile/sodium acetate buffer pH 4. Following fractionation into an organic and aqueous phase the organic phase was analysed by reversed phase HPLC-RAM and selected samples also by TLC. The aqueous phase was not further analysed due to low levels of radioactivity. Polyurethane foam plugs were extracted by acetonitrile and soda lime granules were dissolved in 2 M HCl and released CO₂ was trapped in 2 M NaOH. Radioactivity in liquid fractions was determined by LSC and in residual soil by combustion/LSC. Identification of radioactive fractions was obtained by co-chromatography with reference standards (HPLC and TLC).

Mass balances

Butylphenyl-label: Mass balances were between 81.4 and 105.4% of applied radioactivity (AR) for the irradiated samples and between 87.2 and 102.0% AR for the dark control samples. Unextracted

radioactivity was 44.6–45.6% AR (irradiated, study end) and 45.0% AR (dark control, study end, mean). Volatile radioactivity was at the maximum 2.5% AR in any sample.

Benzoyl-label: Mass balances were between 96.4 and 104.7% of applied radioactivity (AR) for the irradiated samples and dark control samples. Unextractables were approximately 24% AR (irradiated, study end) and approximately 39% AR (dark control, study end). Volatile radioactivity was insignificant ($\leq 0.5\%$ AR).

Cyflumetofen dissipation

Butylphenyl-label: Cyflumetofen dissipated with a single first order DT_{50} of 1 and 0.95 days in irradiated soil and dark controls, respectively. No metabolites exceeded 10% AR. Specific photolytic metabolites were not observed. All metabolite fractions observed in irradiated soil were also present in similar amounts in dark controls.

Benzoyl-label: Cyflumetofen dissipated with a single first order DT_{50} of 1.4 days in irradiated soil and dark controls, respectively. One significant metabolite, B-1, exceeded 10% AR in both the irradiated and dark soil. Specific significant ($> 10\%$ AR) photolytic metabolites were not observed.

In conclusion, photolytic degradation on soil surfaces is not expected to play a role in the overall fate of cyflumetofen residues in soil, regardless of radio-labelled cyflumetofen used.

Hydrolytic degradation in aquatic systems (Nakamura, 2004a)

Portions of 2.5 mL butylphenyl- or benzoyl-label cyflumetofen in acetonitrile were added to 250 mL sterilized, deoxygenated buffer solutions of pH 4, 5, 7 and 9 at a concentration of 0.1 mg/L. The fortified buffer solutions were incubated in the dark at 25 ± 1 °C for 30 days (pH 4, 5 and 7), 10 days (pH 7, benzoyl-label) or 1 day (pH 9). Sterility and pH were checked at the beginning and end of the

incubation period. Samples were taken at various time points. Immediately after sampling, the pH 7 and pH 9 samples were acidified (acetic acid) to slow hydrolysis. Samples were partitioned into an organic phase (acetonitrile) and aqueous phase by C₁₈- SPE. Radioactivity was determined by LSC and the organic phase was subjected to chromatographic analysis (HPLC-RAM, TLC, LC-MS). The aqueous phase for the final sampling point and selected sampling points of benzoyl-label incubations was acidified (HCl) and subjected to PLS-2 SPE. Radioactivity in organic and aqueous phases was determined by LSC. The resulting organic phase (acetonitrile) was subjected to analysis using HPLC-RAM. Metabolite identification was done by comparison of retention times of HPLC, running factors (TLC) and MS spectra (LC-MS ion-trap) with reference standards of metabolites (A1, B1, AB-1, A-18). Metabolites for which no references were available were identified by LC-MS (ion-trap). Hydrolytic half-lives for cyflumetofen were calculated by linear regression using first order kinetics.

The mean total recovery for butylphenyl-label was 94.2 to 103.5% of applied radioactivity and that for benzoyl-label was 97.6 to 102.2%.

Degradation of cyflumetofen and its identified degradates at pH 4–9 at 25 °C are shown in the following Tables. Hydrolysis was fastest at pH 9 and slower in lower pH.

The degradation products of hydrolysis exceeding 10% of the applied radioactivity were A-1 (max 14.44% AR at pH 5–7), A-2 (max 44.12% AR at pH 5–7), A-18 (max 36.22% AR at pH 5–7), AB-1 (max 44.51% AR at pH 5–7) and B-1 (max 53.17% AR at pH 5–7). Other unknown fractions were all ≤ 7.76% AR, with the exception of BU14: 11.39% AR (pH 5, benzoyl-label). This fraction was identical to AU14 (pH 5, butylphenyl-label). When taking the average of the butylphenyl- and benzoyl-label incubations at pH 5, also this fraction was < 10% AR at all time points.

Metabolism and Distribution in Succeeding Crops

Confined Rotational Crop Study (Grosshans et al., 2011a)

A confined rotational crop study was conducted with benzoyl- and butylphenyl-label cyflumetofen. The active substance was applied to bare sandy loam soil in plastic containers (40 cm × 60 cm) at an application rate of 1 × 400 g ai/ha using an automatic spray track system. After the soil aging periods, ploughing was simulated by mixing the treated and untreated soil layers using a spade before replanting. The nature and the quantities of the radioactive residues were investigated in lettuce (immature and mature), white radish (top and root) and spring wheat (forage, hay, straw, chaff and

grain) after plant back intervals (PBI) of 30, 120 and 365 days. They are cultivated under natural climatic conditions but protected from rain. Plant samples were harvested at maturity, and additional immature lettuce samples as well as spring wheat forage samples (in part dried to hay) were taken 26 to 39 days and 47 to 62 days after planting or sowing, respectively. Soil samples were taken after application, after ploughing and after harvest of the mature crops for each plant back interval.

Mature and immature lettuce leaves were sampled with the roots remaining in the soil. Ripe white radishes were pulled from the soil and separated into the root and the remaining green parts (top). Immature green plants of spring wheat were sampled (wheat forage) and partly dried to wheat hay. Furthermore, ears of mature wheat and straw were cut off with scissors. Afterwards, ears were separated into chaff and grain using a thresher. For the plant back intervals of 120 and 356 DAT (benzoyl-label), chaff and straw samples were combined. For the butylphenyl-label, chaff and straw samples were generally combined. Soil samples were taken after application into petri dishes, after the individual plant back intervals and after harvest of the mature crops.

All samples were stored in a freezer at -18 °C or below, immediately after they were taken and until they were transferred to the laboratory. The storage conditions remained constant until analysis started and during the whole period of the study. Lettuce, radish and wheat forage and hay samples were homogenized with dry ice using a planetary mill or a blender. Samples of wheat hay, wheat straw and wheat straw + chaff were also frozen in liquid nitrogen and generally homogenized using a meat grinder. Individual hay samples were frozen and coarsely cut prior to homogenization with the meat grinder or homogenized with the blender. Samples of wheat grain and chaff were frozen in liquid nitrogen or dry ice and homogenized using a centrifugal grinding mill or with the blender (grain 365 PBI).

The radioactive residues in homogenized plant or soil samples were determined by oxidative combustion of small aliquots using LSC. Weighed subsamples of homogenized plant material were extracted three times with a sufficient volume of acetonitrile using a Polytron blender and the radioactivity was determined (LSC). Subsamples of spring wheat hay, straw and chaff were soaked in water before extraction. The residues were further extracted with appropriate volumes of water (two times). The water extracts were also radioassayed. The results of the acetonitrile and the water extraction were summed and referred to as extractable radioactive residues (ERR). The residue after solvent extraction (acetonitrile and water) of each sample was dried at room temperature under a fume hood, homogenized and aliquots were combusted for the determination of the residual radioactive residue (RRR). The total radioactive residues (TRR) were the result of the combustion analyses or the calculated sum of ERR and RRR values.

The residual radioactive residues of spring wheat hay, straw, chaff and grain (plant back interval of 30 days in the case of the benzoyl-label, plant back intervals of 120 and 365 days in the case of the butylphenyl-label) were further characterized using sequential solubilisation procedures. In the case of the benzoyl-label, the first solubilisation step with aqueous ammonia solution was also applied for the other rotational crop matrices. The residues from spring wheat hay, straw, chaff and grain after ammonia solubilisation (both labels) were subjected to two consecutive solubilisation steps applying the following hydrolysing enzymes: macerozyme/cellulase and amylase/amyloglucosidase. In the case of the benzoyl-label (30 PBI), the incubations with enzymes were followed by two non-selective solubilisation steps with hydrochloric acid.

The nature of the radioactive residues in the acetonitrile and aqueous extracts (with a sufficient level of radioactivity) as well as solubilizates (from RRR matrices, only spring wheat grain 30 PBI, benzoyl-label) of individual matrices of the different crops and labels was investigated using different HPLC methods with radio-detection. Peak assignment and identification of degradates in extracts was done by comparison of the retention times and the elution profiles/degradate patterns of extracts with reference items in at least two different HPLC methods. Further information for the identification of degradates in the case of the benzoyl-label was obtained from GC-MS or LC-MS analyses. In addition, ¹⁴C-labelled reference items were combined with selected extracts for co-chromatography to identify the degradates unequivocally.

Following the spray application of cyflumetofen to soil at an application rate of 1×0.40 kg ai/ha, the total radioactive residues (TRR) were measured. They were significantly higher after application of the benzoyl-label compared to the butylphenyl-label for all rotational crop matrices, except for spring wheat grain for the plant back intervals of 120 and 365 days.

The residue concentrations in lettuce (immature and mature samples) did not exceed 0.057 mg eq/kg or 0.018 mg eq/kg for all plant back intervals for the benzoyl- and the butylphenyl-label, respectively.

The TRR in white radish root in the case of the benzoyl-label decreased from 0.027 to 0.008 mg eq/kg with increasing soil aging period, whereas in white radish top, the residue levels were slightly higher (decreasing from 0.137 to 0.036 mg eq/kg). In the case of the butylphenyl-label, all residue concentrations in white radish were below 0.010 mg eq/kg.

In spring wheat, the highest residue levels were measured in chaff (benzoyl-label, 30 PBI: 1.271 mg eq/kg), straw (benzoyl-label, 30 PBI: 0.484 mg eq/kg), straw + chaff (0.259 and 0.058 mg eq/kg for the benzoyl-label, 120 and 365 PBI; 0.027 to 0.107 mg eq/kg for the butylphenyl-label) and hay (decreasing from 0.636 to 0.053 mg eq/kg for the benzoyl-label and ranging from 0.016 to 0.086 mg eq/kg for the butylphenyl-label). The total radioactive residues in wheat forage decreased from 0.133 to 0.004 mg eq/kg in the case of the benzoyl-label and were around 0.010 mg eq/kg in the case of the butylphenyl-label. The total radioactive residues in wheat grain accounted for 0.021 to 0.166 mg eq/kg for the benzoyl-label and < 0.010 to 0.063 mg eq/kg for the butylphenyl-label.

The residue concentrations in the top soil layer after aging and ploughing stayed largely stable (plant back intervals 30, 120 and 365 PBI) for the benzoyl- (0.054 to 0.064 mg eq/kg) and butylphenyl-label (0.062 to 0.075 mg eq/kg). The residue levels in soil after harvest of the mature crops also remained more or less stable for both labels, ranging from 0.020 to 0.089 mg eq/kg (benzoyl-label) and from 0.033 to 0.090 mg eq/kg for the butylphenyl-label.

White radish (440 DAT)	0.035
Spring wheat (463 DAT)	0.066

The extractability of the radioactive residues with acetonitrile and water in the case of the benzoyl-label was equal to or above 75% of the TRR for all rotational crop matrices, except for wheat forage (365 PBI: 66.1% TRR) and wheat grain (30 and 365 PBI: 45.9% to 66.7% TRR). In the case of the butylphenyl-label, the extractability of the radioactive residues was notably lower, accounting for 57.9% TRR for immature lettuce (30 PBI), 35.8% to 65.7% TRR for wheat forage, hay and straw + chaff and 18.8% to 20.4% TRR for wheat grain. For both labels, the main portions of the radioactive residues were generally extracted with acetonitrile, except for spring wheat grain where only low portions were extracted with acetonitrile.

Liquid/liquid partition of the acetonitrile extracts of immature lettuce, spring wheat hay and spring wheat straw + chaff between ethyl acetate and water (performed in the case of the butylphenyl-label only) yielded the main portions of the residues (22.6% to 46.1% TRR) in the organosoluble fraction and minor portions (11.7% to 20.1% TRR) in the water phase.

In the case of the benzoyl-label, the radioactive residues in the extracts of all rotational crop matrices mainly consisted of a medium polar component which was identified as trifluoroacetic acid (38.6% to 105.3% TRR, ranging from 0.004 to 1.076 mg eq/kg). In addition, in spring wheat grain 30 PBI, the main degradate trifluoroacetic acid was accompanied by minor amounts of the degradate B-1 (< 0.001 mg eq/kg or 0.2% TRR in the acetonitrile extract) and a peak representing one or several non-polar components, possibly including the unchanged parent molecule (present in both extracts, 0.006 mg eq/kg or 4.1% TRR in sum). The degradates, trifluoroacetic acid and B-1, are only detectable with the benzoyl-label.

In the case of the butylphenyl-label, a series of label-specific degradates was observed in the samples prepared from the extracts, all in minor concentrations (each below 0.010 mg eq/kg, only one non-polar derivative in immature lettuce (30 PBI, 11.6% TRR) and one medium polar component in wheat hay (120 PBI, 10.2% TRR) were above 10% of the TRR. The main portion of the extracted and analysed radioactive residues in all matrices except wheat grain was composed of medium polar derivatives of cyflumetofen (up to 39.4% TRR in sum per matrix, up to twenty peaks per sample). These medium polar degradates eluted in the same range of polarity as the degradates in the goat urine sample, used as a reference item. Therefore, some of the medium polar degradates formed during metabolism of cyflumetofen in the lactating goat after hydrolytic cleavage of the parent molecule (e.g. hydroxylated derivatives of degradate A-2) or similar components may also be present in rotational crops. Besides the medium polar components, up to seven polar peaks were detected in the extractable radioactive residues (representing up to 14.9% TRR in sum per matrix), one non-polar derivative was found in immature lettuce (30 PBI, 11.6% TRR), and eleven non-polar peaks were observed in spring wheat straw and chaff (30 PBI, 6.8% TRR in sum). In the case of wheat grain (120 PBI), the radioactive residues in the water extract mainly consisted of polar components (4.8% TRR in sum), accompanied by minor amounts of medium polar components (0.5% TRR in sum). Since the absolute concentration of these minor degradates was < 0.01 mg eq/kg, no further characterization was deemed necessary.

The residual radioactive residues after solvent extraction of the matrices sampled after the plant back interval of 30 days ranged from a minimum of 11.0% TRR (white radish top) to a maximum of 54.1% TRR (spring wheat grain) for the benzoyl-label. Therefore, the residual radioactive residues from these matrices (30 PBI) were further characterized by treatment with an aqueous ammonia solution which solubilized portions of 1.5% to 2.4% TRR (except for wheat grain, where 15.1% TRR were solubilized). In the cases of spring wheat hay, straw, chaff and grain, the solubilisation with ammonia was followed by incubation with enzymes (macerozyme/cellulase and amylase/amyloglucosidase) and by homogenization or reflux with hydrochloric acid. The most effective solubilisation steps for most of the wheat matrices were the non-selective reflux with hydrochloric acid which released up to 7.3% TRR (spring wheat hay 30 PBI), followed by incubation with macerozyme/cellulase. In the case of wheat grain (30 PBI), treatment with macerozyme/cellulase solubilized 17.4% TRR, ammonia treatment released 15.1% TRR and incubation with amylases/amyloglucosidase was also quite effective and released 7.7% TRR. HPLC analysis of the ammonia solubilizate of wheat grain 30 DAT showed a degradate pattern similar to that of the water extract.

In the case of the butylphenyl-label, notable amounts of the radioactive residues of wheat hay, wheat straw + chaff and wheat grain (120 PBI and 365 PBI, 39.1% to 81.2% TRR) were not extracted with acetonitrile and water. The residual radioactive residues after solvent extraction of these matrices were therefore further characterized using a sequential solubilisation procedure including treatment with aqueous ammonia solution, macerozyme/cellulase and amylase/amyloglucosidase. The most effective solubilisation step was incubation with macerozyme/cellulase (releasing up to 20.4% TRR, wheat grain 365 PBI), except for wheat straw + chaff (365 PBI), where ammonia treatment was slightly more effective (solubilizing 6.5% TRR).

The solubilized residues had possibly been associated with or embedded/incorporated in insoluble plant material (e.g. proteins, cell wall polymers and starch).

With regard to the degradate patterns described above for the two labels, the degradation pathway of cyflumetofen in rotational crops can be proposed as follows: Hydrolytic cleavage of the parent molecule results in the formation of the degradate B-1, which is only detectable with the benzoyl-label, and one or several butylphenyl-label-specific intermediates which were not identified. The predominant degradate in the case of the benzoyl-label, Trifluoroacetic Acid, can be derived from the parent compound or the degradate B-1. The butylphenyl-label-specific cleavage products (such as the goat degradate A-2 which is formed by hydrolysis of the formic acid ester, decarboxylation and

hydrolytic detachment of the trifluoromethyl benzoyl moiety) are further transformed to a series of minor (< 0.01 mg eq/kg), mainly medium polar degradates.

Figure 3 Proposed metabolic pathway in rotational crops (lettuce, radish and wheat)

RESIDUE ANALYSIS

Analytical methods

The Meeting received descriptions and validation data (including concurrent recovery data) for analytical methods for residues of cyflumetofen and its metabolites.

Analytical methods for plant matrices

The descriptions of the analytical methods used in supervised residue trials and for enforcement are shown below.

Method D1003

Analyte: Cyflumetofen and metabolites B-1, AB-6 and AB-7

Matrix: Dry bean, dried grapes (raisins), orange (fruits, juice and oil), rice (grain, straw), soybean seed, tomato

LOQ: 0.01 mg/kg for each analyte in all matrices (defined as the lowest fortification level successfully tested)

Description: Crop materials Residues are extracted from plant matrices by shaking with acetonitrile followed by acetonitrile:water (75:25, v/v). An aliquot of the extract is centrifuged and, after removal of acetonitrile, acidified with formic acid. The residues are partitioned with a mixture of ethyl acetate: cyclohexane (75:25, v/v). An aliquot of the organic phase is concentrated in the presence of 0.1% aqueous formic acid, and re-dissolved in 0.1% formic acid in acetonitrile for determination with LC-MS/MS. Oil Residues are extracted from oil by shaking with a mixture of acetonitrile:water (75:25, v/v) and hexane. The hexane phase is removed and an aliquot of the aqueous acetonitrile phase is subjected to clean-up by partition with hexane or ethyl acetate:cyclohexane (75:25, v/v) followed by final determination as the above.

Juice Residues are extracted from juice by shaking with a mixture of acetonitrile:water (75:25, v/v). An aliquot of the aqueous acetonitrile extract is subject to clean-up and for final determination as the above.

LC-MS/MS condition

For data collection: Less concentrated final sample was used for analysis with highly sensitive LC-MS/MS instrument. From the acetonitrile extract of crop materials, acetonitrile is removed by concentration rather than centrifugation.

For enforcement: Larger amount of aliquot from the extract for sample clean-up to increase the residue concentration.

Reference: Carter *et al.*, 2011a

Validation of D1003 for data collection

Validation of Method D1003 for collecting data on the concentrations of the parent, B-1, AB-6 and AB-7 was conducted using the sample size of 0.1 g for crop materials, and 5 g for oil and orange juice.

^a Primary transition used for quantification:

Cyflumetofen: m/z 448.2 → 173.0 (ionization mode, positive)

B-1: m/z 189.1 → 69.0 (ionization mode, negative)

AB-6: m/z 466.4 → 173.0 (ionization mode, positive)

AB-7: m/z 448.2 → 344.2 (ionization mode, positive)

^b Secondary transition used for confirmation:

Cyflumetofen: m/z 448.2 → 145.1

B-1: m/z 189.1 → 145.1

AB-6: m/z 466.4 → 145.0

AB-7: m/z 448.2 → 372.2

The method showed good linearity in the range of 0.035–10.0 µg/kg. No known interference was observed from crop components or from reagents, solvents and glassware used, except in rice straw which may show matrix interference for the B-1 secondary ion. As the matrix interference residue was greater than 20% of the LOQ, alternative chromatography was developed for the secondary ion for validation of the method for this analyte.

The mean recoveries for all matrices tested and at all fortification levels ranged between 71 and 116% with relative standard deviations between 2 and 20%. However, some individual recovery values were higher than 120%.

Validation of Method D1003 for enforcement

Validation of Method D1003, as an enforcement method, was conducted using the sample size of 5 g for all matrices tested. In this validation, the parent compound and B-1 metabolite were determined.

		Overall	10	77–104	93	9	83–106	93	9
	B-1	0.01	6	79–116	90	16	79–118	92	16
		1.0	5	78–103	91	12	86–100	94	7
		Overall	10	78–116	90	14	79–118	93	12

^a Primary transition used for quantification:

Cyflumetofen: m/z 448.2 → 173.0 (ionization mode, positive)

B-1: m/z 189.1 → 69.0 (ionization mode, negative)

^b Secondary transition used for confirmation:

Cyflumetofen: m/z 448.2 → 145.1

B-1: m/z 189.1 → 145.1

The method showed good linearity in the range of 0.14–15.0 µg/kg. No known interference was observed from crop components or from reagents, solvents and glassware used, except in rice straw as described above.

The mean recoveries for all matrices tested and at all fortification levels ranged between 70 and 105%, within the acceptable range, with relative standard deviations between 3 and 19%. However, some individual analysis recoveries were slightly higher than 120% and some were lower than 70%.

Independent laboratory validation of Method D1003 (Marin, 2011a)

An independent laboratory validation of Method D1003 was conducted for the determination of cyflumetofen and metabolite B-1 in orange, wheat (grain and hay) and canola seed. Fortification levels used are 0.01 (LOQ) and 1.0 mg/kg.

Some modifications were made to the procedure of Method D1003 as follows:

Analyte: Cyflumetofen and metabolite B-1

LOQ: 0.01 mg/kg for each analyte in all matrices

Description: Residues are extracted from plant matrices by shaking with acetonitrile followed by acetonitrile:water (50:50, v/v) and centrifugation. An aliquot (2 mL) of the extract is transferred to a glass vessel containing aqueous formic acid. The extract is concentrated under a gentle flow of nitrogen and then partitioned with ethyl acetate: cyclohexane (75:25, v/v). After mixing, 2 g of sodium chloride is added and the mixture is partitioned for 5 minutes. After centrifugation, an aliquot (7 mL) of the extract is transferred to a glass tube containing 0.2 mL of aqueous formic acid. The extract is concentrated under a gentle flow of nitrogen and the volume is adjusted to 2.5 mL with acetonitrile containing formic acid. Residues are determined with LC-MS/MS.

Sample size used in this validation was 5 g.

Table 59 Recovery results obtained for the analysis of plant matrices with Method D1003 in independent laboratory validation

^a Primary transition used for quantification:

Cyflumetofen: m/z 448.2 → 173.0 (ionization mode, positive)

B-1: m/z 189.1 $\rightarrow$ 69.0 (ionization mode, negative)

^b Secondary transition used for confirmation:

Cyflumetofen: m/z 448.2 $\rightarrow$ 145.0

B-1: m/z 189.1 $\rightarrow$ 145.0

^c Analysed by modified method.

The method showed good linearity in the range of 0.35–10.0 $\mu\text{g/kg}$. No known interference was observed from crop components or from reagents, solvents and glassware used, except in wheat hay.

The mean recoveries for all matrices tested and at all fortification levels ranged between 71 and 97%, within the acceptable range, with relative standard deviations between 1 and 19% with the exceptions of B-1 in wheat hay in which even the mean recoveries at 0.01 and 1 mg/kg were lower than 70%. Some individual analysis recoveries for matrices tested were lower than 70%.

Analytical methods for animal matrices

The descriptions of the analytical methods related to the current review are shown below.

All of these methods showed good linearity with a correlation coefficient ≥ 0.99 . There were no interferences at the analyte concentration higher than 30% of LOQ. Additional information on method performance is described later.

Method D1202

Analyte: Cyflumetofen and Metabolite B-1

Matrix: Bovine liver, meat and milk; and poultry eggs

LOQ: 0.001 mg/kg for each analyte in bovine milk; and 0.01 mg/kg for each analyte in other matrices.

Description: Bovine Liver and Poultry Eggs: Residues are extracted 5 g of sample by shaking with acetonitrile followed by acetonitrile-water (50:50, v/v). A salt mixture of magnesium sulfate (400 mg), sodium chloride (100 mg), sodium citrate sesquihydrate (50 mg), and sodium citrate dihydrate (100 mg) is added to an aliquot of the sample vortexed and centrifuged. The process is repeated with another salt mixture of magnesium sulfate (75 mg) and CUPSA (12.5 mg). An aliquot of the extract is concentrated to remove the acetonitrile to the aqueous phase in the presence of 20% formic acid in water. The extract is re-acidified and saturated with sodium chloride and partitioned with a mixture of ethyl acetate-cyclohexane (75:25, v/v). An aliquot of the organic phase is concentrated in the presence of 0.1% formic acid in water, and re-dissolved in 0.1% formic acid in acetonitrile for LC-MS/MS determination.

Bovine Meat: Residues are extracted from 5 g of sample by shaking with acetonitrile followed by acetonitrile-water (50:50, v/v). An aliquot of the extract is concentrated to remove the acetonitrile to the aqueous phase in the presence of 0.1% formic acid in water. The extract is saturated with sodium chloride and partitioned with a mixture of ethyl acetate-cyclohexane (75:25, v/v). An aliquot of the organic phase is concentrated in the presence of 0.1% formic acid in water, and re-dissolved in 0.1% formic acid in acetonitrile for LC-MS/MS determination.

Bovine Milk: Residues are extracted from 5 g or mL of sample by shaking with acetonitrile. An aliquot of the extract is concentrated to remove the acetonitrile to the aqueous phase in the presence of 20% formic acid in water. The extract is saturated with sodium chloride and partitioned with a mixture of ethyl acetate-cyclohexane (75:25, v/v). Aliquots of the organic phase are concentrated in the presence of 0.1% formic acid in water, and re-dissolved in 0.1% formic acid in acetonitrile. A salt mixture of magnesium sulfate (400 mg), sodium chloride (100 mg), sodium citrate sesquihydrate (50 mg), and sodium citrate dihydrate (100 mg) is added and vortexed and centrifuged. Another salt mixture of magnesium sulfate (75 mg) and CUPSA

(12.5 mg) mixture is then added and vortexed and centrifuged. An aliquot is taken for LC-MS/MS determination.

^a Primary transition used for quantification:

Cyflumetofen: m/z 448.2 → 173.2 (ionization mode, positive)

B-1: m/z 189.0 → 69.1 (ionization mode, negative)

^b Secondary transition used for confirmation:

Cyflumetofen: m/z 448.2 → 145.1

B-1: m/z 189.1 → 145.1

^c Results obtained using matrix matched standards.

The method showed good linearity in the range of 0.20–10.0 µg/kg. No known interference was observed from animal components or from reagents, solvents and glassware used.

The mean recoveries for bovine matrices tested and at all fortification levels ranged between 77 and 115% with RSDs between 3 and 19%. The mean recoveries of the parent in poultry eggs ranged between 65–67% with the standard deviations between 3–6% while those for B-1 ranged between 86–95% with the standard deviations between 3–8%.

Stability of pesticide residues in stored analytical samples

The Meeting received information on freezer storage stability of cyflumetofen and three of its metabolites, B-1, AB-6 and AB-7 in various plant matrices, such as orange (fruit, juice and oil), apple (fruit and juice), leaf lettuce, kidney bean (dry), radish root, wheat grain and almond nutmeat (Gorden, 2011a and 2013a).

Homogenized samples (5 g) of each matrix were fortified separately with standard solutions containing Cyflumetofen and metabolites B-1, or AB-6 or AB-7 at a level of 0.1 mg/kg for each analyte and stored at –20 to –10 °C for up to 743–910 days (24–30 months).

After each specified period, a portion of sample was analysed with Method D1003 with the LOQ at 0.01 mg/kg. At the same time, a sample was freshly spiked at 0.1 mg/kg and analysed for concurrent procedural recovery.

Table 61 summarizes the storage periods, mean percent remaining and mean concurrent recovery at each time point.

Table 61 Stability of cyflumetofen and its metabolites B-1, AB-6 and AB-7 in frozen plant matrices fortified at 0.1 mg/kg

The results of the storage stability showed high uncertainty associated with the analytical method used.

Cyflumetofen was stable (> 70% remaining) when stored frozen at the temperature of –20– –10 °C for the longest time tested (24 or 25 months) in almond, apple fruit, apple juice, orange fruit, orange juice, orange oil and wheat grain. However, it showed stability only up to 9 months in lettuce and 3 months in radish root.

Metabolite B-1 was stable frozen up to: 30 months, the longest time tested, in almond, kidney bean, lettuce, orange fruit, orange juice and wheat grain, 22 months in apple fruit and apple juice, and 6 months in orange oil.

Metabolite AB-7 was stable frozen up to: the longest period tested (26 months) in almond, apple fruit, apple juice, kidney bean, orange juice, and orange oil, 19 months in orange fruit and wheat grain, 12 months in lettuce, and 1 month in radish root.

Cyflumetofen is used either alone or in combination with other active substances and provides knock-down and residual control of tetranychid mites shown in the following table. It is highly active contact miticides on egg, nymph and adult stage of these mites.

<i>Bryobia rubrioculus</i>	<i>Panonychus ulmi</i>
<i>Eotetranychus willamettei</i>	<i>Petrobia lateens</i>
<i>Eotetranychus yumensis</i>	<i>Tetranychus cinnabarinus</i>
<i>Eutetranychus banksi</i>	<i>Tetranychus mcdanieli</i>
<i>Oligonychus pratensis</i>	<i>Tetranychus pacificus</i>
<i>Oligonychus ununguis</i>	<i>Tetranychus turkestani</i>
<i>Panonychus citri</i>	<i>Tetranychus urticae</i>

For the current review, a US label was provided which indicates that thorough and uniform spray coverage of foliage, with direct contact to target pest, is required for effective control and therefore sufficient volume of water is necessary to ensure thorough coverage of foliage.

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received residue data from supervised field trials conducted on citrus fruits (orange in Brazil and the USA, grapefruit and lemon in the USA), pome fruits (apple in Italy and the USA and pear in the USA); grapes (in the USA); strawberry (in the USA); fruiting vegetables, other than Cucurbits (tomato in the USA and eggplant in Japan; and tree nuts (in the USA).

Application rates and residue concentrations were reported as Cyflumetofen. Residue concentrations are recorded unadjusted for recoveries or for residue values in control samples. Where multiple samples were taken from a single plot, individual results are reported, and the calculated mean concentration is put in parentheses and used for estimation of maximum residue level. Where trials were conducted in the same location, with the same or similar varieties, same or similar formulations, and same equipment, and at the same or similar timing, they are not regarded as independent and only one result from these trials was chosen for the estimation of a maximum residue level. All the trials, except those on eggplant in Japan, were conducted outdoor using 20% SC formulations except one trial conducted in Italy on apple (25% SC). Residue concentrations are expressed in parent equivalents.

Residues from the trials conducted according to maximum GAP have been used for the estimation of maximum residue levels and they are underlined.

The results of supervised trials are summarized in the following tables:

Crop group	Commodities	Table no
Citrus fruits	Orange, grapefruit, lemon	Table 64
Pome fruits	Apple, pear	Table 65
Berries and other small fruits	Grapes	Table 66
	Strawberry	Table 67
Fructing vegetables, other than Cucurbits	Tomato	Table 68
	Eggplant	Table 69
Tree nuts	Almond, pecan	Table 70
By-products, used for animal feeding purposes, derived from fruits and vegetable processing	Almond hulls	Table 71

Citrus fruits (orange, grapefruit and lemon)

During the growing season of 2009 and 2010, 23 supervised residue trials were conducted on citrus fruits (orange, grapefruit and lemon) in Arizona (one trial), California (eight trials), Florida (12 trials) and Texas (two trials) in the USA. Three (two in CA and one in FL) of these trials were decline trials. At each test location, one untreated and one treated plot were established. The treated plot received two broadcast foliar applications of cyflumetofen (20% SC formulation) each at 0.193–0.207 kg ai/ha, with a 14-day (+/- one day) re-treatment interval (RTI), except one trial that had a 12-day RTI. The applications were made with ground equipment using 280–2818 L/ha of water. Commercially mature fruits of orange, grapefruit or lemon were collected 7 days after treatment (DAT). In the three decline trials, citrus samples were collected 0, 1, 3, 7, 14 and 21 DAT.

All samples were analysed for residues of cyflumetofen and its metabolites B-1, AB-6 and AB-7 using Method D1003 (with modifications), which quantifies residues by LC-MS/MS. Mean recoveries for all analytes were within the acceptable range of 70–120%. A recovery of 66% was obtained for B-1 on lemon fortified at the 0.01 mg/kg level. Several recovery values exceeded 120%. The LOD and LOQ for all analytes were 0.002 and 0.01 mg/kg, respectively. For B-1, when its concentration is expressed in parent equivalents, the LOQ will be 0.02 mg/kg.

In Brazil, during the growing season of 2007, four trials were conducted on oranges to determine the magnitude of the residues of cyflumetofen after treatment with 20% SC formulation of cyflumetofen. The formulation was applied two times at an application rate of 0.160 kg ai/ha and a spray volume of 2000 L/ha. In two of the four trials, the samples were taken immediately after the last application, 1, 7, 14 and 21. In the other two trials the samples were collected 7 days after the last application.

The residues of cyflumetofen were determined by LC-MS/MS. The LOQ was 0.05 mg/kg. The mean recoveries at 0.05 mg/kg spiked level were within the acceptable range of 70–120%.

Table 64 Results of supervised residue trials on citrus fruits (orange, grapefruit and lemon) conducted in Brazil and the USA.

^a Metabolite residues expressed in parent equivalents.

n.r. = Not reported

Pome fruits (apple and pear)

During the years 2009 and 2010, 12 trials were conducted on apple in the USA (two trials in New York, one in Pennsylvania, one in Georgia, two in Wisconsin, one in Utah, one in California, two in Idaho, one in Oregon and one in Washington). At each test location, two broadcast foliar applications of 200 g/L SC formulation of cyflumetofen were made to apple trees, at a target application rate of 0.200 kg ai/ha, with a 13–15 day retreatment interval. The applications were made to plots at each site using either concentrate (478–857 L/ha of water, Treatment 2) or dilute (1129–2274 L/ha of water, Treatment 3) spray volumes with ground equipment (airblast sprayers). At each location, apple samples (fruit, one sample per untreated plot and duplicate samples per treated plot) were harvested at a 6 to 7 day preharvest interval (PHI). At one trial in New York (trial no. R090479) treated samples were collected at 1, 3, 8, 10, and 15 days after the last application, to evaluate residue decline. The residues of cyflumetofen and metabolites B-1, AB-6 and AB-7 were quantitated by Method D1003 (LC-MS/MS). Acceptable concurrent recovery data were obtained for each analyte. The LOQ was 0.01 mg/kg for each analyte. Apparent residues of cyflumetofen, B 1, AB 6 and AB 7 were < LOQ in/on all untreated samples.

During the growing season 2006, one trial was conducted in Italy in which apple trees were treated with two applications of 250 g/L SC formulation of cyflumetofen at either 0.1 kg ai/ha, 0.2 kg ai/ha, 0.3 kg ai/ha or 0.4 kg ai/ha, diluted with water immediately prior to application to a good coverage spray volume. Samples of apple fruit from the untreated and treated plots were taken immediately after the last application, 3, 7, 14 and 21 days after last application. The LOQ for cyflumetofen in apple was set at 0.05 mg/kg. Procedural recoveries run currently with test specimen at levels of 0.05 mg/kg and 5.0 mg/kg gave an overall mean recovery of 93% and 85% respectively.

During the years 2009 and 2010, five trials were conducted on pear in the USA (one trial in New York, one in California, one in Oregon and two in Washington). At each test location, two broadcast foliar applications of 200 g/L SC formulation of cyflumetofen were made to pear trees, at a target application rate of 0.200 kg as/ha, with a 13–15 day retreatment interval. The applications were made to plots at each site using either concentrate (565–831 L/ha of water) or dilute (1111–1996 L/ha of water) spray volumes with ground equipment (airblast sprayers). At each location, pear samples

(fruit, one sample per untreated plot and duplicate samples per treated plot) were harvested at a 7 to 8 day pre-harvest interval (PHI). At one trial in Washington, treated samples were collected at 1, 3, 7, 10, and 14 days after the last application, to evaluate residue decline. The residues of cyflumetofen and metabolites B-I, AB-6 and AB-7 were quantitated using Method D1003. Acceptable concurrent recovery data were obtained for each analyte. The LOQ was 0.01 mg/kg for each analyte. Apparent residues of cyflumetofen, B 1, AB 6 and AB 7 were < LOQ in/on all untreated pear samples.

n.r.= Not reported

*Berries and Other Small Fruits**Grapes*

During the 2009 growing season, a total of 12 trials were conducted on grapes in the USA (two trials in New York, eight in California, one in Washington, and one in Oregon. One in California was a decline trial. In all trials, two broadcast foliar applications of 200 g/L SC formulation of cyflumetofen at 0.193–0.206 kg ai/ha were made with a 14–15 re-treatment interval. The applications were made with ground equipment using either a dilute or concentrated spray volume. Grape Samples were collected at 14 DAT. In the decline trial, the samples were collected at 0, 3, 7, 14, 21 and 28 DAT.

Samples of grape were analysed for residues of cyflumetofen and metabolites B-1, AB-6 and AB-7 using Method D1003. Acceptable concurrent recovery data for grape commodities between 69% and 111% were obtained for each analyte. The LOQ was 0.01 mg/kg for each analyte.

Strawberry

During the growing season 2009–2010, a total of eight field trials on strawberries were conducted in the USA (one trial in New York, one in Georgia, one in Florida one in Wisconsin, three in California, and one in Oregon). Each trial location consisted of one untreated and one treated plot. Each treated plot received two broadcast foliar applications of 200 g/L SC formulation of Cyflumetofen at 0.196–0.206 kg ai/ha, with a retreatment interval targeting 14 ± 1 days. The actual retreatment interval was 13–15 days, with the exception of one site in California (trial no. R090501) where a 7 day retreatment interval was used. The applications were made using ground equipment in 225–460 L/ha of water spray volumes. Strawberry samples were harvested at a 1-day preharvest interval (PHI). At one trial in California (trial no. R090502), additional treated samples were collected at 0, 3, 7 and 10 days after the last application, in addition to the targeted 1-day PHI, to evaluate residue decline.

Samples of strawberry were analysed for residues of cyflumetofen and metabolites B-1, AB-6 and AB-7 using Method D1003. Acceptable concurrent recovery data for strawberry commodities were obtained for each analyte. The LOQ was 0.01 mg/kg for each analyte. Apparent residues of cyflumetofen, B-1, AB-6 and AB-7 were < LOQ in/on all samples of untreated strawberries.

Fruiting vegetables, other than Cucurbits (Tomato, eggplant)

During the growing season 2009–2010, a total of 16 field trials were conducted on tomatoes in the USA (one trial in New York, one in Georgia, two in Florida, one in Kansas, 10 in California and one in Arizona). Two of these trials were decline trials (one trial in NY and the other in CA). At each test location, one untreated and one treated plot were established. The treated plot received two broadcast foliar applications of 200 g/L CS formulation of cyflumetofen at 0.196–0.211 kg ai/ha/application, with a 14-day (+/– one day) re-treatment interval. The applications were made with ground equipment using 115–472 L/ha of water. Commercially mature, tomato samples were collected 3 days after treatment (DAT).

All samples were analysed for residues of cyflumetofen, and its metabolites, B-1, AB-6, and AB-7, using Method D1003. Mean recoveries for all analytes were within the acceptable range of 70–120%. Three individual recoveries were in the range of 65–69%. The LOD and LOQ for all analytes were 0.002 and 0.01 mg/kg, respectively.

During the growing season 2004, two trials were conducted on eggplants in greenhouses in Japan to determine the magnitude of the residues of cyflumetofen after treatment with 20% SC formulation of cyflumetofen. The formulation was applied two times at an application rate of 0.400 kg ai/ha and a spray volume of 2000 L/ha. The samples were taken at 1, 3, 7 and 21 days after the last application. The residues of cyflumetofen were determined by LC-UV detection. The LOQ was 0.05 mg/kg.

Tree nuts (Almond and pecan)

During the growing season 2009, five trials were conducted on almonds in California in the USA. Each trial consisted of one untreated control and one treated plot except for sites that where both dilute and concentrate applications in which case there were two treated plots and one non-treated plot. For the concentrate plots, the treated plot received two air-blast foliar broadcast applications of 200 g/L SC formulation of cyflumetofen at 0.195–0.202 kg ai/ha, with a 14 day re-treatment interval. The applications were made with ground equipment using 469–656 L/ha of water. For the dilute plots, the treated plot received two airblast foliar broadcast applications of 200 g/L SC formulation of cyflumetofen at 0.197–0.200 kg ai/ha/, with a 13–14 day re-treatment interval. The applications were made with ground equipment using 1219–1875 L/ha of water. Almond samples were harvested 7 days after the last application for all trials except the decline trial (R090478). For the decline trial, samples were collected 0, 1, 3, 7, 14, and 21 days after the last application.

All samples were analysed for residues of cyflumetofen, and its metabolites, B-1, AB-6, and AB-7, using Method D1003. Mean recoveries for all analytes were within the acceptable range of 70–120%. The LOD and LOQ for all analytes were 0.002 and 0.01 mg/kg, respectively.

During the growing season 2009, five trials were conducted on pecans in the USA (two trials in Georgia, one in Louisiana, one in Texas and one in Oklahoma). Each trial consisted of one untreated control and one treated plot except for sites that where both dilute and concentrate applications in which case there were two treated plots and one non-treated plot. For the concentrate plots, the treated plot received two air-blast foliar broadcast applications of 200 g/L SC formulation of cyflumetofen at 0.195–0.204 kg ai/ha, with a 13–14 day re-treatment interval. The applications were made with ground equipment using 540–794 L/ha of water. For the dilute plots, the treated plot received two airblast foliar broadcast applications of 200 g/L SC formulation of Cyflumetofen at 0.198–0.205 kg ai/ha, with a 13–14 day re-treatment interval. The applications were made with ground equipment using 1104–2376 L/ha of water. Pecan samples were harvested 7 or 8 days after the last application.

All samples were analysed for residues of cyflumetofen, and its metabolites, B-1, AB-6, and AB-7, using Method D1003. Mean recoveries for all analytes were within the acceptable range of 70–120%. The LOD and LOQ for all analytes were 0.002 and 0.01 mg/kg, respectively.

FATE OF RESIDUES IN STORAGE AND PROCESSING

In processing

The Meeting received information on the fate of residues of Cyflumetofen during hydrolysis and processing of oranges, apples, grapes and tomato reflecting the relevant processing procedures and household preparations.

Hydrolysis (Hassing, J, 2013a)

To simulate the degradation of cyflumetofen during pasteurization, hydrolysis of cyflumetofen was tested using benzoyl-ring-U-¹⁴C labelled and t-butylpheny-ring-U-¹⁴C labelled cyflumetofen in aqueous buffer solutions at pH 4, 5 and 6 under reflux at 90 °C for 20 min. Due to the rapid degradation of cyflumetofen under the light, each test procedure was done in the dark.

Also for simulating baking, brewing and boiling, the test was conducted similarly but under reflux at 100 °C for 60 minutes. For sterilization, the test was conducted at about 120 °C in an autoclave for 20 minutes.

Aliquots were taken right before starting a test and at the end of the test for LSC-measurements after cooling of the solution. Additionally, aliquots for HPLC-analysis were taken before and at the end of a test. Because of the photolytic and hydrolytic instability of the test item and its metabolites, no work-up for an eventual confirmation by MS-analysis could be performed. Direct MS-analysis was not possible due to the low concentration of the test item especially metabolites in the samples.

The following table demonstrates the results of hydrolysis tests using the radioactive Cyflumetofen labelled at different positions.

Table 72 Effect of hydrolysis on Cyflumetofen simulating pasteurization, baking, brewing and boiling, and sterilization

Simulated process	Hydrolysis condition			% TAR				
	pH	Temp °C	Time, min	Parent	B-1	AB-1	Others	Sum
[Benzoyl-ring-U- ¹⁴ C]-cyflumetofen								
Pasteurization	4	90	20	70.9	23.2	4.2	nd	98.3
Baking, brewing and boiling	5	100	60	17.9	58.7	31.7	nd	108.2
Sterilization	6	120	20	Nd	75.3	38.8	1.0	115.1
Simulated process	Hydrolysis condition			% TAR				
	pH	Temp °C	Time, min	Parent	A-2	AB-1	Others	Sum
[t-Butylphenyl-ring-U- ¹⁴ C]-cyflumetofen								
Pasteurization	4	90	20	69.3	14.3	Nd	15.4	99.1
Baking, brewing and boiling	5	100	60	5.0	52.9	39.9	4.3	102.2
Sterilization	6	120	20	Nd	44.4	49.1	1.8	95.2

nd =not detected

No loss of radioactivity of the both radio-labelled cyflumetofen occurred during heating in buffers of pH 4, 5 and 9 at 90–120 °C for 20 min or 60 min.

At the pH 4/90 °C condition, benzoyl-ring labelled cyflumetofen was degraded to 70.9% after 20 min. The major degradate was metabolite B-1 (23.2% TAR) followed by AB-1 (4.2% TAR). At the pH 5/100 °C condition, benzoyl-ring labelled cyflumetofen was degraded to 17.9% after 20 min. The major metabolites were B-1 (58.7% TAR) and AB-1 (31.7% TAR). At the pH 6/120 °C condition, benzoyl-ring labelled cyflumetofen was completely degraded to B-1 (75.3% TAR) and AB-1 (38.8% TAR) after 60 min.

At pH 4/90 °C, t-butylphenyl-ring labelled cyflumetofen was degraded to 68.3% TAR. The main metabolite was A-2 (14.3% TAR) with no other metabolite no more than 5% TAR. At pH 5/100 °C, t-butylphenyl-ring labelled cyflumetofen was degraded to 5.0%. The main metabolites were A-2 (52.9% TAR) and AB-1 (39.9% TAR). At pH 6/120 °C, t-butylphenyl-ring labelled cyflumetofen was completely degraded to A-2 (44.4% TAR) and AB-1 (49.1% TAR).

These results indicate that the higher the temperature of heating, the more cyflumetofen degrades and heating splits the Cyflumetofen into t-butylphenyl ring and benzoyl ring.

Oranges (Hattermann & Cowen, 2011c)

In two trials conducted in Florida and California in the USA during the 2009 growing season, 200 g/L SC formulation of cyflumetofen was applied as two foliar broadcast sprays to oranges at a target rate of 1.0 kg ai/ha (5 times GAP rate), with a 14-day re-treatment interval. The actual rate in the trials was 1.00 to 1.02 kg ai/ha, with a 14–15-day re-treatment interval. One trial had the application made in a concentrated spray volume and one in a dilute spray volume of 703 and 2457 L/ha of water,

respectively, using ground equipment. Orange samples were harvested 7 days after the last application and sent for processing into processed commodities.

Two bulk samples were sent for processing, one treated and one untreated. These bulk orange samples were separately processed (untreated first) using simulated commercial processing procedures for citrus production to generate the required fractions of unwashed fruit, peel, wet pomace, dried pulp, meal, molasses, marmalade, fresh juice and citrus oil with slight variation to the commercial methodology.

The residues of cyflumetofen, B-1, AB-6, and AB-7 in orange processed commodity samples were quantitated using Method D1003. Acceptable concurrent recovery data for orange commodities were obtained for each analyte. The LOQ was 0.01 mg/kg each for parent and the metabolites B-1, AB-6, and AB-7 in/on processed orange samples. The LOD was set at 20% of the LOQ, or 0.002 mg/kg each for parent cyflumetofen and the metabolites B-1, AB-6, and AB-7. The residue levels detected in the treated specimens and processed fractions as well as the calculated processing factors are presented in the following tables. The concentrations of metabolites were expressed in cyflumetofen equivalents.

	Molasses	0.055	< 0.02
	Marmalade	0.057	< 0.02

^a Expressed in cyflumetofen equivalents.

^b As the concentration of B-1 is sometimes higher than that of the parent, for the calculation of sum and processing factor, the LOQ value was used when the concentration is below the LOQ.

The results from these trials show that after two applications of cyflumetofen at 5× the maximum GAP rate, residues of cyflumetofen or its metabolites (B-1, AB-6 and AB-7) in the treated bulk orange RAC samples ranged from 0.013 to 0.664 mg/kg. Residues of cyflumetofen and its metabolites in processed commodities wet pomace, peel, dried pulp, juice, oil, meal, molasses and marmalade ranged from < 0.01 mg/kg (LOQ) to 2.675 mg/kg in all matrices but oil. The residues in oil from the CA test site ranged from 0.600 mg/kg for metabolite AB-6 to 90.716 mg/kg for cyflumetofen.

A comparison of the total residues of cyflumetofen and all three metabolites combined in the processed RAC with those in each of the processed matrix samples showed that the total residue concentrated in peel and oil only (2.2× to 2.7× and 64× to 123×, respectively). Residue in all the other processed matrices did not concentrate and was diluted to concentrations less than the RAC samples collected before processing.

Apples (White, 2011b)

In two trials conducted in NY and PA during the 2009 growing season, 200 g/L SC formulation of cyflumetofen was applied as two airblast foliar sprays to apples at a rate of 0.996–1.027 kg ai/ha (5× the maximum GAP rate), with a 14 day retreatment interval. The first application was made approximately 3 weeks (21 days) prior to the harvest of fruit, when fruit were ripening (growth stage BBCH 79 to BBCH 81). The applications were made in 606–872 L/ha of water using ground equipment. Apple bulk RAC samples were harvested 7 days after the last application. The two bulk apple RAC samples were separately processed using simulated commercial processing procedures into wet pomace and juice. In addition, apple sauce, canned apples, and dried apples were collected for analysis.

The residues of cyflumetofen and metabolites B-1, AB-6 and AB-7 in apple RAC and processed commodity samples were quantitated using Method D1003. Acceptable concurrent recovery data for apple commodities were obtained for each analyte. The LOQ was 0.01 mg/kg for each analyte. Apparent residues of cyflumetofen, B-1, AB-6 and AB-7 were < LOQ in/on all untreated apple RAC and processed commodities.

^a Expressed in cyflumetofen equivalents.

^b As the concentration of B-1 is sometimes higher than that of the parent, for the calculation of sum and processing factor, the LOQ value was used when the concentration is below the LOQ.

The results from these trials show that after two applications of cyflumetofen targeting 2.0 kg as/ha/season, mean parent cyflumetofen residues in the treated apple RAC samples collected 7 days after the last application were 0.58 mg/kg and 0.45 mg/kg. For the individual analytes, expressed in parent equivalents, residues of the metabolites B-1, AB-6, and AB-7 were < 0.02 mg/kg, 0.01 mg/kg, and 0.01 mg/kg, respectively, in the treated apple RAC samples collected 7 days after the last application.

A comparison of the residues in the RAC with those in each processed fraction indicate that parent cyflumetofen residues concentrate in apple sauce (2.5–2.9×, average processing factor 2.7×), but do not concentrate appreciably in any other apple processed commodities, wet pomace, juice, dried apples, or canned apples.

Grapes (Hattermann & Lott, 2011b)

In four trials conducted in NY, CA and OR during the 2009 growing season, 200 g/L SC formulation of cyflumetofen was applied as two foliar broadcast sprays to grape at a target rate of 1.0 kg ai/ha (5× the maximum GAP rate), with a 14-day re-treatment interval (13-day interval at one CA site). The actual application rates were 1.99 to 2.02 kg ai/ha. The applications were made in 465–2600 L/ha of water using ground equipment. Two trials had product applied in a dilute application (935.4–3741.6 L/ha) and two in a concentrate spray volume (187.1–935.4 L/ha range). Grape samples were harvested 14 days after the last application except for one CA trial which was harvested at 15-day after the final application. One treated and one non-treated bulk sample was processed for each of four trials. Dried grapes, dried grape stems, juice, wine (young), wet pomace, must, yeast and grape stems were collected for analysis. The study was planned to include two trials, each performed on red and white grape varieties. However, an exception to protocol occurred when a white grape variety was used at the King County, CA trial instead of red. The white grapes from this trial were processed using the red grape procedure for wine, such that there were two trials processed with red and two with white grape procedures.

The residues of cyflumetofen, B-1, AB-6, and AB-7 in grape RAC and processed commodity samples were quantitated using Method D1003. Acceptable concurrent recovery data for grape commodities were obtained for each analyte. The LOQ was 0.01 mg/kg each for parent cyflumetofen and the metabolites B-1, AB-6, and AB-7 in/on grape RAC and processed commodity samples. The

LOD was set at 20% of the LOQ, or 0.002 mg/kg each for parent cyflumetofen and the metabolites B-1, AB-6 and AB-7.

^a Expressed in cyflumetofen equivalents.

^b As the concentration of B-1 is sometimes higher than that of the parent, for the calculation of sum and processing factor, the LOQ value was used when the concentration is below the LOQ.

The results from these trials show that after two applications of cyflumetofen, targeting 1.0 kg ai/ha per application, residues of cyflumetofen, B-1, AB-6 or AB-7 (expressed in parent equivalents) in the treated grape RAC samples (whole fruit) collected 14–15 days after the last application ranged from < 0.01–1.71 mg/kg for cyflumetofen or its metabolites.

RAC grape samples showed measurable levels of parent cyflumetofen and the three metabolites. A comparison of the residues in the treated grape RAC samples with those in each processed fraction indicated that combined residues of cyflumetofen and its metabolites concentrated in dried grape at 2.37 and 4.62× at the OR and NY test sites, respectively, and in dried grape stem (6.63–17.6×), wet pomace (1.10–3.91×), yeast (1.43–8.99×), and grape stems (1.08–3.11×) at all four test sites. The compound did not concentrate in any of the other processed grape matrices and was actually diluted in these matrices (i.e. concentration factors less than or equal to 1×).

Tomato (Crawford, 2011b)

In two trials conducted in NY and CA during the 2009 growing season, 200 g/L SC formulation of cyflumetofen was applied as two foliar broadcast sprays to tomato at a rate of 1.00–1.01 kg ai/ha, with a 14-day retreatment interval, resulting in a total exaggerated rate (5×) of 2.01–2.02 kg ai/ha. The applications were made in 187–360 L/ha using ground equipment, and an adjuvant was added to the spray mixture for all applications. Tomato samples were harvested 3 days after the last application. A total of two separate treated bulk samples were processed for a total of two processing tests. The treated bulk tomato RAC samples were separately processed using simulated commercial processing procedures into paste and puree. In addition, canned tomatoes, peeled tomatoes, tomato juice, tomato peels, wash water, washed tomatoes, and wet pomace were collected for analysis.

The residues of cyflumetofen and metabolites B-1, AB-6, and AB-7 in tomato processed commodity samples were quantitated using Method D1003. Acceptable concurrent recovery data for tomato commodities were obtained for each analyte. The LOQ was 0.01 mg/kg each for parent and the metabolites B-1, AB-6, and AB-7 in/on tomato processed commodity samples. The LOD was set at 20% of the LOQ, or 0.002 mg/kg each for parent cyflumetofen and the metabolites B-1, AB-6, and AB-7.

^a Expressed in cyflumetofen equivalents.

^b As the concentration of B-1 is sometimes higher than that of the parent, for the calculation of sum and processing factor, the LOQ value was used when the concentration is below the LOQ.

The results from these trials show that after two applications of cyflumetofen targeting 1.0 kg ai/ha to each field trial to obtain 5× the maximum GAP per-season rate of 0.400 kg ai/ha, residues of cyflumetofen (metabolites B-1, AB-6 and AB-7 expressed in parent equivalents) in the treated tomato RAC samples (whole fruit) sampled 3 days PHI were < LOQ to 0.24 mg/kg. For the processed commodity samples, parent residues in the treated fractions from fruit sampled 3 days PHI were < LOQ to 4.05 mg/kg; residues of the metabolites B-1, AB-6, and AB-7 ranged from < LOQ to 1.46 mg/kg.

A comparison of the residues in the RAC tomato with those in each processed fraction indicated that combined residues of cyflumetofen concentrated in wash water (1.9×) at the New York site only and in paste (1.2 to 2.1×), wet pomace (1.3 to 4.2×) and tomato peel (8.1 to 15.0×) at both test sites. The compound did not concentrate in any other processed tomato fractions.

RESIDUES IN ANIMAL COMMODITIES

Farm animal feeding studies

No information on farm animal feeding studies were received by the current Meeting.

APPRAISAL

Cyflumetofen (consisting of RS isomers) is a bridged diphenyl acaricide (miticide) for control of *Tetranychus* sp. and influences the mitochondrial electron transport chain by inhibiting the complex II substance in the cell. It has been registered in a number of countries.

The Meeting received information on physical and chemical properties, animal and plant metabolism, environmental fate, analytical methods, storage stability, use patterns, supervised trials, and processing. Cyflumetofen was scheduled by the Forty-fifth Session of the CCPR for review by the 2014 JMPR for the first time.

In this Appraisal, the following abbreviated names were used for referred metabolites.

Code (MW)	IUPAC name	Structure	Metabolite or degradate found in
Cyflumetofen (447.45)	2-methoxyethyl (RS)-2-(4-tert-butylphenyl)-2-cyano-3-oxo-3-(α,α,α -trifluoro- <i>o</i> -tolyl)propionate		Goat Satsuma mandarin Apple Eggplant
B-1 (190.12)	2-(trifluoromethyl)benzoic acid		Rat

			Goat Satsuma mandarin Apple Eggplant Soil
AB-1 (345.36) Syn: M9210I003	(RS)-2-(4-tert-butylphenyl)-3-oxo-3-[2-(trifluoromethyl)phenyl]propanenitrile		Rat Goat Hydrolysis in buffer Hydrolysis simulating processing Soil
AB-6 (465.45)	2-methoxyethyl-2-((R,S)-4-tert-butylphenyl)-3-oxo-3-({[2-(trifluoromethyl)phenyl]carbonyl}amino)propanoate		Satsuma mandarin Apple Eggplant
AB-7 (447.45)	2-methoxyethyl-((R,S)-4-tert-butyl-2-{{[2-(trifluoromethyl)phenyl]carbonyl}phenyl}(cyano)acetate		Satsuma mandarin Apple Eggplant
A-2 (173.26) Syn: M9210I001	4-tert-butylphenyl-acetonitrile		Goat Soil
A-12 (178.23) Syn: M9210I002	4-tert-butylbenzoic acid		Goat Soil

Animal metabolism

The Meeting received information on the fate of orally-dosed cyflumetofen in lactating goats.

In metabolism studies, total radioactive residues are expressed in mg eq./kg cyflumetofen equivalents unless otherwise stated.

Metabolism of cyflumetofen in rat

Metabolism studies on laboratory animals including rats were reviewed in the framework of toxicological evaluation by the current JMPR.

In a rat metabolism study, highest residues were found in the liver followed by kidney regardless of sex, dose and label position and time point of measurement. Cyflumetofen was extensively metabolized. B-1, 2-trifluoromethylbenzoic acid, was the major metabolite (occurring up to 28% of the applied dose). The predominant metabolic pathway for cyflumetofen involves cleavage of the tert-butylphenyl and trifluorotolyl moieties. Major reactions on the tert-butylphenyl ring are cleavage of the methoxyethyl group, hydroxylation at the butyl group, decarboxylation and glucuronidation at the butyl group. Major reactions on the trifluorotolyl-ring are glutathione conjugation at the carboxyl group and further changes of the glutathione group to mercapturic acid or thiolactic acid. In addition, hydroxylation and oxidation reactions at the butyl group and cleavage of the carboxylic ester moiety are observed on the parent molecule.

Metabolism of cyflumetofen in lactating goat

Two lactating goats were orally administered [benzoyl-ring- U - ^{14}C]-cyflumetofen (hereafter abbreviated as benzoyl-label) for 12 consecutive days at 0.43 or 0.48 mg/kg bw (13 or 12 ppm in feed). Other two goats were orally administered [t-butylphenyl-ring- U - ^{14}C]-cyflumetofen (hereafter abbreviated as butylphenyl-label) for 10 consecutive days at 0.27 or 0.30 mg/kg bw (15 or 12 ppm in feed). The goats were sacrificed 18–24 hours after the last dose.

After radio-labelled cyflumetofen was administered orally to lactating goats, it was excreted in faeces and urine (total > 78% excreted during the testing periods) and only a small portion accounting for < 0.3% of the administered radioactivity (AR) remained in body tissues/organs. Radioactive residues were the highest in liver (0.29–0.40 mg eq./kg) followed by kidney (0.17–0.19 mg eq./kg) but low in fat (0.028–0.033 mg eq./kg) and muscle (0.009–0.020 mg eq./kg). Milk of each day contained $\leq 0.02\%$ AR and milk collected throughout the study period contained, in total, 0.008–0.19 mg eq./kg (0.03–0.14% AR).

The parent compound, cyflumetofen, was found only in fat but at low concentration of 0.003 mg/kg accounting for 20–21% of the total radioactive residues (TRR). The predominant metabolite in all tissues/organs and milk was B-1 at around 0.1 mg eq./kg in liver (32% TRR) and kidney (54% TRR), and lower than 0.01 mg eq./kg in muscle (46–51% TRR), fat (21–40% TRR) and milk (4.5% TRR).

The metabolism of cyflumetofen in goat involves extensive hydrolysis of formic acid ester and trifluoromethylbenzoyl moiety, decarboxylation, conjugation, hydroxylation and oxidation. In principle, excretion and distribution of cyflumetofen and its metabolism in goat are similar to those in rats with some differences in metabolites identified.

Plant metabolism

Satsuma mandarin

When Satsuma mandarin trees (grown outdoor) were sprayed with benzoyl- or butylphenyl-label cyflumetofen at a rate approximating 0.60 kg ai/ha (3 $\times$ GAP rate of the USA), and Satsuma mandarin fruit samples were collected 1, 7 and 30 days after the treatment, the majority of the radioactivity was recovered from the acetonitrile surface rinse of fruits: 95–96% TRR on 1DAT; 91–93% TRR on 7DAT; and 88–89% on 30 DAT.

The predominant radioactive residue on/in mandarin fruits was cyflumetofen at 0.52–0.55 mg/kg (88–90% TRR) on 1DAT, decreasing to 0.33–0.37 mg/kg (79–83% TRR) on 7 DAT and further to 0.25–0.31 mg/kg (44–54% TRR) on 30 DAT.

Other than the parent, metabolites AB-6, AB-7, A-12 and B-1 were formed. B-1 increased over time from 0.028 mg eq./kg (4.7% TRR) on 1 DAT to 0.064 mg eq./kg (11% TRR) on 30 DAT. None of AB-6, AB-7 and A-12 exceeded 10% TRR. A number of unknown peaks were observed but none of them exceeded 10% of TRR.

The radioactive residues on/in leaves showed similar profile as those on/in fruits with the majority (>87% TRR) of radioactive residues found in the surface rinse, although the TRR was >50

times that on/in fruits. A majority of radioactive residues remaining in leaves were extracted. Cyflumetofen was also the predominant identified fraction in leaves: >73% TRR in rinse and extract together. Four metabolites were identified but none exceeded 10% TRR.

Apple

When an apple tree (grown outdoor) was sprayed with benzoyl- or butylphenyl-label cyflumetofen at a rate approximating 0.60 kg ai/ha (3X GAP rate of the USA), and apple fruit samples were collected 1, 7 and 30 days after the treatment, the majority of the radioactivity was recovered from the acetonitrile surface rinse of fruits: 95–96% TRR on 1 DAT, 82–89% TRR on 7 DAT; and 67–71% TRR on 30 DAT.

The predominant radioactive residue on/in apple fruits was cyflumetofen at 0.061–0.066 mg/kg (58–61% TRR) in rinse while pulp extract contained too little radioactivity for further analysis on 1DAT, 0.061–0.14 mg/kg (78–84% TRR) on 7 DAT and decreased to 0.037–0.042 mg/kg (53–65% TRR) on 30 DAT.

There were minor metabolites identified. However, none of them exceeded 5% TRR.

The radioactive residues on/in leaves showed similar profile as those on/in fruits with the majority (>72% TRR) of radioactive residues found in the surface rinse, although the TRR was >50 times that on/in fruits. Cyflumetofen was also the predominant identified fraction in leaves: >44% TRR in rinse and extract together. No metabolites exceeded 10% TRR.

Eggplant

When eggplants (grown outdoor) were sprayed with benzoyl- or butylphenyl-label cyflumetofen at a rate approximating 0.60 kg ai/ha (3X GAP rate of the USA), and eggplant samples were collected 1, 7 and 14 days after the treatment, the majority of the radioactivity was also recovered from the acetonitrile surface rinse of fruits: 87–92% TRR on 1 DAT, 79–86% TRR on 7 DAT; and 56–81% TRR on 30 DAT.

The predominant radioactive residue on/in eggplant fruits was also cyflumetofen accounting for 0.31–0.44 mg/kg (91–95% TRR) on 1 DAT, decreased to 0.25–0.39 mg/kg (67–71% TRR) on 7 DAT and then to 0.18–0.20 mg/kg (42–62% TRR) on 14 DAT.

Metabolites B-1, AB-6 and AB-7 were identified from the fruit rinse and/or extracts. B-1 was found at 0.059 mg eq./kg (11% TRR) on 7 DAT and at 0.061 mg eq./kg (15% TRR) on 14 DAT on/in fruits. AB-6 and AB-7 did not exceed 10% TRR.

The tentatively identified U1/U2 (likely to be acid labile conjugates of B-1) and U4 were also found in 7 DAT and 14 DAT fruits but not in 1 DAT fruits. U1 was present at 0.067 mg eq./kg (16% TRR) on 14 DAT but <10% TRR on 1 DAT and 7 DAT. No other metabolites exceeded 10% TRR. U1 and U2 were found only in the fruit extracts but not in rinse, indicating that they were formed in the fruits.

The radioactive residues on/in leaves showed similar profile as those on/in fruits with the majority (>69% TRR) of radioactive residues found in the surface rinse, although the TRR was >50 times that on/in fruits. Cyflumetofen was also the predominant identified fraction in leaves: >47% TRR in rinse and extract together. No metabolites exceeded 10% TRR.

Summary of plant metabolism

The metabolism of cyflumetofen in these crops involves hydrolysis, acyl migration, oxidation and conjugation (U1 and U2 are the conjugate of B-1).

The plant metabolism studies on Satsuma mandarin, apple and eggplant showed similar pattern. Applied radioactively was mostly recovered from surface rinse with decreasing trend over time. Fruit flesh contained far less radioactivity. The predominant radioactive residue was cyflumetofen accounting for >42% TRR at all time points. The next important radioactive residue was

B-1 but at the maximum 15% TRR (around 0.06 mg eq./kg). B-1 may be present in fruits in conjugated forms.

Environmental fate

Aerobic soil metabolism

The studies on aerobic soil degradation of cyflumetofen indicate that cyflumetofen sprayed on soil was rapidly and completely degraded with DT50 around 1.8–4.3 days in various soils at 20–25°C. Additionally, aerobic soil degradation of B-1 and AB-1 was studied resulting in DT50 of 6–36 days and 0.07–0.11 days respectively at 20°C.

Photolysis on soil surface

Photolysis of cyflumetofen on soil was found to be insignificant as the degradation rates of cyflumetofen with and without light irradiation were not significantly different.

Hydrolysis in aquatic system

Cyflumetofen is susceptible to hydrolysis and was hydrolysed faster at higher pH in aqueous buffer solutions at 25°C. DT50 was calculated using first order kinetics to be 7.7 days at pH 4, 6.0 days at pH 5, 9.8 h at pH 7 and 10.3 min at pH 9.

At slightly acidic to neutral pH, a number of degradates exceeded 10% of the applied dose: A-1 (max. 14% at 8 h), A-2 (max. 44% at 720 h), A-18 (max. 36% at 120 h), B-1 (max. 53% at 48 h) and AB-1 (max. 45%, at 120 h).

Residues in succeeding crops

A confined rotational crop study was conducted to examine the nature and level of residues of cyflumetofen in three succeeding crops (white radish, lettuce and wheat) using benzoyl- and butylphenyl-label cyflumetofen. A single application of radio-labelled cyflumetofen was made on bare soil in plastic containers at a rate of 0.40 kg ai/ha (2x GAP rate of the USA). After plant back interval (PBI) of 30, 120 and 365 days, lettuce, white radish and spring wheat were sown into the treated soil.

Following the application of cyflumetofen to soil, uptake of radioactivity from soil into rotational crops was observed, in particular, with benzoyl-label (up to 1.25 mg eq./kg in wheat chaff of 30 PBI but much lower in edible portions with the maximum of 0.17 mg eq./kg in wheat grain of 30 PBI). With butylphenyl-label, uptake of radioactivity into rotational crops were lower (maximum of 0.11 mg eq./kg in wheat straw+chaff of 120 PBI). Uptake was, in general, less with longer plant back interval.

The only major radioactive residue identified from benzoyl-label treatment was trifluoroacetic acid in all crops (39–100% TRR). B-1, specific to this label, was detected as a minor component.

With the butylphenyl-label, a series of label-specific metabolites were observed in the extracts but all of them were less than 0.01 mg eq./kg.

No parent compound was detected from any of the crop extracts.

No significant residues of cyflumetofen, other than trifluoroacetic acid, were expected to be found in rotational crops on the basis of aerobic soil degradation studies and confined succeeding crop study.

Methods of analysis

Analytical methods for determination of residues of cyflumetofen and its metabolites B-1, AB-6 and AB-7 were developed for a wide range of matrices of plant and animal origin.

In general, the method for data generation and enforcement for plant matrices employ extraction by shaking with acetonitrile and then a mixture of acetonitrile:water (75:25, v/v) or only with acetonitrile:water, clean-up by partitioning with a mixture of ethyl acetate:cyclohexane (75:25, v/v) and determination of the analytes using LC-MS/MS.

The method for plant matrices was validated for cyflumetofen, B-1, AB-6 and AB-7 resulting in acceptable recoveries and relative standard deviations (RSDs) with the LOQ of 0.01 mg/kg for various plant matrices.

The analytical method developed for cyflumetofen and B-1 in animal matrices was similar to the one for plant matrices but employs acetonitrile:water (50:50, v/v) for extraction instead of acetonitrile:water (75:25, v/v) and different clean-up procedure. This method was validated for cyflumetofen and B-1 resulting in acceptable recoveries and RSDs with the LOQ of 0.01 mg/kg for bovine liver, and meat and 0.001 mg/kg for bovine milk. The mean recoveries for cyflumetofen in poultry eggs were low at 65–67% (RSD, 3–6%) while those for B-1 were acceptable between 86–95%.

A number of scientific papers report the validation of the QuEChERS multi-residue method with GC-MS/MS for cyflumetofen in various plant commodities with the LOQ around 0.01 mg/kg.

Stability of pesticide residues in stored analytical samples

The stability of cyflumetofen, B-1, AB-6 and AB-7 in homogenates of almond, apple (fruit, juice) kidney bean, lettuce, orange (fruit, juice, oil), radish and wheat grain at -20 to -10 °C was tested at a spike level (each analyte separately spiked) of 0.1 mg/kg for 743–910 days (24–30 months).

Cyflumetofen was stable when stored frozen for 25 months, the longest storage time tested, in almond, apple fruit, apple juice, orange fruit (24 months), orange juice, orange oil and wheat grain. However, it was stable only up to 9 months in kidney bean and lettuce, and 3 months in radish root.

B-1 was stable when stored frozen for 30 months, the longest storage time tested, in almond, kidney bean, lettuce, orange fruit, orange juice and wheat grain. It was stable up to 22 months in apple fruit, apple juice and radish root, and 6 months in orange oil.

AB-6 was stable when stored frozen for 28 months, the longest storage time tested, in almond, apple fruit, kidney bean, orange juice, orange oil, radish root, and wheat grain. It was stable up to 21 months in apple juice, lettuce and orange fruit.

AB-7 was stable when stored frozen for 26 months, the longest storage time tested, in almond, apple fruit, apple juice, kidney bean, orange juice, and orange oil. It is stable up to 19 months in orange fruit and wheat grain, 12 months in lettuce, but one month in radish root.

Definition of the residue

In goat metabolism studies, radioactive residues were highest in liver followed by kidney. Far less radioactive residues were found in fat, muscle and milk.

When benzoyl-label cyflumetofen was administered, metabolite B-1 (2-trifluoromethylbenzoic acid) was the predominant residue in all edible tissues/organs (21–54% TRR) and milk (4.5% TRR). B-1 was also found in rat metabolism and is considered to be no more toxic than the parent and, therefore, toxicologically covered by the ADI for parent compound. Cyflumetofen was detected only in fat at 0.003 mg/kg (20% TRR). No other metabolites were detected above 10% TRR.

When butylphenyl-label cyflumetofen was administered, cyflumetofen was not detected in any of edible tissues/organs or in milk. None of all the identified metabolites exceeded 0.01 mg eq./kg and 10% TRR.

There is a validated LC-MS/MS method for cyflumetofen and B-1 in bovine matrices. The Meeting considered that both cyflumetofen and B-1 were suitable residues for enforcement of MRLs and for estimating dietary intake.

LogP_{ow} of cyflumetofen is 4.3 at 25 °C and cyflumetofen was found only in the fat at < 0.01 mg/kg in the goat metabolism study. B-1 is a carboxylic acid and was present at 0.13 mg eq./kg in liver and 0.10 mg eq./kg in kidney but < 0.01 mg eq./kg in fat. The Meeting considered that, over all, residues (cyflumetofen and B-1) were not fat soluble.

In the plant metabolism studies on Satsuma mandarin, apple and eggplant, cyflumetofen was the predominant residue and accounted for > 42% TRR in the fruits of these crops at any time points. The Meeting considered that for enforcement of MRLs, cyflumetofen was a suitable residue.

The next important radioactive residue was B-1 but at the maximum 15% TRR (around 0.06 mg eq./kg). In the supervised residue trials, the concentrations of B-1 were mostly 1/10–1/2 of those of cyflumetofen. Conjugated forms of B-1 (U1 and U2) were found in the eggplant metabolism at slightly higher concentrations (in total) than B-1 itself but they were not found in the studies on Satsuma mandarin or apple. A validated LC-MS/MS method is available and used in the trials for quantification of cyflumetofen and B-1 but it determines the free form of B-1.

The Meeting considered that, for calculating dietary intake from commodities of plant origin, cyflumetofen and B-1 were suitable residues.

Based on the above, the Meeting recommended the following residue definition for plant and animal commodities:

Definition of the residue for plant commodities (for compliance with the MRL): *Cyflumetofen*.

Definition of the residue for plant commodities (for estimation of dietary intake): *Sum of cyflumetofen and 2-trifluoromethylbenzoic acid, expressed as cyflumetofen*.

Definition of the residue for animal commodities (for compliance with the MRL and estimation of dietary intake): *Sum of cyflumetofen and 2-trifluoromethylbenzoic acid, expressed as cyflumetofen*.

Residue is not fat-soluble.

Results of supervised residue trials on crops

The Meeting received supervised trial data for cyflumetofen on citrus fruits, pome fruits, grapes, strawberry, tomato, eggplant and tree nuts conducted outdoor (except trials on eggplant in Japan) using foliar spray of 20% SC formulation of cyflumetofen (except in a trial on apple in Italy).

Residues were expressed in cyflumetofen equivalents. The analytical results for B-1 were converted to cyflumetofen equivalents by multiplying the analytical results for B-1 with a factor of 2.35 based on the molecular weights of cyflumetofen (447.45) and B-1 (190.12).

For the estimation of a sum of cyflumetofen and B-1, where B-1 was below the LOQ, it was regarded as 0.02 mg eq./kg (LOQ of 0.01 mg/kg for B-1 is converted to 0.02 mg eq./kg) as B-1 was sometimes present at concentrations comparable to those of parent in trials.

Although in a number of trials conducted in the USA the water volume was smaller than the minimum water volume on the label, the Meeting agreed to use the results of these trials in estimating maximum residue levels as the purpose of the minimum requirement was for better efficacy and not for safety, and residues from lower water volume trials were not always lower than those from higher water volume trials.

Citrus fruits

A total of 23 supervised trials were conducted on orange (12), grapefruit (6) and lemon (5) in the USA in 2009 and 2010. GAP in the USA for citrus fruits allows 2 applications at a maximum rate of 0.2 kg ai/ha (at least 935 L/ha) with a PHI of 7 days.

Residues of cyflumetofen from 11 independent orange trials matching GAP for citrus fruits in the USA were: 0.01, 0.01, 0.04, 0.06, 0.06, 0.08, 0.09, 0.10, 0.10, 0.11 and 0.12 mg/kg (median 0.08 mg/kg).

The information on four trials conducted on orange in Brazil in 2007 was also provided but they did not match the GAP in Brazil (one application at a spray concentration of 0.08 kg ai/hL).

Residues of cyflumetofen from six grapefruit trials matching GAP for citrus fruits in the USA were: < 0.01, 0.02, 0.04, 0.04, 0.04 and 0.07 mg/kg (median 0.04 mg/kg).

Residues of cyflumetofen from five lemon trials matching GAP for citrus fruits in the USA were: < 0.01, 0.02, 0.02, 0.08 and 0.14 mg/kg (median 0.02 mg/kg).

As the GAP in the USA is established for the group of citrus fruits, the median values from the trials conducted in the USA on these three commodities were not different more than 5-fold, and Kruskal-Wallis test indicated that the residues of orange, grapefruits and lemon were not statistically different, the Meeting decided to estimate a group maximum residue level. The residues of orange, grapefruits and lemon were combined for estimating a maximum residue level for estimating a maximum residue level for citrus fruits (n=22): < 0.01, < 0.01, 0.01, 0.01, 0.02, 0.02, 0.02, 0.04, 0.04, 0.04, 0.04, 0.06, 0.06, 0.07, 0.08, 0.08, 0.09, 0.10, 0.10, 0.11, 0.12 and 0.14 mg/kg.

The Meeting estimated a maximum residue level of 0.3 mg/kg for citrus fruit.

For the estimation of STMR, the sum of cyflumetofen and B-1 was calculated: < 0.03, < 0.03, 0.03, 0.03, 0.04, 0.04, 0.04, 0.06, 0.06, 0.06, 0.06, 0.08, 0.08, 0.09, 0.10, 0.10, 0.11, 0.12, 0.12, 0.13, 0.14 and 0.16 mg eq./kg.

The Meeting estimated an STMR of 0.07 mg/kg expressed as cyflumetofen.

Pome fruits

A total of 17 supervised trials were conducted in the USA in 2009 and 2010 on apples (12) and pear (5). One trial was conducted in Italy in 2006 on apples. The GAP in the USA for pome fruits allows 2 applications at a maximum rate of 0.2 kg ai/ha (at least 935 L/ha) with a PHI of 7 days.

The trial from Italy was provided but did not match any GAP and was not considered.

Residues from 12 apple trials matching US GAP were: 0.01, 0.04, 0.06, 0.07, 0.09, 0.10, 0.13, 0.14, 0.16, 0.18, 0.19 and 0.24 mg/kg (median 0.115 mg/kg).

Residues from five pear trials matching US GAP were: 0.06, 0.08, 0.12, 0.12 and 0.20 mg/kg (median 0.12 mg/kg).

As the GAP in the USA is established for the group of pome fruits, and the median values from the trials conducted in the USA on the two commodities did not differ by more than 5-fold, the Meeting decided to estimate a group maximum residue level.

Man-Whitney test indicated that the residues from apple trials and those from pear trials were not statistically different. The Meeting decided to combine the data for estimating a maximum residue level. Residues were (n=17): 0.01, 0.04, 0.06, 0.06, 0.07, 0.08, 0.09, 0.10, 0.12, 0.12, 0.13, 0.14, 0.16, 0.18, 0.19, 0.20 and 0.24 mg/kg.

The Meeting estimated a maximum residue level of 0.4 mg/kg for pome fruits.

The sum of cyflumetofen and B-1 was calculated: 0.03, 0.06, 0.08, 0.08, 0.09, 0.10, 0.11, 0.12, 0.14, 0.14, 0.15, 0.16, 0.18, 0.20, 0.21, 0.22 and 0.26 mg eq./kg.

The Meeting estimated an STMR of 0.14 mg/kg expressed as cyflumetofen.

*Berries and Other Small Fruits**Grapes*

A total of 12 supervised trials were conducted on grapes in the USA in 2009. The GAP in the USA for grapes allows 2 applications at a maximum rate of 0.2 kg ai/ha (at least 468 L/ha) with a PHI of 14 days.

Residues from 11 independent trials matching US GAP were: 0.02, 0.09, 0.10, 0.12, 0.15, 0.16, 0.19, 0.22, 0.22, 0.27 and 0.42 mg/kg.

The Meeting estimated a maximum residue level of 0.6 mg/kg for grapes.

The sum of cyflumetofen and B-1 was calculated: 0.04, 0.12, 0.12, 0.16, 0.20, 0.22, 0.23, 0.25, 0.25, 0.33 and 0.46 mg eq./kg.

The Meeting estimated an STMR of 0.22 mg/kg expressed as cyflumetofen.

Strawberry

A total of eight supervised trials were conducted on strawberry in the USA in 2009 and 2010. The GAP in the USA for strawberry allows 2 applications at a maximum rate of 0.2 kg ai/ha (at least 468 L/ha) with a PHI of 1 day.

Residues from eight trials matching US GAP were: 0.04, 0.10, 0.14, 0.14, 0.16, 0.20, 0.23 and 0.36 mg/kg.

The Meeting estimated a maximum residue level of 0.6 mg/kg for strawberry.

The sum of cyflumetofen and B-1 was calculated: 0.06, 0.13, 0.16, 0.16, 0.20, 0.24, 0.28 and 0.40 mg eq./kg.

The Meeting estimated an STMR of 0.18 mg/kg expressed as cyflumetofen.

*Fruiting Vegetables, Other Than Cucurbits**Tomato*

A total of 16 supervised trials were conducted on tomato in the USA in 2009 and 2010. The GAP in the USA for tomato allows 2 applications at a maximum rate of 0.2 kg ai/ha (at least 468 L/ha) with a PHI of 3 days.

Residues from 14 independent trials matching US GAP were: 0.01, 0.02, 0.02, 0.04, 0.04, 0.04, 0.04, 0.06, 0.06, 0.06, 0.07, 0.09, 0.12 and 0.15 mg/kg.

The Meeting estimated a maximum residue level of 0.3 mg/kg for tomato.

The sum of cyflumetofen and B-1 was calculated: 0.03, 0.04, 0.06, 0.06, 0.06, 0.06, 0.06, 0.08, 0.08, 0.09, 0.10, 0.11, 0.17 and 0.18 mg eq./kg.

The Meeting estimated an STMR of 0.07 mg/kg expressed as cyflumetofen.

Eggplant

Two supervised trials were conducted on eggplant, green house grown, in Japan in 2004 with the analysis of cyflumetofen and the conjugates of B-1. The current GAP of Japan allows 2 applications at a spray concentration of 0.02 kg ai/hL with a PHI of 1 day. A spray volume of 1000–3500 L can be sprayed per ha. In the trials, spray concentration was 0.02 kg ai/hL and spray volume was 1996 L/ha, matching Japanese GAP. Residues from these trials were: 0.34 and 0.46 mg/kg.

The Meeting concluded that the data were insufficient for estimating a maximum residue level for eggplant.

Tree nuts

Five trials were conducted on almonds and five other trials were conducted on pecans in the USA in 2009. The GAP in the USA for tree nuts allows 2 application at a maximum rate of 0.2 kg ai/ha (in at least 935 L/ha) with a PHI of 7 days.

Residues in almond nutmeat from five trials matching US GAP were: < 0.01 (5) mg/kg.

Residues in pecan nutmeat from five trials matching US GAP were: < 0.01 (5) mg/kg.

As the GAP in the USA is established for the group of tree nuts and as the residues were all < 0.01 mg/kg, the Meeting agreed to estimate a maximum residue level for the tree nuts group at 0.01* mg/kg.

As the B-1 was also below the LOQ in all the trials, and the nutmeat is protected by the hull and not exposed to cyflumetofen foliar spray, the Meeting estimated an STMR to be 0.01 mg/kg expressed as cyflumetofen.

Animal feeds*Almond hulls*

Five trials were conducted on almond in the USA in 2009. The GAP in the USA allows 2 application at a maximum rate of 0.2 kg ai/ha (in at least 935 L/ha) with a PHI of 7 days.

Residues in almond hull from five trials matching US GAP were: 0.35, 0.53, 0.56, 0.86 and 1.87 mg/kg.

The Meeting estimated a maximum residue level of 4 mg/kg.

The sum of cyflumetofen and B-1 was calculated: 0.38, 0.63, 0.67, 0.98 and 2.11 mg/kg. The Meeting estimated a median residue of 0.67 mg/kg.

Fate of residues during processing*High temperature hydrolysis*

To simulate the degradation of cyflumetofen during pasteurization, baking, brewing, boiling and sterilization, the hydrolysis of radio-labelled cyflumetofen was investigated in sterile buffered aqueous solutions.

After incubation at 90 °C (pH 4) for 20 minutes, 100 °C (pH 5) for 60 minutes or 120 °C (pH 6) for 20 minutes, no loss of radioactivity occurred. After heating at 90 °C for 20 minutes, about 69–71% of cyflumetofen remained with 14–23% of the applied radioactivity degraded to B-1. At 100 °C for 60 minutes, only 5–18% of cyflumetofen remained with the formation of B-1 (53–59% AR) and AB-1 (32–40% AR). At 120 °C, cyflumetofen was completely hydrolysed with the formation of B-1 (44–75% AR) and AB-1 (39–49% AR). Cyflumetofen was susceptible to hydrolysis at high temperature.

Processing

The Meeting received information on processing of orange, apple, grape and tomato.

Processing factors calculated for the processed commodities of the above raw agricultural commodities are shown in the table below. STMR-Ps were calculated for processed commodities of orange, apple and grape for which maximum residue levels were estimated.

Processed Orange Product	Cyflumetofen		Cyflumetofen and B-1*		STMR-P or median
	Processing factor	Best estimate	Processing factor	Best estimate	
Orange					0.07
Juice	< 0.02, < 0.08	0.05	< 0.04, < 0.022	0.031	0.0022
Oil	102, 137	120	88.0, 133	111	7.77

Processed Orange Product	Cyflumetofen		Cyflumetofen and B-1*		STMR-P or median
	Processing factor	Best estimate	Processing factor	Best estimate	
Marmalade	0.026, < 0.08	0.026	0.059, < 0.22	0.14	0.0098

* expressed as cyflumetofen.

As the residue concentration is higher in orange oil than in fresh orange, the Meeting estimated a maximum residue level of 36 mg/kg for citrus oil by multiplying the maximum residue level of citrus fruits (0.3 mg/kg) by 120.

As the residue concentration is higher in dried grapes than in fresh grapes, the Meeting estimated a maximum residue level of 1.5 mg/kg by multiplying the maximum residue level for grapes (0.6 mg/kg) by 2.0.

In processing of foods, heating in aquatic system at high temperature may be employed, and therefore it is likely that AB-1 is present at significant concentrations after processing at slightly acidic to neutral pH (≥ 5). It may also occur from cyflumetofen during the storage of processed foods with high water content at room temperature. However, the Meeting concluded that AB-1 is covered by the ADI for the parent compound.

Residues in animal commodities

Estimation of dietary burden

The maximum and mean dietary burdens were calculated using the median residues of cyflumetofen (sum of cyflumetofen and B-1 expressed as cyflumetofen, to cover the worst case) estimated at the current Meeting on a basis of the OECD Animal Feeding Table.

Summary of livestock dietary burdens (ppm of dry matter diet)

	US-Canada		EU		Australia		Japan	
	Max	Mean	max	Mean	Max	Mean	Max	mean
Beef cattle	0.007	0.007	0.090	0.090	0.934 ^a	0.934 ^b	0	0
Dairy cattle	0.119	0.119	0.052	0.052	0.934 ^a	0.934 ^b	0	0
Broilers	0	0	0	0	0	0	0	0
Layers	0	0	0	0	0	0	0	0

^a Suitable for estimating maximum residue levels for milk, meat, fat and edible offal of cattle.

^b Suitable for estimating STMRs for milk, meat, fat and edible offal of cattle.

Residues in milk and cattle tissues

In the goat metabolism studies, in which goats were administered benzoyl-label cyflumetofen at a dose equivalent to 12.8 ppm in feed for 12 consecutive days and sacrificed one day later, cyflumetofen was found only in fat at 0.003 mg/kg. B-1 were found in liver, kidney, muscle, fat and milk at 0.125, 0.102, 0.005, 0.006 and 0.001 mg eq./kg respectively. The sum of cyflumetofen and B-1 in fat is 0.009 mg/kg as cyflumetofen. Neither cyflumetofen nor metabolites were found above 0.01 mg/kg or 10% TRR when butylphenyl-label cyflumetofen was administered to goats.

These concentrations were multiplied by 0.934/12.8 for estimating STMRs. The Meeting estimated STMRs of 0.010, 0.008, 0, 0 and 0 mg/kg for liver, kidney, meat, fat and milk, respectively.

The Meeting estimated maximum residue levels of 0.02, 0.01*, 0.01* and 0.01* mg/kg expressed as cyflumetofen for edible offal (mammalian), meat (from mammals other than marine mammals), mammalian fats (except milk fat) and milks, respectively.

The dietary burden for poultry was calculated to be 0 ppm of dry matter diet. No metabolism or feeding studies on laying hens were conducted.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of the residue for plant commodities (for compliance with the MRL): *Cyflumetofen*.

Definition of the residue for plant commodities (for estimation of dietary intake): *Sum of cyflumetofen and 2-trifluoromethylbenzoic acid, expressed as cyflumetofen*.

Definition of the residue for animal commodities (for compliance with the MRL and estimation of dietary intake): *Sum of cyflumetofen and 2-trifluoromethylbenzoic acid, expressed as cyflumetofen*.

Residue is not fat-soluble.

Expressed on an “as received” basis.

^a Sum of cyflumetofen and B-1 expressed as cyflumetofen.

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Dietary Intakes (IEDIs) of cyflumetofen were calculated for the 17 GEMS/Food cluster diets using STMRs estimated by the current Meeting (Annex 3 of the 2014 Report). The ADI is 0–0.1 mg/kg bw and the calculated IEDIs were 0–1% of the maximum ADI. The Meeting concluded that the long-term intake of residues of cyflumetofen resulting from the uses considered by the current JMPR is unlikely to present a public health concern.

Short-term intake

The 2014 JMPR decided that an ARfD was unnecessary. The Meeting therefore concluded that the short-term intake of residues of cyflumetofen is unlikely to present a public health concern.

DICHLOBENIL (274)*see also FLUOPICOLIDE (235)**First draft prepared by Dr Samuel Margerison, Australian Pesticides and Veterinary Medicines Authority, Canberra, Australia***EXPLANATION**

Dichlobenil is a herbicide belonging to the benzonitrile group of chemicals. It is a systemic herbicide, which acts by inhibition of cell wall (cellulose) biosynthesis, thereby inhibiting actively dividing meristems, germination of seeds, and damaging rhizomes. It is used for control of annual and perennial weeds, principally in orchard crops.

At the Forty-fifth session of the CCPR (2013), dichlobenil was scheduled for evaluation as a new compound by the 2014 JMPR.

The Meeting received information on identity and physical and chemical properties, animal and plant metabolism, environmental fate in soil and water, rotational cropping, analytical methods, storage stability, use patterns, supervised residue trials, fate of residues on processing, and animal feeding studies.

IDENTITY

Common name:	Dichlobenil
Chemical names	
IUPAC:	2,6-Dichlorobenzonitrile
CAS:	2,6-Dichlorobenzonitrile
CAS number:	1194-65-6
Synonyms:	Casoron
Structural formula:	

Molecular formula:	C ₇ H ₃ Cl ₂ N
Molecular weight:	172.0

SPECIFICATIONS

Specifications for dichlobenil have not been published by FAO.

PHYSICAL AND CHEMICAL PROPERTIES

Table 1a Physical and chemical properties of dichlobenil

Appearance	Off-white crystalline solid (technical material)
Melting point	143.8–144.3 °C (technical material)
Boiling point	270 °C (101.3 kPa)
Relative density	1.55
Water solubility	25 mg/L (25 °C)

Solubility in organic solvents	Acetone: 86 g/L (20 °C) Cyclohexane: 3.7 g/L (25 °C) Methanol: 17.2 g/L (20 °C) Dichloromethane: 151 g/L (20 °C) Ethyl acetate: 59.3 g/L (20 °C) Xylene: 53 g/L (25 °C)
Hydrolysis	Stable in pH 5, 7 and 9 unsterilized buffers at 22 ± 1 °C, with half-life >150 days (Buisman, 1988)
Aqueous photolysis (sterile pH 7 buffer in sealed ampoules at 25 ± 1 °C)	10 days under spring/summer sunlight at 40°N latitude. Metabolites included 4-chloro-2(3H)benzoxazolone, 2,6-dichlorobenzoic acid, 2,6-dichlorobenzamide, 2-hydroxybenzonitrile, 2,6-dichloro-4-hydroxybenzonitrile, 2-chlorobenzonitrile and various small polar molecules (Boelhouwers <i>et al.</i> , 1989)
Vapour pressure	0.14 Pa (25 °C)
Octanol/water partition coefficient ($\log_{10}P_{OW}$)	2.70 (pH 3, 22 °C)
pH	6.7
Stability	Stable for 3 months at 54 °C
Explosive characteristics	Not explosive
Corrosive characteristics	Not corrosive

Table 1b Physico-chemical properties of 2,6-dichlorobenzamide

Appearance	Crystalline solid
Melting point	195–203 °C
Boiling point	335 °C (estimated)
Density	1.44 g/cm ³
Water solubility	2.7 g/L (20–25 °C)
Vapour pressure	$0.35\text{--}4.35 \times 10^{-3}$ Pa at 25 °C (various estimated values)
Octanol/water partition coefficient ($\log_{10}P_{OW}$)	0.77 (Nakagawa <i>et al.</i> , 1992)
Hydrolysis (5.19–5.26 mg/L ¹⁴ C-(U-phenyl) label in pH 5, 7, and 9 buffers at 25 ± 2 °C in the dark)	No degradation over 33 days (Nag, 2000)
Aqueous photolysis (¹⁴ C-1-phenyl) label in sterile pH 5 buffer at 25 °C irradiated with 40.3°N summer sunlight in a 12 hour light/dark cycle)	Compound was not photolysed or hydrolysed over 31 days (Reynolds, 2000)

FORMULATIONS

GAPs have been reported for two formulations, a capsule suspension (CS) containing 168 g/L dichlobenil, and a granular formulation containing 40 g/kg dichlobenil.

METABOLISM AND ENVIRONMENTAL FATE

The metabolism of dichlobenil has been investigated in grapes, rats, laying hens and lactating goats. Metabolism of the major plant metabolite 2,6-dichlorobenzamide has also been investigated in lactating goats and laying hens.

Metabolism studies for dichlobenil and 2,6-dichlorobenzamide were conducted with compound uniformly labelled with carbon-¹⁴ in the benzyl ring.

Figure 1: [^{14}C -U-phenyl]-dichlobenil and [^{14}C -U-phenyl]-dichlorobenzamide using in the metabolism studies

Table 2 Metabolites of dichlobenil and 2,6-dichlorobenzamide

Code name, common name	IUPAC name	Structure	Where found
Dichlobenil (parent compound)	2,6-Dichlorobenzonitrile		
BAM	2,6-Dichlorobenzamide		Grapes, apples, soil
BAM-4-OH	2,6-Dichloro-4-hydroxybenzamide		Grapes
	4-Chloro-2(3H)benzoxazolone		Aqueous photolysis

Code name, common name	IUPAC name	Structure	Where found
Methylthio- dichlobenil	6-Chloro-2-methylthiobenzonitrile		Goat, hen (tentative)
Methylsulfonyl- dichlobenil	6-Chloro-2-methylsulfonylbenzonitrile		Goat, hen
Dichlobenil-OH- cysteine	S-(3-Chloro-2-cyano-6-hydroxyphenyl)-cysteine		Goat, hen
BAM-OH-SH	6-Chloro-3-hydroxy-2-thiobenzamide		Goat metabolite of BAM
Methylsulfinyl- BAM-OH	6-Chloro-3-hydroxy-2-methylsulfinylbenzamide		Goat metabolite of BAM
Methylthio-BAM- OH	6-Chloro-3-hydroxy-2-methylthiobenzamide		Goat metabolite of BAM

Animal metabolism

Rats

The metabolism of dichlobenil in rats was investigated and was evaluated by the WHO Panel of the 2014 JMPR.

Rats: dichlobenil

Following oral gavage dosing of rats, dichlobenil was rapidly absorbed: about 89 and 97% of the administered dose in male and female in 7 days, respectively, based on comparison of urinary excretion following oral and intravenous routes of exposure. Oral absorption after repeated exposure is at least 60%, irrespective of dose and sex, based on radiolabel recovered from urine, faeces and cage wash. Liver, kidney and kidney-fat retained the highest concentrations of radiolabel, peaking 1 hour after administration. The elimination of the radioactivity associated with [¹⁴C]dichlobenil following oral administration was rapid, with the majority (about 80%) of the radioactivity being eliminated within 24 hours at the low dose level. Around 60% is excreted in the urine and around 20% in the faeces, irrespective of sex or dose regime, 9 to 10 days after initiation of exposure. Approximately 79% of the administered dose was excreted in the bile in 24 hours in bile duct cannulated rats. Ten metabolites were identified in urine, although no parent compound was identified in urine. Most metabolites were conjugates such as sulphate, glutathione (and derivatives) and glucuronic acid conjugates. In faeces, three major metabolites (each representing 5% of the administered dose or more) were observed as well as parent compound (dichlobenil). The proportion of conjugated metabolites decreases with increasing and multiple doses, while the amount of parent compound in faeces increases. No chemical names were provided for the identified metabolites. Dichlobenil is metabolized in rats via two metabolic pathways: hydroxylation at the 3 or 4 position followed by glucuronidation or sulphation and the second pathway include substitution of one chlorine atom by glutathione.

Lactating goats: dichlobenil

Metabolism of [¹⁴C-U-phenyl]-dichlobenil was investigated in lactating goats (Cameron and Dunsire, 1988 and Ruijten *et al.*, 1988). Three animals were dosed orally twice daily by capsule for three consecutive days at the same dose of 10 mg/kg bw/day (one animal, goat 10P, as a pilot study and the other two, goats 7M and 8M, comprising the main study). Two further goats were dosed with unlabelled material at the same level.

The goats were kept in metabolism cages during the feeding phase of the study. Fresh drinking water and hay were available *ad libitum*, while commercially available diet was provided twice daily at milking. The dose was administered orally twice daily at approximately 0900 and 1700 using gelatin capsules. Actual dose levels were 9.9–10.2 mg/kg bw/day (mean = 10.0 mg/kg bw/day). Feed consumption was not recorded. Based on an estimated dry matter consumption figure of 4% of the body weight per day, these doses would equate to a mean of 250 ppm in feed.

The goats were milked twice daily and milk was sampled. Blood samples were taken prior to first and fifth doses, and at intervals of 30 minutes to 8 hours after each of these doses. A final blood sample was taken just prior to sacrifice. The goats were sacrificed 15 hours after the final dose, and samples of liver, kidney, muscle, fat, gastrointestinal (GI) tract and contents, and the remaining carcass were collected.

Total radioactive residues in liquid samples (urine, cage wash and plasma) were mixed with scintillation cocktail and analysed by liquid scintillation counting (LSC). Prior to combustion and LSC of the captured ¹⁴CO₂, faeces and residual carcass samples were homogenised with water, tissue samples were finely chopped, while the GI tract samples were separated into tissue and contents, with the contents being homogenised in water, and the tissue being minced then homogenised in water with carboxymethylcellulose.

The majority of the administered dose was excreted (39–45% in urine, 24–31% in faeces, 2.9–4.0% in cage wash, and 0.06 to 0.33% in milk). Carcass tissue accounted for 3.2 to 3.4 % of the

administered radioactivity, while 1.1–3.3% remained in GI tract tissue, and 0.4–3.3% GI tract contents.

Table 3 Total radioactive residues in milk after dosing of dichlobenil at 250 ppm

Sampling interval (hours)	Concentration (mg eq./kg)

Carcass	1.40	1.18	1.09	1.22

Residues in milk and tissues of goats 7M and 8M from the main study were further characterised. To provide additional material to aid identification, the samples from the goats treated with unlabelled compound were co-processed, except for muscle, for which no unlabelled samples were available. Instead, the muscle from the pilot study goat was used.

The samples were homogenised, with water in the case of liver, kidney and milk, and with blank skim milk in the case of fat and muscle, and then filtered and centrifuged to remove solid material. The samples were then freeze concentrated if necessary to reduce the volume, prior to HPLC with on-line clean-up using a pre-column. Metabolic profiles of the sample extracts were analysed by HPLC with gradient elution (mobile phases were 3 g/L ammonium hydrogen phosphate and methanol) and radiodetection with fraction collection. Isolated fractions were further purified by passing them through the HPLC system a second time, and by thin layer chromatography.

The proportions of residue extracted were relatively low, and variable, at 65–70% of TRR in milk, 65% in liver, 26% in fat, 13% in muscle, and 28% in kidney. It is noted that no further characterisation was carried out for residues not extracted by the initial homogenisation with water or skim milk.

The metabolites were identified using mass spectrometry and ^1H NMR, and the data are presented in tables 5 and 6 below. Radioactivity present at each step of the work up process was reported as a percentage of the TRR. Significant losses were noted in several of the sample work-ups. It is noted that no attempt was made to characterise residues in the post-extraction solids. The metabolic profile was determined at different stages during the extraction and purification processes, with the relative proportions remaining consistent, indicating that losses were non-selective.

Components identified in the milk and tissues of lactating goats given ^{14}C -phenyl dichlobenil were: parent compound, the hydroxylated cysteine conjugate of deschloro dichlobenil, and the subsequent metabolites of the cysteine conjugate (without hydroxylation), 6-chloro-2-methylthiobenzonitrile (tentatively identified on the basis of comparison of retention times with a standard) and 6-chloro-2-methylsulfonylbenzonitrile. Parent compound was only present in significant quantities in fat. The cysteine conjugate was the most significant component of the liver residue, and was also noted in the milk samples, which contained higher proportions of this and other polar metabolites, such as 2-chloro-6-methylsulfonylbenzonitrile. 2-Chloro-6-methylthiobenzonitrile, a cleavage product of the cysteine conjugate, was found in significant proportions in muscle and kidney and the later milk samples, consistent with its position further down the metabolic pathway. The key metabolic pathway for dichlobenil in goats is cysteine conjugation at one of the chlorine positions on the phenyl ring, followed by cleavage and oxidation of the cysteine side chain, together with hydroxylation at the 3-position which may occur in parallel with the cysteine conjugation.

Laying hens: dichlobenil

Metabolism of ^{14}C -phenyl labelled dichlobenil was investigated in laying hens (Cameron and Dunsire, 1988 and Ruijten *et al*, 1988). Eight birds were dosed orally twice daily by capsule for three consecutive days, with radiolabelled material at 9.8-10.2 mg/kg bw/day (mean = 10.0 mg/kg bw/day). Feed consumption was not recorded. Based on an estimated dry matter consumption figure of 7.5% of the body weight per day, these doses would equate to a mean of 133 ppm in feed.

The hens were kept in metabolism cages during the feeding phase of the study. Fresh drinking water and layer pellets were available *ad libitum*. The dose was administered orally twice daily at approximately 0900 and 1700 using gelatin capsules. .

Eggs, excreta and cage washings were collected twice daily prior to administration of each dose, and 15 hours after the final dose. Blood samples were taken from all birds just prior to sacrifice. Two of the hens additionally had blood samples taken and plasma separated prior to doses 1 and 5, and at 1, 3 and 6 hours after these doses. The other six hens were sacrificed 15 hours after the final dose, and samples of liver, kidney, breast muscle, abdominal fat, gastrointestinal (GI) tract and contents, and the remaining carcass were collected.

Total radioactive residues in liquid samples (cage wash and plasma) were mixed with scintillation cocktail and analysed by liquid scintillation counting (LSC). Prior to combustion and LSC of the captured $^{14}\text{CO}_2$, excreta and residual carcass samples were homogenised with water; and tissue and GI tract samples were finely chopped.

The majority of the administered dose was excreted (64–73%) with 0.17–0.59% found in eggs, 2.8–16% in the GI tract at sacrifice, and 0.9–11% in the carcass. The recoveries of the total administered radioactivity were 74–92%.

Table 7 Total radioactive residues in eggs

Sampling interval (hours)	Concentration (mg eq./kg)						
	Hen 6P	Hen 7P	Hen 1M	Hen 2M	Hen 3M	Hen 4M	Mean

Carcass	1.3	0.89	3.2	3.9	1.8	1.9	2.2

The highest levels of total radioactive residue are found in fat and the GI tract, with significant levels also being observed in the liver.

Residues in eggs and tissues of hens from the study were further characterised. The samples were homogenised, with water in the case of liver, kidney and eggs, and with skim milk in the case of fat and muscle, and then filtered and centrifuged to remove solid material. The samples were then freeze concentrated if necessary to reduce the volume, prior to HPLC with on-line cleanup using a pre-column. Metabolic profiles of the sample extracts were analysed by HPLC with gradient elution (mobile phases were 3 g/L ammonium hydrogen phosphate and methanol) and radio-detection with fraction collection. Isolated fractions were further purified by passing them through the HPLC system a second time, and by thin layer chromatography.

The proportions of residue extracted were variable, at 60% of TRR in eggs, 90% in liver, 15% in fat, 8% in muscle, and 39% in kidney.

The metabolites were identified using mass spectrometry and ^1H NMR, and the data are presented in table 9 below. Significant losses were noted in several of the sample work-ups. It is noted that no attempt was made to characterise residues in the post-extraction solids.

Components identified in the eggs and tissues of laying hens given ^{14}C -phenyl dichlobenil were: parent compound, the hydroxylated cysteine conjugate of deschloro dichlobenil, and the subsequent metabolites of the cysteine conjugate, 6-chloro-2-methylthiobenzonitrile and 6-chloro-2-methylsulfonylbenzonitrile. Parent was the only component identified in the more hydrophobic matrices, fat and eggs, with parent also being found in smaller proportions in the other tissues. A metabolite tentatively identified as 2-chloro-6-methylthiobenzonitrile was the predominant component of the residue in liver and muscle, while kidney showed the greatest number of residue components, and a higher proportion of the more water soluble metabolites, the hydroxylated cysteine conjugate, and its oxidative cleavage product, 2-chloro-6-methylsulfonylbenzonitrile. The key metabolic pathway for dichlobenil in hens is cysteine conjugation at one of the chlorine positions on the phenyl ring, followed by cleavage and oxidation of the cysteine side chain, together with hydroxylation at the 3-position.

Overview of metabolism of dichlobenil in animals

The major metabolic pathway for dichlobenil in food producing animals is conjugation, substituting cysteine for one of the chlorine atoms accompanied by hydroxylation of the phenyl ring. Cleavage and oxidation of the cysteine side chain of the unhydroxylated conjugate also takes place, giving 6-chloro-2-methylthiobenzonitrile and 6-chloro-2-methylsulfonylbenzonitrile.

Figure 2: Metabolism of dichlobenil in animals

There are strong similarities to the metabolism of dichlobenil in rats. In rats, hydroxylation at the 3-position also takes place, as well as substitution of one of the chlorine atoms, initially by glutathione, which is subsequently cleaved to give a cysteine moiety. Further cleavage and oxidation of the cysteine substituent to give the methylthio-dichlobenil and methylsulfonyl-dichlobenil also takes place in the rat.

Given that almost the only component of the residue in fruit crops is 2,6-dichlorobenzamide, with no parent being identified, the metabolism of dichlobenil in animals is of secondary importance to the animal metabolism of 2,6-dichlorobenzamide.

Rats: 2,6-Dichlorobenzamide

Metabolism data for 2,6-dichlorobenzamide in rats was not provided to the Meeting.

Lactating goats: 2,6-dichlorobenzamide

Metabolism of ^{14}C -phenyl labelled 2,6-dichlorobenzamide was investigated in lactating goats (Burke, 1994a and Ruijten *et al*, 1994a). Dairy goats were dosed with ^{14}C -2,6-dichlorobenzamide daily at 13 ppm (0.32 mg/kg bw/day) for five days or 252 ppm (7.2 mg/kg bw/day) for three days.

The goats were kept in metabolism cages during the feeding phase of the study. Fresh drinking water was available *ad libitum*, while measured quantities of feed (commercially available diet, shredded molasses beet pulp, and hay) were provided each morning and afternoon, with feed consumption being monitored. The dose was administered orally using gelatin capsules. No overt signs of toxicity were observed during the study, and the dosing did not have any adverse effects on the weight of the animals, feed intake, or milk production.

Urine and faeces were collected at 24 hour intervals, with milk being collected twice daily and pooled for each 24 hour period. The cages were rinsed after each collection of excreta and the cage wash was collected. The low dose animal was sacrificed approximately 23 hours after the final dose, while the high dose animal was sacrificed around 4 hours following the final dose. Samples of skeletal muscle (composite of fore and hind quarter), fat (composite of omental and perirenal), liver, and kidney were collected. The tissue and faeces samples were macerated and sub-sampled prior to frozen storage, with the liquid samples being appropriately sub-sampled.

Samples of urine, milk and cage wash were analysed for total radioactivity directly by liquid scintillation counting (LSC), with the tissue and faeces samples being combusted prior to capture and LSC of the liberated $^{14}\text{CO}_2$.

In the low dose goat, 62% of the administered dose was recovered in urine, 17% in faeces, 0.3% in milk, and 11% in tissues, with >90% total recovery. For the high dose animal, 48% of the dose was recovered in urine, 18% in faeces, 0.4% in milk and 5% in tissues (>70% total recovery).

Table 10 Total radioactive residues in milk

Sampling interval (hours)	Concentration (mg eq./kg)	
	Low dose animal	High dose animal
0-24	0.033	0.95

72-96	0.048	NA
96-120	0.045	NA
120-126	0.019	NA

NA = not applicable.

Residues of 2,6-dichlorobenzamide reached a plateau in milk at about day 3 of dosing.

Table 11 Total radioactive residues in goat tissues

Tissue	Residue (mg eq./kg)	
	Low dose animal (12.8 ppm)	High dose animal (252 ppm)
Fat	0.024	2.15
Kidney	1.19	17.9
Liver	9.41	67.6
Muscle	0.25	4.47

Goat tissues and milk were homogenised and uniformly mixed with Lichroprep® 25–40 µm silica, then loaded into a column subjected to online (milk and liver) or off-line (all other matrices) extraction and HPLC analysis using gradient elution with 50 mM ammonium acetate in distilled water adjusted to pH 3 and 50 mM ammonium acetate in methanol, with UV (254 nm) and radio detection with fraction collection. For the off-line extractions, homogenates of muscle and kidney were mixed with the Lichroprep silica, with fat homogenates additionally being mixed with DMSO prior to extraction. An analytical scale of the HPLC method was used for determination of the metabolite profile, with a preparative scale of the same method being used for isolation of the metabolites from the liver of goats from the high dose group. Liver was chosen as it contained the highest amount of total radioactive residue, as well as the greatest number of residue components. The isolated metabolites were further purified using thin layer chromatography and a second HPLC-UV-radio-detection method with fraction collection using 5 g/L ammonium bicarbonate in water and methanol as the mobile phases. Metabolites were identified using a combination of comparison of the HPLC chromatograms with authentic compounds, ¹H NMR, and mass spectrometry.

The extraction efficiencies of the on-line HPLC method for the matrices are presented in Table 12 below, together with the composition of the residue in each matrix.

The column extraction methods were effective, with 92% of TRR extracted from liver, 94% from milk, 103% from kidney, 110% from muscle and 121% from fat. The high figures for muscle and fat were attributed to uncertainties in the measurement of small amounts of radioactivity in large extraction volumes.

2,6-Dichlorobenzamide was present in all matrices and was the largest component of the residue in all matrices except liver. Metabolism was most extensive in liver, with three sulphur containing compounds identified, which appear to be degradates of a cysteine conjugate of 2,6-dichlorobenzamide. The largest component of the residue in liver was 6-chloro-3-hydroxy-2-thiobenzamide, present at 6.6 mg eq./kg, or 70% of the TRR. The dichlobenil-cysteine conjugate metabolites 6-chloro-3-hydroxy-thiobenzamide, 6-chloro-3-hydroxy-2-methylthiobenzamide, and 6-chloro-3-hydroxy-2-methylsulfinylbenzamide were found in varying proportions in all matrices. Small amounts of a metabolite found only in muscle and fat were postulated to be dichlobenil on the

basis of matching chromatographic retention times with a standard. However, this assignment should be regarded as tentative, as no structural confirmation was carried out using mass spectrometry or nuclear magnetic resonance.

Cysteine conjugation, together with hydroxylation at the 3-position, followed by cleavage of the cysteine side chain and oxidation of the sulphur therefore forms the main metabolic pathway for 2,6-dichlorobenzamide in goats.

Laying hens: 2,6-dichlorobenzamide

Metabolism of ^{14}C -phenyl labelled 2,6-dichlorobenzamide was investigated in laying hens (Burke, 1994b and Ruijten *et al.*, 1994b). A group of five hens was dosed with ^{14}C -2,6-dichlorobenzamide daily for 5 days at a target dose of 10 ppm in feed on a dry matter basis. A second group of five birds was given an exaggerated dose at a target level of 200 ppm in feed daily for 3 days to provide additional samples to facilitate identification of residues. Finally, a single untreated control hen was kept in order to provide material for determination of analytical method LODs and LOQs.

The hens were kept in metabolism cages during the feeding phase of the study. Fresh drinking water was available *ad libitum*, while measured quantities of feed (commercially available diet and grit) were provided each morning and afternoon, with feed consumption being monitored. The dose was administered orally using gelatin capsules. Actual dose levels ranged from 11–14 ppm (mean = 12 ppm), or 0.78–0.92 mg/kg bw/day (mean = 0.86 mg/kg bw/day) and 218–249 ppm (mean value = 236 ppm), or 15–19 mg/kg bw/day (mean value = 17 mg/kg bw/day) for the low and high dose birds respectively. No overt signs of toxicity were observed during the study, and the dosing did not have any adverse effects on the weight of the animals, feed intake, or egg production.

Excreta, and cage debris if required, were collected at 24 hour intervals, with eggs being collected twice daily and pooled for each 24 hour period. Whole eggs were pooled for the low dose birds, with yolks and white being pooled separately for the high dose birds. The cages were rinsed after each collection of excreta and the cage wash was collected. The low dose birds were sacrificed approximately 23 hours after the final dose, while the high dose birds were sacrificed around 4 hours following the final dose. Samples of skeletal muscle (composite of breast and thigh), fat (peritoneal), skin with adhering subcutaneous fat, liver, and kidney were collected. The tissue were macerated and sub-sampled prior to frozen storage, while the egg and excreta samples were homogenised and sub-sampled, the excreta samples after addition of a minimum volume of water, then stored frozen.

Samples of excreta, whole eggs, egg yolks, and tissues were analysed for total radioactivity by liquid scintillation counting (LSC), after combustion and capture of the liberated $^{14}\text{CO}_2$. Cage wash and egg whites were added directly to scintillant solutions and LSC was conducted without combustion.

In the low dose hens, 49% of the administered dose was recovered in excreta, 1.5% in cage wash, 3.7% in eggs, and 23% in tissues, with a total recovery of 77%. In the high dose birds, 15% was recovered in excreta, 1.8% in eggs and 30% in tissues (total recovery of 47%).

A good recovery of the total administered radioactive dose was achieved for the low dose birds, while recovery is poor for the high dose group. It is noted that the digestive tract and contents were not analysed, and a significant proportion of the radioactivity could be present there, especially given that sacrifice of the high dose birds took place only 4 hours after the final dose.

Table 13 Total radioactive residues in eggs

Sampling interval (hours)	TRR (mg eq./kg)		
	Low dose birds, whole eggs	High dose birds	
		Egg yolk	Egg white
0-24	0.41	8.35	6.97
24-48	1.01	13.5	10.9
48-52	NA	28.8	21.9
48-72	1.90	NA	NA
72-96	2.09	NA	NA
96-120	2.36	NA	NA

NA = not applicable.

Total radioactive residue concentrations in eggs do not appear to have reached a plateau by the end of the dosing phase, although it is noted that the rate of increase in the whole egg samples from the low dose birds is slowing after three days, indicating that the levels are approaching a plateau.

Table 14 Total radioactive residues in hen tissues

Tissue	Low dose birds, mg eq./kg	High dose birds, mg eq./kg
Fat	1.29	18.0
Skin with attached fat	1.85	25.1
Kidney	5.03	40.4
Liver	8.58	55.3
Muscle	1.93	32.9

Tissues and eggs were homogenised and uniformly mixed with Lichroprep® 25-40 µm silica, then loaded into a pre-column subjected to inline extraction and HPLC analysis using gradient elution with 50 mM ammonium acetate in distilled water adjusted to pH 3 and 50 mM ammonium acetate in methanol, with UV (254 nm) and radio detection with fraction collection. An analytical scale of the HPLC method was used for determination of the metabolite profile, with a preparative scale of the same method being used for isolation of the metabolites from liver from the high dose group of hens, which contained the largest amount of radioactive residue for characterisation. The isolated metabolites were further purified using a second HPLC-UV-radio-detection method with fraction collection using 5 g/L ammonium bicarbonate in water and methanol as the mobile phases. Metabolites were identified using a combination of comparison of the HPLC chromatograms with standard chromatograms, ¹H NMR, and mass spectrometry.

The extraction efficiencies of the on-line HPLC method for the matrices are tabulated below, together with the composition of the residue in each matrix. The column extraction methods were essentially quantitative, with 95% of the TRR in kidney extracted, while >99% was extracted from liver, skin, muscle, fat and eggs.

Table 15 Extraction yields and composition of the radioactive residues from hen matrices (low dose birds)

Matrix	% Recovery by extraction and HPLC	2,6-Dichlorobenzamide		Unknown	
		mg eq./kg	%TRR	mg eq./kg	%TRR
Liver	99.3	8.52	99.3	-	-
Kidney	94.6	4.76	94.6	-	-
Skin	99.4	1.84	99.4	-	-
Muscle	99.6	1.87	96.9	0.053	2.7
Fat	99.6	1.28	99.6	-	-
Egg (96 hours)	99.9	1.97	94.3	0.12	5.6

The only component of the residue identified was unchanged 2,6-dichlorobenzamide, with the exception of muscle and egg, in which a single unidentified component was found, comprising 3% and 6% of the radioactivity respectively. 2,6-Dichlorobenzamide is essentially not metabolised by hens, and is largely excreted unchanged.

Overview of metabolism of 2,6-dichlorobenzamide in animals

2,6-Dichlorobenzamide is metabolised in goats in a similar manner to dichlobenil, with the principal metabolic pathway being conjugation with cysteine (replacing one of the chlorine atoms), accompanied by hydroxylation of an adjacent position on the phenyl ring. Subsequently, the cysteine side chain is cleaved and oxidised, giving residues such as 6-chloro-3-hydroxy-2-methylthiobenzamide, 6-chloro-3-hydroxy-2-thiobenzamide, and 6-chloro-3-hydroxy-2-methylsulfinylbenzamide.

Figure 3 Metabolism of 2,6-dichlorobenzamide in goats

By contrast, 2,6-dichlorobenzamide appears to be excreted largely unchanged by laying hens, with only one other component observed (but not identified) at low levels (3-6% of the TRR) in muscle and eggs.

Plant metabolism

The Meeting received studies on the metabolism of dichlobenil in apples and grapes.

Apples

Small outdoor plots of one apple tree each (Gravenstein variety) were treated with ^{14}C -dichlobenil prepared as a liquid formulation at 6.72 kg ai/ha by a single soil application in mid-February (late dormancy; flowering was noted 20 days after application) (Hubert, 1990b). The total radioactive residues in soil and fruit samples were determined by combustion and liquid scintillation counting (LSC) analysis. Homogenised apple was extracted with methanol. Radioactivity in the post-extraction solids was quantified by combustion and LSC. The methanol extract was concentrated and the resulting solid residue filtered out and rinsed then sonicated with methanol. Residues in the methanol extract were further characterised using separate partitions of portions of the extract with ether and toluene. Radioactivity in the various methanol extracts and ether and toluene partitions were analysed by LSC, with residues in the extracts containing sufficient residue (the ether and toluene partitions) being identified with the aid of reference standards using HPLC-UV with fraction collection and LSC, and TLC.

Table 16 Total radioactive residues in apple and soil samples

DALA	Matrix	TRR (mg eq./kg)
-0	Soil 0-7.6 cm	ND
	Soil 7.6-15.2 cm	ND
0	Soil 0-7.6 cm	1.292
	Soil 7.6-15.2 cm	ND
30	Soil 0-7.6 cm	0.494
	Soil 7.6-15.2 cm	ND
77	Soil 0-7.6 cm	0.486
	Soil 7.6-15.2 cm	0.098
107	Soil 0-7.6 cm	0.746
	Soil 7.6-15.2 cm	0.166
137	Soil 0-7.6 cm	0.601
	Soil 7.6-15.2 cm	0.166
77	Fruit	0.012
107	Fruit	0.028
137	Fruit	0.042

The greater amount of the soil residue was found in the upper sections of the cores, consistent with the volatility of dichlobenil. Total residues in mature fruit were low, at 0.042 mg eq./kg. Most of the residue was extracted with methanol, at 81% of the TRR (0.034 mg eq./kg). Around 86% of the methanol extracted radioactivity partitioned into ether, while around 73% partitioned into toluene.

Table 17 Characterisation and identification of residues in apples collected at normal harvest (using the results from the ether partition)

Component/extract	Residue	
	mg eq./kg	%TRR
2,6-Dichlorobenzamide	0.024	56.5
Unidentified residue components in the ether partition	< 0.01 (0.0055)	13.2
Aqueous partition	< 0.01 (0.0057)	16.7
Unextracted residue	< 0.01 (0.0045)	10.7
Sum of identified and extracted/characterised residues	0.039	97.1
Total radioactive residue	0.042	100

The only metabolite identified in apples was 2,6-dichlorobenzamide, at 0.024 mg eq./kg, or 57% of the TRR. Other unidentified components were present at < 0.01 mg eq./kg.

Grapes

A single soil application of ^{14}C -dichlobenil was made to small plots (two plants per plot) of outdoor grown Emperor variety grape vines in mid-February (late dormancy) using a liquid formulation at 6.72 kg ai/ha (Hubert, 1990a). Soil and fruit samples were frozen and homogenised and the total radioactive residues determined by combustion radio-analysis. Homogenised grape samples were

extracted four times with methanol and the extracts combined. The methanol extract was reduced to an aqueous residue and partitioned with dichloromethane. HPLC and TLC analyses were conducted on the aqueous and organic phases. Further characterisation of the aqueous phase was carried out by acid and enzyme (β -glucosidase) hydrolysis followed by LSC analysis.

Table 18 Total radioactive residues in grape and soil samples

DALA	Matrix	TRR (mg eq./kg)
0	Soil 0-7.6 cm	7.924
	Soil 7.6-15.2 cm	ND
61	Soil 0-7.6 cm	1.838
	Soil 7.6-15.2 cm	0.210
159	Soil 0-7.6 cm	0.160
	Soil 7.6-15.2 cm	0.616
190	Soil 0-7.6 cm	0.389
	Soil 7.6-15.2 cm	0.139
222	Soil 0-7.6 cm	0.507
	Soil 7.6-15.2 cm	0.216
159	Immature fruit	0.322
190	Immature fruit	0.286
222	Mature fruit	0.357, 0.392*

*A second combustion radio-analysis of the mature grapes was conducted at the time of extraction and characterisation of the residues, and the %TRRs are based on this second, higher figure.

Nearly all the residue in mature grapes (99% or 0.39 mg eq./kg) was extractable with methanol, with only 7.1% (0.03 mg eq./kg) remaining in the post-extraction solids (PES). Due to the low residue levels, no further characterisation was conducted for the PES. Around 81-85% of the total residue was found in dichloromethane after the initial neutral partition, with a much smaller amount (1.8%) found in dichloromethane after the second partition under acidic conditions.

Table 19 Characterisation and identification of residues in mature grapes

Component/extract	Residue	
	mg eq./kg	%TRR
2,6-Dichlorobenzamide	0.34	86.7
2,6-Dichloro-4-hydroxybenzamide	< 0.01	2.1
Unidentified residue components	0.06	15.3
Unextracted residue	0.03	7.2
Sum of identified and characterised residues	0.43	109.7
Total radioactive residue	0.39	100

The major component of the residue in grapes was 2,6-dichlorobenzamide, which was found at 0.34 mg eq./kg (86.7% of the TRR), when summing the amounts found in the neutral dichloromethane partition and the amounts tentatively identified in other fractions. A trace amount (< 0.01 mg eq./kg) of 2,6-dichloro-4-hydroxybenzamide was tentatively identified in the aqueous partition after acid hydrolysis of the initial aqueous partition.

Plant metabolism summary

The metabolism of dichlobenil in fruit crops is straightforward, with the only significant transformation being hydrolysis to give 2,6-dichlorobenzamide, which comprised 57% of the TRR in apples and 87% of the TRR in grapes. A very minor component of the residue in grapes was 2,6-dichloro-4-hydroxybenzamide, indicating some hydroxylation of the phenyl ring was taking place. 2,6-Dichlorobenzamide is a significant environmental metabolite, indicating that the transformation of the nitrile to the amide may be taking place in soil, with the 2,6-dichlorobenzamide then being taken up by the roots, rather than the hydrolysis taking place within the plant. However, this cannot be confirmed without further data, such as plant metabolism studies for 2,6-dichlorobenzamide itself.

Figure 4 Metabolism of dichlobenil in fruit crops

Environmental fate

Data on aerobic soil metabolism, aqueous photolysis, soil surface photolysis, and aerobic and anaerobic hydrolysis of dichlobenil, and hydrolysis and aqueous photolysis of the soil and plant metabolite 2,6-dichlorobenzamide were supplied.

Based on the environmental data requirements in the 2009 FAO Manual and considering the use pattern of dichlobenil (a soil applied herbicide), the soil metabolism, soil surface photolysis and hydrolysis studies are considered pertinent to the compound. Soil studies are evaluated below, while the results of the hydrolysis studies are summarised in Tables 1a and 1b above.

Aerobic soil metabolism: dichlobenil

Sandy loam soil samples were spiked with ^{14}C -dichlobenil at 2.1 mg/kg (Walstra *et al.*, 1989) and incubated in the dark at 24 °C for intervals up to 50 weeks. The biometer sample flasks were equipped with a trap filled with dilute aqueous potassium hydroxide for capturing CO_2 and other volatiles.

Soil samples were extracted twice by homogenising with methanol and twice by refluxing with methanol. The combined extracts were analysed by LSC and HPLC, with the unextracted residues determined by combustion and LSC. Radioactivity in the KOH traps was determined by LSC both before and after partition with dichloromethane. Some of the dichloromethane partitions were also analysed by HPLC.

The composition of the residues extractable from soil and captured in the traps is tabulated below.

Table 20 Degradation of ^{14}C -Dichlobenil in sandy loam soil under aerobic conditions

Sampling interval (weeks)	Volatiles (%TAR)			Extracted (%TAR)				Bound (%TAR)	Total Recovery (%TAR)
	Total	$^{14}\text{CO}_2$	dichlobenil	Total	dichlobenil	2,6-dichloro-benzamide	Other metabolites		
0	-	-	-	101	101	< 0.1	< 0.1	< 0.2	101
2	14.8	0.1	13.3	80.7	80.3	0.4	< 0.1	2.2	97.8
5	19.0	0.7	18.0	74.2	71.7	0.8	0.5	5.1	98.2
10	39.2	0.7	37.2	52.9	49.8	1.3	< 0.1	5.8	97.8
20	46.0	1.9	41.9	44.4	35.6	7.3	1.2	8.2	98.5

Sampling interval (weeks)	Volatiles (%TAR)			Extracted (%TAR)				Bound (%TAR)	Total Recovery (%TAR)
	Total	¹⁴ CO ₂	dichlobenil	Total	dichlobenil	2,6-dichloro-benzamide	Other metabolites		
30	63.9	1.5	61.0	26.8	20.6	5.2	< 0.6	8.2	98.9
40	62.3	2.7	58.5	26.1	16.2	8.4	0.5	8.0	96.4
50	61.0	2.3	56.8	26.7	11.6	13.1	0.7	10.2	97.9

Over half the applied dichlobenil was observed to dissipate via evaporation due to the high volatility of dichlobenil, mostly as parent compound (up to 61% of the TAR and up to 96% of the volatilised residue), with a small amount ($\leq 2.7\%$ of the TAR) being recovered as ¹⁴CO₂. At 2 weeks incubation, over 99% of the radioactivity extractable from soil was parent compound together with a trace (0.5% of the extractable soil residues) of 2,6-dichlorobenzamide. At 50 weeks, the proportion of dichlobenil had declined to 45% of the soil extractable residues, while 2,6-dichlorobenzamide had risen to 50%. Smaller amounts of the applied radioactivity were bound to the soil (2.2% of the TRR after 2 weeks, rising to 10.2% at 50 weeks).

The calculated DT₅₀ for dichlobenil in sandy loam soil is 13 weeks. Most of the loss of dichlobenil in soil is due to volatilisation rather than metabolism.

A second laboratory study of the aerobic degradation of soil (Nimmo, 1985) considered the fate of phenyl ¹⁴C-dichlobenil in several soil types, with both sterilised and unsterilised samples. ¹⁴C-Phenyl-dichlobenil was uniformly mixed into soil at a target of 1.8 mg/kg. The samples were stored in stoppered Erlenmeyer flasks in the dark at 20 °C. To determine the effect of soil microbes on degradation, some soil samples were sterilised in an autoclave, with the fortification solution being micro-filtered and added to the soil under aseptic conditions. Samples were extracted using ethanol/water, initially at room temperature and then under reflux, and the extracts analysed by LSC. The extracts were isotopically diluted with dichlobenil, 2,6-dichlorobenzamide and 2,6-dichlorobenzoic acid, the components separated by recrystallization then analysed by LSC and TLC.

Degradation of dichlobenil, and formation of the metabolites 2,6-dichlorobenzamide and 2,6-dichlorobenzoic acid is shown in the table below for the unsterilised soil samples. Only trace amounts of 2,6-dichlorobenzoic acid were observed (maximum of 0.4% of applied dose), while 2,6-dichlorobenzamide was a much more significant metabolite at up to 57% of the applied dose. The half lives of dichlobenil in the six soil types tested ranged from 4 to 30 weeks.

Table 21 Degradation of dichlobenil in unsterilized soils (percentages of applied dose)

Incubation time (weeks)	Compound	Light clay (pH 6.3, OM 5.9%)	Clay loam (pH 5.6, OM 1.9%)	Silty clay loam (pH 6.7, OM 3.3%)	Sandy peat (pH 5.1, OM 24.4%)	Sandy clay (pH 7.5, OM 1.3%)	Calcareous clay (pH 7.8, OM 1.2%)
0	Parent	94	101	93	95	97	100
2-3	Parent	84	79	70	86	54	91
6-7	Parent	75	65	33	62	28	71
	BAM	-	-	57	-	-	27
	DCBA	-	-	-	-	-	0.2
12-14	Parent	60	39	21	59	-	46
	BAM	31	-	-	41	-	48
	DCBA	0.4	-	-	0.4	-	-
18	Parent	51	-	13	41	-	28
	BAM	-	-	-	-	-	-
	DCBA	-	-	0.4	-	-	-
26	Parent	43	-	-	31	-	-
36	Parent	-	-	-	-	-	19
52	Parent	29	-	-	21	-	-

BAM = 2,6-Dichlorobenzamide. DCBA = 2,6-dichlorobenzoic acid.

Degradation of dichlobenil in the sterilised soil samples was essentially zero, strongly suggesting that soil microbes were largely responsible for the degradation of dichlobenil.

Table 22 DT₅₀ values (by soil type)

Soil type	DT ₅₀ (weeks)
Light clay	30
Clay loam	11
Silty clay loam	6.2
Sandy peat	24
Sandy clay	3.8
Calcareous clay	14

This study is not considered fully representative of the expected fate of dichlobenil in soil under field conditions as the samples were stored in stoppered flasks, preventing losses of parent by volatilisation which was the major route of dissipation in the first study (Walstra *et al.*, 1989).

Soil surface photolysis: dichlobenil

The photolytic fate of ¹⁴C-phenyl dichlobenil (Kabler and Carpenter, 1990) coated on irradiated soil was studied. Soil samples (sandy loam) were fortified with radio-labelled dichlobenil at a concentration of 10 mg/kg and placed in glass photolysis chambers equipped with water cooled jacketing, traps to capture volatiles, and a constant flow through of CO₂ free water saturated air was maintained. The samples were constantly irradiated using a xenon arc UV lamp at an intensity that resulted in irradiation over a 24-hour period equivalent to a solar day at the spring equinox at 40° N latitude. A number of samples were not irradiated and were wrapped with aluminium foil in order to act as dark controls. Samples of soil were analysed at intervals from 0 to 30 days.

Soil samples were extracted with methanol and the extracts and trapping solutions were analysed using LSC and HPLC. Radioactivity remaining in the extracted soil samples was determined by combustion and LSC.

For the irradiated samples, a DT₅₀ of 50 days was calculated, while for the dark control samples, a much shorter DT₅₀ of 4.7 days was determined.

Given that the calculated DT₅₀ for the irradiated samples were much longer than those for the dark control samples, this study is not considered to be reliable and no conclusion on aqueous photolysis of dichlobenil on the soil surface can be reached.

Aerobic soil metabolism: 2,6-dichlorobenzamide

Studies on metabolism of 2,6-dichlorobenzamide in soil were not provided. However, the EFSA evaluation of dichlobenil reported in-field DT₅₀ values of 73–257 days for 2,6-dichlorobenzamide calculated from field dissipation studies in fluopicolide, of which 2,6-dichlorobenzamide is also a metabolite (European Food Safety Authority, 2010). Most losses were through leaching. DT₅₀ values of 186–261 days were reported for laboratory experiments with 2,6-dichlorobenzamide in Finnish topsoil samples (Pukkila and Kontro, 2014).

Environmental metabolism summary

Dichlobenil is lost from soil in significant quantities by volatilisation, and is also metabolised in soils, mainly to 2,6-dichlorobenzamide. A laboratory DT₅₀ value of 13 weeks was determined for sandy loam soil. Dichlobenil was stable to hydrolysis in buffer solutions.

The key plant and soil metabolite of dichlobenil, 2,6-dichlorobenzamide, was stable to hydrolysis. It is more persistent in soil than dichlobenil, with laboratory DT₅₀ values of up to 261 days.

Field dissipation studies for dichlobenil and 2,6-dichlorobenzamide were not available to the Meeting.

Residues in succeeding crops

Uses considered are only for permanent crops and no studies on residues of dichlobenil in rotational crops were made available to the Meeting.

RESIDUE ANALYSIS

Methods of residue analysis

Details of validated analytical methods were supplied for the determination of dichlobenil in plant and animal matrices.

Plant matrices

A GC-ECD method (method number L 3-53-71) was developed and validated for determination of 2,6-dichlorobenzamide in berry fruits, stone fruits and hazelnuts (Ver Hey, 1990). Samples were homogenised with anhydrous sodium sulphate and filter pulp, then extracted with ethyl acetate. An aliquot of the ethyl acetate extract was filtered, evaporated to dryness, and reconstituted in 1:9 v/v acetone/petroleum ether, and cleaned up by solid phase extraction using neutral alumina. The residue was eluted from the column using 3:17 v/v ethanol/petroleum ether, evaporated to dryness, and reconstituted in ethyl acetate, before analysis by GC-ECD. An additional cleanup by partition between acetonitrile and hexane, with the hexane phase being discarded, was incorporated prior to the solid phase extraction step for hazelnut samples to remove oily contaminants.

Quantification was achieved by linear regression using the external standard method. The method linearity was good, with an r^2 value of 0.9978 over a concentration range 1–100 µg/L, or 0.008–0.8 mg/kg in samples (depending on the dilution factor). The method LOQ is 0.01 mg/kg. Method recoveries and precision were generally good, with all recoveries except for those in hazelnuts and prunes in the range 70–120%, and RSD values all <20%.

A second method (study number 2005-046) using GC-ECD and GC-MS/MS as alternative analytical techniques was validated for analysis of both dichlobenil and 2,6-dichlorobenzamide in grapes (Bacher, 2005). Separate extractions and analyses were conducted for the two analytes.

For determination of dichlobenil, grape samples were macerated with anhydrous sodium sulphate and 1:4 v/v ethyl acetate/hexane, then filtered. The extraction was repeated twice more and the extracts were filtered and combined. To an aliquot of the combined extracts, a small amount of 1% decanol in acetone was added, prior to concentration by rotary evaporation using a water bath at 40 °C. Hexane was added, and the volume was reduced again before addition of a second volume of hexane and further evaporation prior to transfer to a sample tube and making up to volume with hexane. The extract was then cleaned up by solid phase extraction using 5% deactivated neutral alumina. The column was rinsed with hexane, with these eluates being discarded, prior to elution of the residue with 2% acetone in hexane. The eluted residue was transferred to an evaporation flask, and a small amount of 1% decanol in acetone was added before concentration by rotary evaporation at 40 °C, prior to adjustment of the extract to volume with hexane. The cleaned up extract was analysed by GC-MS/MS (detection transition was 171 → 136 for dichlobenil, and 173 → 145 for 2,6-dichlorobenzamide), or GC-ECD.

For determination of 2,6-dichlorobenzamide, samples were macerated with ethyl acetate, anhydrous sodium sulphate, and filter pulp. After centrifuging and filtration, an aliquot of the extract

was evaporated to dryness by rotary evaporation followed by a gentle stream of nitrogen, and reconstituted in 1:9 v/v acetone/petroleum ether. The extract was cleaned up by solid phase extraction with 2% deactivated alumina. After loading the extract onto the column, the flask was rinsed with 1:9 v/v acetone/petroleum ether and the rinses added to the column. The initial eluates were discarded, and the 2,6-dichlorobenzamide residues were eluted with 3:17 v/v ethanol/petroleum ether, evaporated to dryness by rotary evaporation at 40 °C followed by a gentle stream of nitrogen, then re-dissolved in ethyl acetate. The cleaned up extract was analysed by GC-MS/MS or GC-ECD.

The method LOQ is 0.01 mg/kg for both analytes. The method linearity was good, with r^2 values >0.99 for both analytes using GC-MS/MS. Linearity was less good for GC-ECD, although r^2 values were >0.98. Method accuracy and precision in grapes were good, with recoveries all in the range 70–120%, and RSD values all <20%.

Table 25 Recovery of dichlobenil and 2,6-dichlorobenzamide from grapes (method 2005-046)

Analyte	Fortification (mg/kg)	n	Recovery, GC-MS/MS determination (%)		Recovery, GC-ECD determination (%)	
			Range	Mean $\pm$ RSD	Range	Mean $\pm$ RSD

		0.20	94, 95, 96

*Rejected due to fortification error.

An independent validation of the method was conducted for both metabolites with no significant modifications to the extraction procedures, with analyses using both GC-ECD and GC-MS rather than GC-MS/MS (Wolf, 2006). Good recoveries were achieved in grapes (70–120%), with an LOQ of 0.01 mg/kg being confirmed for both analytes.

Animal matrices

A GC-MS method (96045) was developed and validated for determination of both dichlobenil and 2,6-dichlorobenzamide in animal matrices (Batorewicz, 1997).

Fat samples were extracted twice by homogenisation with hexane. The hexane extracts were then cleaned up by partitioning twice with acetonitrile, with the hexane being discarded and the acetonitrile phases combined and concentrated by rotary evaporation before addition of the internal standard, adjustment to volume and analysis.

Kidney, muscle and liver samples were homogenised with water and extracted twice with ethyl acetate. An aliquot of the combined ethyl acetate supernatants was evaporated to dryness and reconstituted in hexane. The hexane extract was then partitioned twice with acetonitrile, with the hexane being discarded and the combined acetonitrile extracts being washed with hexane. The combined acetonitrile extracts were evaporated to about 1 mL by rotary evaporation at 30–40 °C followed by a gentle stream of nitrogen. The internal standard was added and the sample adjusted to volume.

Milk samples were homogenised and then extracted twice with ethyl acetate. Combined aliquots of the ethyl acetate supernatants were evaporated, then reconstituted in hexane. The extract was then cleaned up by solid phase extraction (deactivated Florisil column). The residue was eluted with 1:1 v/v hexane/ethyl acetate and concentrated. The internal standard was added and the extract adjusted to volume.

Samples were analysed by GC-MS using 4-chlorobenzonitrile as an internal standard. Quantification was achieved by linear regression. The method LOQ is 0.01 mg/kg. Method linearity was good, with r^2 values >0.99 for dichlobenil and 2,6-dichlorobenzamide.

Multiresidue methods were not provided by the sponsor.

The USA FDA official multiresidue method PAM I has been successfully validated (complete recoveries, i.e. >80%) (US FDA, 1999). For dichlobenil parent compound this involved using Method 302 (E1-E3, DG1-19), corresponding to acetone extraction followed by solvent partition or removal of the aqueous component using diatomaceous earth, and GC analysis with a low temperature column (detector not specified) and Method 304 E1-E3 + C1-C4 + DG1-19 (extraction with acetone followed by solvent partition or removal of the aqueous component followed by solid phase extraction cleanup and GC analysis). Analysis of 2,6-dichlorobenzamide was successful using Method 302 (E1-E3, DG1-19).

EFSA reported good recoveries from unspecified high water content matrices for dichlobenil parent compound using a QuEChERS method (mean = 94%, RSD = 5.3%, n = 12 at 0.05 mg/kg fortification and mean recovery = 97%, RSD = 10%, n = 25 at 0.1 mg/kg fortification) (European Food Safety Authority, 2013).

Stability of pesticide residues in stored analytical samples

Plant matrices

No separate stability study was submitted for residues of dichlobenil or 2,6-dichlorobenzamide in plant matrices. However, stability was verified concurrently with the analyses of the samples in the residue trials.

Table 30 Storage stability data for dichlobenil and 2,6-dichlorobenzamide in sweet cherries at 0.20 mg/kg fortification (Gaydosh, 1996)

Analyte	Storage interval (months)	Stored recovery (%)	Concurrent recovery (%)
Dichlobenil	0	-	90
	0.5	73, 92, 95 (mean = 87, RSD = 14%)	73
	1	99, 105, 113 (mean = 106, RSD = 6.6%)	87
	2	74, 88, 88 (mean = 83, 9.7%)	98
	6 (197 days)	62, 76, 77 (mean = 72, RSD = 12%)	94
2,6-Dichlorobenzamide	0	-	95
	0.5	100, 101, 101 (mean = 101, RSD = 0.6%)	101
	1	93, 94, 95 (mean = 94, RSD = 1.1%)	98
	2	94, 101, 104 (mean = 100, RSD = 5.1%)	102
	8 (246 days)	88, 90, 92 (mean = 90, RSD = 2.2%)	100

The above data for sweet cherries is sufficient to confirm that the samples from the cherry residue trials, which were stored for a maximum of 198 days (dichlobenil analyses), and 251 days (2,6-dichlorobenzamide analyses) before analysis.

*See also the data in Table 32 below for grapes, raisins and juice.

With the exception of prunes, the data listed in Table 31 above is sufficient to verify the stability of 2,6-dichlorobenzamide residues in relevant stone and berry fruit matrices for the period the samples were stored between collection and analysis for the appropriate residue trials.

Table 32 Residue stability data for dichlobenil and 2,6-dichlorobenzamide in raw and processed grape matrices at a 0.10 mg/kg fortification (Maselli, 1998)

Analyte	Matrix	Storage interval (months)	Stored recovery (%)	Concurrent recovery (%)

			=105, RSD = 3.4%)	
		9 (266 days)	97, 104, 107 (mean = 103, RSD = 5.0%)	100, 110
	Grape juice	0	-	96, 98
		1	101, 101, 102 (mean = 101, RSD = 0.6%)	103, 111
		3	89, 92, 95 (mean = 92, RSD = 3.3%)	102, 107
		6	87, 96, 97 (mean = 93, 5.9%)	105, 107
		11 (343 days)	102, 103, 105 (mean = 103, RSD = 1.5%)	91, 99

The above results show 2,6-dichlorobenzamide residues to be stable for at least 9 months of frozen storage in raisins, and for at least 11 months in raw grapes and grape juice. Residues of dichlobenil parent compound are stable for at least 11 months in raw grapes and grape juice and for 3 months in raisins, with lower recoveries being observed in raisins after 6 months of storage.

Animal matrices

Storage stability data for residues of dichlobenil and 2,6-dichlorobenzamide in cattle matrices (milk, muscle, fat, liver and kidney) was generated concurrently with the cattle feeding study (Batorewicz, 1998). Storage stability for 2,6-dichlorobenzamide residues was acceptable in all matrices over the period for which trial samples were stored, as well as for dichlobenil in muscle, milk and fat. Poor stability was noted for dichlobenil residues in kidney and particularly liver samples. However, based on the plant metabolism studies and field trial data, residues in plant commodities are expected to consist only of 2,6-dichlorobenzamide, with finite residues of dichlobenil not being expected in livestock feed. Further, as the animal metabolism studies for 2,6-dichlorobenzamide show that dichlobenil is not a significant animal metabolite of 2,6-dichlorobenzamide, parent dichlobenil is not expected to be found in animal commodities.

USE PATTERN

Dichlobenil is registered in the USA in stone fruit (cherries, both sweet and sour varieties,) and berries and other small fruits (blueberries, blackberries, cranberries, grapes and raspberries).

Table 33 Registered uses of dichlobenil in the USA relevant to the evaluation

Comments:

^{1.} Spray prior to weed emergence or when emerged weeds are less than 2 inches tall. Apply from late fall through to early spring.

^{2.} Apply as a soil surface treatment for perennial weeds in late fall (15 November to 15 February). Apply as an incorporated treatment for perennial weeds in late fall or very early spring prior to 1 May. For control of annual weeds, apply in early spring before germination of weeds or after cultivation. Incorporation or irrigation recommended..

^{3.} Apply to well prepared weed free soil in early spring or late fall before annual weed seeds have germinated. Do not apply more than the recommended amount per season. Application in spring should be made well before bud burst.

^{4.} Spray prior to weed emergence or when emerged weeds are less than 2 inches tall. Apply from late fall through to early spring.

^{5.} For control of annual weeds, apply in early spring before germination of weeds or after cultivation. Incorporation or irrigation recommended.

^{6.} Apply in the dormant period (late winter).

^{7..} Apply in early spring while perennial weeds are still dormant and annual weeds have not started to germinated or in late fall after crop has been harvested. Apply pre-budbreak or postharvest. Thoroughly incorporate granules into the surface through watering in.

^{8.} Apply in early spring when perennial weeds are still dormant and annual weeds have not started to germinate or in late fall after the crop has been harvested. Thoroughly incorporate through watering in. Do not apply more than 4.5 kg ai/ha in a 12-month period.

^{9.} Do not make a spring application after application the previous fall.

^{10.} Apply two equal applications in early spring with an interval of 3 to 6 weeks between each application. Use the higher rate only every second year. Do not apply after flowering. Do not make fall applications

^{11.} For seedling weeds apply this rate in early spring or fall.

^{12.} For perennial weeds apply this rate in the fall.

RESIDUES RESULTING FROM SUPERVISED RESIDUE TRIALS

The Meeting received information on dichlobenil supervised field residue trials for stone fruit (peaches, plums and cherries) and berries and other small fruits (blueberries, blackberries, cranberries, grapes and raspberries).

Trials were well documented with laboratory and field reports. The laboratory reports included method validation with determination of recoveries at the method LOQ and one other fortification level. Dates of sample collection and analysis were provided, allowing determination of storage intervals. At all trials, a granular formulation of dichlobenil was applied using either a hand spreader (e.g. shaker can), cyclone spinner applicator, or by a tractor-mounted granular spreader. A single plot was treated at each trial site. Plot areas and sample sizes were adequate. Samples were frozen within 6 hours of collection and stored frozen until analysis, with the exception of plums from the processing study (Hamilton, 1993) where the unprocessed fruit sample was frozen the day after collection. Generally, a single untreated control sample and duplicate or triplicate treated plot samples were collected.

In some studies, only residues of 2,6-dichlorobenzamide have been determined, while for others, both 2,6-dichlorobenzamide and dichlobenil have been tested for. Residues were not found in untreated control samples except where noted. Residues and application rates have generally been rounded to two significant figures. The tabulated results have not been corrected for recovery. When residues were not detected, they are shown as below the LOQ, and the LOQ value was used for maximum residue level determination and dietary intake assessment. Where replicate samples were analysed, results for the individual samples are reported together with the mean result, with the mean results used for maximum residue level estimation and dietary risk assessment.

The residue data is presented in the following tables:

Crop group	Commodity	Table
Stone fruits	Cherries	34
	Peach	35
	Plum	36
Berries and other small fruits	Blueberries	37
	Blackberries	38, 39
	Cranberries	40
	Grapes	41, 42
	Raspberries	43, 44

Stone fruits

Cherries

A series of residue trials was conducted in both sour and sweet varieties of cherries (Maselli, 1996 and Gaydosh, 1996 respectively). A single banded or broadcast soil application of a 4% w/w granular formulation of dichlobenil was made at a target application rate of 6.7 kg ai/ha when the fruit was at mid maturity, followed by irrigation with 0.6-1.3 cm of water (this was not required at some sites due to adequate rainfall being received shortly after application). Mature fruit was harvested at a single interval from each site, approximately 28 days after application.

Samples were analysed for residues of both dichlobenil and 2,6-dichlorobenzamide using a GC-ECD method very similar to study number 2005-046. Residues were determined on the edible portion (minus stones). Concurrent and method validation recoveries for dichlobenil and 2,6-dichlorobenzamide in sweet and sour cherries were within 70–120%. Sour cherry samples were stored frozen for up to 198 and 226 days between collection and analysis of dichlobenil and 2,6-dichlorobenzamide respectively, while sweet cherry samples were stored for up to 184 and 251 days respectively. A concurrent storage stability study was conducted for sweet cherries as part of the residue study, with mean recoveries of 72% for dichlobenil after 197 days of frozen storage, and 90%

for 2,6-dichlorobenzamide after 246 days of frozen storage. The samples are therefore unlikely to have been adversely affected by storage.

No residues were found above the LOQ (0.02 mg/kg for dichlobenil and 0.003 mg/kg for 2,6-dichlorobenzamide) in the untreated control samples.

Peaches

Four residue trials were conducted in peaches in South Carolina and California during 1990 and 1991 (Dykstra, 1991a and Ver Hey, 1992a). A single banded or broadcast soil application of dichlobenil was made using a 4% granular formulation at a target application rate of 6.72 kg ai/ha. Mature fruit was sampled at varying intervals (20–68 days) after application.

Peach samples were analysed for 2,6-dichlorobenzamide residues using a GC-ECD method (method number L 3-53-71), evaluated in detail above. It is not clear whether the residues have been calculated on a whole fruit basis (including stones), or only on the edible portion. Concurrent recoveries of 2,6-dichlorobenzamide in peach samples were within 70–120%. Samples were stored frozen for up to 60 days before analysis. Untreated control peach samples were fortified with 2,6-dichlorobenzamide and stored frozen for up to 59 days: mean recoveries after storage were all within the range 70–120%, indicating that the peach samples are unlikely to have been adversely affected by storage.

Table 35 Residues of dichlobenil in peaches (mature fruit)

Location, Trial no., Year (Variety)	Application				DAT	2,6-Dichlorobenzamide residue (mg/kg)	Reference
	Date	Growth stage	Application method	Rate (kg ai/ha)			
Madera, CA, USA, C 201 50 020, 1990 (Springcrest)	05/05/90	5.0-7.5 cm diameter fruit	Banded soil	6.8	20	< 0.01 (< 0.01, < 0.01, < 0.01)	Dykstra, 1991a
Kline, SC, USA, C 201 50 021, 1990 (Winblo)	26/04/90	not stated	soil broadcast	7.1	47	0.01 (0.01, 0.01, < 0.01)	Dykstra, 1991a
Fresno, CA, USA, C 201 50 031, 1991 (Flavorcrest)	22/04/91	2.5 cm diameter fruit	Banded soil	7.7	63	0.023 (0.027, 0.021, 0.02)	Ver Hey, 1992a
Kline, SC, USA, C 201 50 032, 1991 (Winblo)	17/04/91	not stated	soil broadcast	7.4	68	0.037 (0.038, 0.035, 0.039)	Ver Hey, 1992a

No residues were found above the LOQ (0.01 mg/kg) in the untreated control samples.

Plums

Two trials were conducted in plums in Idaho during 1991 and in Michigan during 1992 (Ver Hey, 1992b and Hamilton, 1993). A single soil broadcast or banded application of a 4% granular formulation of dichlobenil was made at a target rate of 6.72 kg ai/ha. Mature fruit was sampled around 4-5 months after treatment.

Plum samples were analysed for 2,6-dichlorobenzamide residues using a GC-ECD analytical method (method number L 3-53-71, evaluated in detail above). For the Michigan trial, residues were determined on the edible portion while for the Idaho trial it is not clear whether the residues have been calculated on a whole fruit basis (including stones), or only on the edible portion. Samples were stored frozen for up to 41 days prior to analysis. Concurrent recoveries of 2,6-dichlorobenzamide from plum samples were within the range 70–120%, as were those in fortified samples stored frozen for up to 35 days, indicating that the plum samples are unlikely to have been adversely affected by storage.

The results from the Parma, Idaho trial are anomalously high when compared with other trial results in stone fruit.

Table 36 Residues of dichlobenil in plums (mature fruit)

Location, Trial no., Year (Variety)	Application				DAT	2,6-Dichlorobenzamide residue (mg/kg)	Reference
	Date	Growth stage	Application method	Rate (kg ai/ha)			
Parma, ID, USA, C 201 50 034, 1991 (Empress)	19/04/91	not stated	soil broadcast	7.9	154	0.39 (0.37, 0.40)	Ver Hey, 1992b
Conklin, MI, USA, C 201 50 048, 1992 (Stanley)	15/04/92	not stated	banded soil	6.7	139	< 0.01 (< 0.01, < 0.01, < 0.01)	Hamilton, 1993

Residues were not found above the LOQ (0.01 mg/kg) in the untreated control samples.

Berries and other small fruits

Blueberries

Four trials in blueberries were reported (Reibach, 2013). A single broadcast soil application of dichlobenil was made using a 4% w/w granular formulation at a target rate of 4.48 kg ai/ha. Mature fruit was sampled, typically around 50–90 days after application.

Samples were analysed for both dichlobenil and 2,6-dichlorobenzamide residues using a GC-ECD method, a modification of the method in study number 2005-046 evaluated above, without the solid phase extraction cleanup. Mean and individual method validation recoveries and mean concurrent recoveries were within the range 70–120%. Samples were stored frozen for up to 90 days prior to analysis.

Table 37 Residues of dichlobenil in blueberries (mature fruit)

Location, Trial no., Year (Variety)	Application			DAT	Residue (mg/kg)	
	Date	Application method	Rate (kg ai/ha)		Dichlobenil	2,6-Dichlorobenzamide
Lehigh, PA, USA, 2012-01-PA, 2012 (Blueray)	07/05/12	soil broadcast	4.3	53	< 0.01 (< 0.01, 0.01)	0.015 (0.016, 0.014)
Bucks, PA/NJ, USA, 2012-02-PA/NJ, 2012 (Bluecrop)	08/05/12	soil broadcast	4.3	51	< 0.01 (< 0.01, 0.01)	< 0.01 (< 0.01, 0.01)
Ottawa, MI, USA, 2012-03-MI, 2012 (Draper)	10/05/12	soil broadcast	4.3	56	< 0.01 (< 0.01, 0.01)	< 0.01 (< 0.01, 0.01)
Washington, OR, USA, 2012-04-OR, 2012 (Bluecrop)	14/05/12	soil broadcast	4.3	58	< 0.01 (< 0.01, 0.01)	< 0.01 (< 0.01, 0.01)

No residues were found in the untreated control samples above the LOQ (0.01 mg/kg for each analyte).

Blackberries

A single residue study in blackberries was conducted in Oregon, USA during 1990 (Dykstra, 1991b). A single broadcast soil application of dichlobenil was made using a granular formulation at a target application rate of 4.48 kg ai/ha. Mature fruit was harvested 3 months after application.

Blackberry samples were analysed for 2,6-dichlorobenzamide using a GC-ECD method (method number L 3-53-71, evaluated in detail above). Mean and individual method validation recoveries in blackberries were within 70–120%. Storage stability recoveries for samples of blackberries fortified with 2,6-dichlorobenzamide and stored frozen for 26 days were within 70–

120%. Samples were stored frozen for up to 35 days between collection and analysis, and are unlikely to have been adversely affected by storage.

A further four trials in blackberries were reported (Reibach, 2013). A single broadcast soil application of dichlobenil was made using a 4% w/w granular formulation at a target rate of 100 pounds per acre (4.48 kg ai/ha). Mature fruit was sampled, typically around 50–90 days after application.

Samples were analysed for both dichlobenil and 2,6-dichlorobenzamide residues using a GC-ECD method, a modification of the method in study number 2005-046 evaluated above, without the solid phase extraction clean-up. Mean and individual method validation recoveries and mean concurrent recoveries in blackberries were within the range 70–120%. Samples were stored frozen for up to 70 days before analysis.

Table 38: Residues of dichlobenil in blackberries, mature fruit (Dykstra, 1991b)

Washington, OR, USA, 2012-07- OR, 2012 (Chester)	14/05/1 2	soil broadcast	4.3	88	< 0.01 (< 0.01, < 0.01)	<u>0.035</u> (0.035, 0.034)
Washington, OR, USA, 2012-08- OR, 2012 (Evergreen blackberry)	22/06/1 2	soil broadcast	4.3	53	< 0.01 (< 0.01, < 0.01)	<u>0.031</u> (0.029, 0.032)

No residues were found in the untreated control samples above the LOQ (0.01 mg/kg for each analyte).

Cranberries

Two residue studies in cranberries were conducted in Massachusetts and Wisconsin during 1991 (Ver Hey, 1992c). A single broadcast soil application of dichlobenil was made during spring using a granular formulation at a target application rate of 4.48 kg ai/ha. Mature fruit was harvested around 5–6 months after application.

Cranberry samples were analysed for residues of 2,6-dichlorobenzamide using a GC-ECD method (method number L 3-53-71, evaluated in detail above). Mean and individual method validation recoveries in cranberry samples were within the range 70–120%. Samples were stored frozen between collection and analysis for up to 94 days. Mean and individual storage stability recoveries for untreated control samples of cranberries fortified with 2,6-dichlorobenzamide and stored frozen for up to 87 days were within the range 70–120%; the residue trial samples are therefore unlikely to have been adversely affected by storage.

Table 40: Residues of dichlobenil in cranberries, mature fruit (Ver Hey, 1992c)

Location, Trial no., Year (Variety)	Application				DAT	2,6-Dichlorobenzamide residue (mg/kg)
	Date	Growth stage	Application method	Rate (kg ai/ha)		
East Wareham, MA, USA, C 201 50 037, 1991 (not specified)	19/04/91	mid spring	soil broadcast	5.7	158	0.020 (0.018, 0.024, 0.018)
Warrens, WI, USA, C 201 50 038, 1991 (not specified)	19/04/91	mid spring	soil broadcast	4.8	166	0.019 (0.015, 0.023, 0.020)

Residues were not found at levels above the LOQ (0.01 mg/kg) in the untreated control samples.

Grapes

Four trials were conducted in the USA (Chickering and Koch, 1991). A banded soil application was made to grapevines using a granular formulation (40 g/kg dichlobenil) at a target rate of 6.73 kg ai/ha in mid to late spring. Approximately 2.5-3.8 cm of irrigation was applied by sprinkler shortly after application at the Biola and Fresno trial sites. Mature grapes were sampled around 4-5 months after application.

Residues of 2,6-dichlorobenzamide in grapes were determined using a GC-ECD method based on method number L 3-53-71, evaluated in detail above. Individual and mean method validation and concurrent recoveries were within the range 70–120%. Grapes were analysed within 196 days of harvest. Fortified grape samples were stored frozen for 112-133 days, and showed individual and mean recoveries within the range 70–120%. Given that residues of dichlobenil and 2,6-dichlorobenzamide were shown to be stable for 323 and 345 days of frozen storage respectively during the Maselli, 1998 study (see below), the grape samples are unlikely to have been adversely affected by storage.

Additional residue data for grapes is available from the field component of a processing study in grapes (Maselli, 1998). Field trials were conducted at two sites in California during 1996. A single banded soil application of a 4% w/w granular formulation of dichlobenil was made around the end of dormancy at a target application rate of 8.75 kg ai/ha. At least 6.4 mm of water was applied within 48 hours of application, either by rainfall or irrigation if rainfall was insufficient to prevent sublimation of the test material. Mature grapes were sampled around 6 months after application.

Residues of dichlobenil and 2,6-dichlorobenzamide in raw and processed grape samples were determined using a GC-ECD method very similar to method number 2005-046 (evaluated in more detail above). Acceptable individual and mean method validation and concurrent recoveries in the range 70–120% were achieved in grapes, for both dichlobenil and 2,6-dichlorobenzamide. Analyses of dichlobenil were completed within 289 days of sample collection, while those for 2,6-dichlorobenzamide were completed within 124 days. A concurrent storage stability study was conducted, showing recoveries of dichlobenil and 2,6-dichlorobenzamide remaining within the range 70–120% after storage for 323 and 345 days respectively.

Table 41 Residues of dichlobenil in grapes, mature berries (Chickering and Koch, 1991)

Location, Trial no., Year (Variety)	Application				DAT	2,6-Dichlorobenzamide residue (mg/kg)
	Date	Growth stage	Application method	Rate (kg ai/ha)		
Biola, CA, USA, C 201 50 014, 1990 (Thompson Seedless)	30/04/90	15 cm bunch length	Banded soil	7.1	119	0.041 (0.042, 0.037, 0.043)

Except where otherwise noted, residues were <LOQ in untreated control samples.

Table 42: Residues of dichlobenil in grapes, mature berries (Maselli, 1998)

Location, Trial no., Year (Variety)	Application				DAT	Residues (mg/kg)	
	Date	Growth stage	Application method	Rate (kg ai/ha)		Dichlo benil	2,6- Dichlorobenza mide
Madera, CA, USA, CEJ- 96001, 1996 (Thompson seedless)	02/03/96	end of dormancy	Banded spray	8.1	177	< 0.02	0.029
Fresno, CA, USA, CEJ- 96002, 1996 (Thompson seedless)	01/03/96	end of dormancy	Banded spray	8.3	178	< 0.02	0.004

No residues were found in untreated control samples above the LOQ (0.02 mg/kg for dichlobenil, and 0.003 mg/kg for 2,6-dichlorobenzamide).

Raspberries

Two residue trials in raspberries were conducted in Oregon and Washington during 1990 (Dykstra, 1991c). A single broadcast soil application of dichlobenil was made during spring using a granular formulation at a target application rate of 4.48 kg ai/ha.

Raspberry samples were analysed for 2,6-dichlorobenzamide using a GC-ECD method (method number L 3-53-71, evaluated in detail above). Individual and mean method validation recoveries were within the range 70–120%. Samples were analysed within 49 days of collection. Mean storage stability recoveries for untreated control samples of raspberries fortified with 2,6-dichlorobenzamide were within the range 70–120% after 41 days storage. The residue trial samples are therefore unlikely to have been adversely affected by storage.

A further four trials in raspberries were reported (Reibach, 2013). A single broadcast soil application of dichlobenil was made using a 4% w/w granular formulation at a target rate of 4.48 kg ai/ha. Mature fruit was sampled, typically around 50–90 days after application.

Samples were analysed for both dichlobenil and 2,6-dichlorobenzamide residues using a GC-ECD method, a modification of the method in study number 2005-046 evaluated above, without the solid phase extraction cleanup. Mean method validation and quality control recoveries in raspberries were within the range 70–120%. Samples were stored frozen for up to 79 days between collection and analysis.

No residues were found in the untreated control samples above the LOQ (0.01 mg/kg for each analyte).

FATE OF RESIDUES IN PROCESSING

Plums

A processing trial for plums was conducted in Michigan (Hamilton, 1993). After a single banded soil application during spring of a 4% w/w granular formulation of dichlobenil at a target rate of 6.7 kg ai/ha, mature plums were harvested and shipped unfrozen for processing. Processing commenced the day after harvest. An unwashed raw plum sample was set aside, before processing the remaining plums into prunes using a batch process. Plums were dried to a target moisture content of 18-22% over a period of approximately 24 hours at temperatures from 66-82 °C. Samples were frozen within a few hours of completion of processing.

Frozen whole plums and prune samples were shipped to the laboratory for analysis of 2,6-dichlorobenzamide residues using a GC-ECD method (method number L 3-53-71, evaluated in detail above). The mean concurrent recovery for 2,6-dichlorobenzamide from prunes were within the range of 70–120%, although it is noted that some individual concurrent recovery values and the recoveries after only four days of frozen storage were < 70%. The plum samples showed storage stability recoveries within the 70–120% range after 35 days of storage. Plum and prune samples were analysed 39–40 days after harvest/processing, and prune samples may therefore have been adversely affected by storage.

Table 45 Residues of dichlobenil in plums and prunes

Location, Trial no., Year (Variety)	Application				Sam- ple	D A T	2,6-Dichlorobenzamide residue (mg/kg)	Referenc e
	Date	Growth stage	Application method	Rate (kg ai/ha)				
Conklin, MI, USA, C 201 50 048, 1992 (Stanley)	15/0 4/92	not stated	banded soil	6.7	plu ms	13 9	< 0.01 (< 0.01, < 0.01, < 0.01)	Hamilto n, 1993
					pru nes		0.01 (0.01, 0.01, 0.01)	

No residues were found in untreated control samples above the LOQ (0.01 mg/kg).

Residues of 2,6-dichlorobenzamide were observed to concentrate slightly in plums.

Grapes

Residue trials for generating processing data for grapes were conducted at two sites in California (Maselli, 1998). Plots of grapevines were treated with a single banded spray application at a target rate of 8.8 kg ai/ha of 4G dichlobenil formulation. The application was made just as the dormancy period was finishing. Grapes were sampled at maturity from the treated plots and untreated control areas, with separate samples for analysis of unprocessed grapes, and for processing into juice and raisins being collected. Unprocessed grapes were frozen within 4 hours of collection, while grapes for processing were kept at ambient temperature, with processing into raisins commencing on the day of harvest, and processing into juice 3 days after harvest.

For juice processing, grapes were crushed and destemmed using a commercial crusher-stemmer, and the wet mash was loaded into a hydraulic press for juicing. Juice samples were collected and stored frozen until analysis, while the wet pomace was discarded.

Grapes were processed into raisins by sun drying on paper trays for approximately 3 weeks, with the drying grapes being turned twice. Untreated control grapes were kept well separated from the treated grapes during drying. After drying to approximately 20% of the fresh weight, the stems were removed using simulated commercial equipment, involving first passing over a screen shaker to remove loose impurities such as leaf and stem fragments, then destemming followed by passing over a vacuum unit to remove remaining stem fragments and substandard raisins. The raisins were then passed through a sizing shaker to separate the smaller raisins normally used for baking or breakfast cereals, with the remaining raisins being passed over two further vacuum units to remove any remaining substandard raisins, and C-grade, which are discarded. The combined A- and B-grade raisins were washed and then rehydrated to commercial specification using a 'riffle' washer, followed by cleaning and visual inspection. A sample of raisins was collected and placed in frozen storage prior to analysis.

Residues of dichlobenil and 2,6-dichlorobenzamide in raw and processed grape samples were determined using a GC-ECD method very similar to method number 2005-046 evaluated in more detail above. Acceptable individual and mean method validation and concurrent recoveries in the range 70–120% were achieved in grapes, for both dichlobenil and 2,6-dichlorobenzamide. Analyses of dichlobenil in grapes were completed within 289 days of sample collection, those for raisins were completed within 277 days, and those for grape juice were completed within 277 days. Analyses of 2,6-dichlorobenzamide in grapes were completed within 124 days, those for raisins were completed within 276 days, and those for grape juice were completed within 275 days. A concurrent storage stability study was conducted, showing recoveries of dichlobenil and 2,6-dichlorobenzamide remaining within the range 70–120% after storage for 323 and 345 days respectively for grapes. In raisins, a storage stability trial was carried out over 273 days for dichlobenil, and 266 days for 2,6-dichlorobenzamide, with mean recoveries remaining within 70–120% at the end of storage. In grape juice, fortified samples were stored for 322 days (dichlobenil) and 343 days (2,6-dichlorobenzamide),

with mean recoveries remaining within 70–120%. The storage stability data shows that the raw and processed grape residue trial samples are unlikely to have been adversely affected by storage.

A second processing study was conducted in the USA (Ver Hey, 1992d). At a site in California, a single application of dichlobenil was made using a granular formulation at a target rate of 150 pounds of a 4% w/w formulation per treated acre (6.72 kg ai/ha), with the application made prior to flowering. The vines were irrigated (5.0-7.5 cm) on the day of application. Mature grape samples were collected for processing into juice and raisins.

Processing of grapes into juice and raisins commenced on the day of harvest. Limited information on processing was provided. Processing was conducted using domestic kitchen equipment rather than simulated commercial processes. The grapes were juiced using a food processor, and the juice was decanted. The remaining solids were collected as the wet pomace fraction, and a portion was placed in a cloth bag and the moisture squeezed to generate dry pomace. Raisins were sun dried over 19 days, and separated into raisins and raisin waste (stems and debris). Samples were frozen within 6 hours of collection.

Samples of grape juice, raisins, raisin waste, and wet and dry grape pomace were analysed for residues of 2,6-dichlorobenzamide using a GC-ECD method (method number L 3-53-71, evaluated above). Concurrent and stored recoveries (after 99, 108, 111, 79 and 101 days for juice, wet pomace, dry pomace, raisins and raisin waste respectively) were within the range 70–120%, with the exception of stored recoveries for raisins (mean stored recovery = 64%). Samples were analysed within 124–163 days of harvest of the grapes. Given the storage stability results for this and the Maselli study, with the possible exception of raisins, it is unlikely that the samples have been adversely affected by storage.

Samples were analysed in triplicate. The results are tabulated below. However it is noted that residues were not reported for raw grapes from the field site, so processing factors cannot be calculated.

Table 46: Processing study in grapes (Maselli, 1998)

Location, Trial no., Year (Variety)	Application				Sample	DA T	Residues (mg/kg)	
	Date	Growth stage	Applicatio n method	Rate (kg ai/ha)			Dichlobe nil	2,6-Dichloroben zamide
Madera, CA, USA, CEJ-96001, 1996 (Thompson seedless)	02/03/96	end of dormancy	Banded soil	8.1	Mature berries	177	< 0.02	0.029

Product	Processing factor
Raisins	<1, 2.8
Juice	0.93, 1.4

Moderate concentration of residues of 2,6-dichlorobenzamide is noted in both grape juice and raisins.

RESIDUES IN ANIMAL COMMODITIES

Farm animal feeding studies

Lactating cattle

A feeding study for the major plant metabolite of dichlobenil, 2,6-dichlorobenzamide (BAM), was conducted in lactating cattle (Batorewicz, 1998).

Sixteen lactating Holstein cattle were purchased and placed in quarantine for 7 days followed by a further 14 days of acclimatisation. Twelve cattle aged between 3-6 years and weighing 534-758 kg (mean milk production during the feeding phase was 17.9 L/animal/day, while mean feed intake was 18.9 kg dry matter/animal/day) were selected for the study on day 6 of acclimatisation from the group of sixteen. Three animals were randomly selected for each of the four groups: group I (untreated control), group II (low dose, 1× at a level of 0.6 ppm), group III (mid dose, 3×, at a level of 1.6 ppm), and group IV (high dose, 5×, at a level of 5.3 ppm). BAM was administered to the animals in groups II-IV orally once daily after the morning milking by capsule for 28 days. The control animals received blank capsules at the same time as the treated animals. The cattle were kept in outdoor pens with overhead shelter, with the different feeding groups being separated. *Ad libitum* access was allowed to fresh drinking water and a total mixed ration containing alfalfa hay, corn silage, rolled corn, cotton seed and various seed and grain by-products and mineral supplements. No adverse effects on cattle weight, feed consumption or milk yield were noted during the trial.

Milk samples were collected twice daily, and weighted pooled 200 gram subsamples (PM and the following AM) from selected days were frozen and submitted for analysis. The animals were sacrificed with 6 hours of the final dose and samples of liver, kidney, muscle (thigh and loin composite) and fat (composite of mesenteric and perirenal) were collected for analysis and frozen. Frozen tissue samples were processed by grinding in the presence of liquid nitrogen. The liquid nitrogen was allowed to evaporate in the freezer, and subsamples were collected for submission for analysis (250 grams for fat and 500 grams for other tissue types).

Samples were analysed for both dichlobenil and 2,6-dichlorobenzamide using a GC-MS method (method number 96145, evaluated in detail above). Mean concurrent recoveries in fortified control samples were generally within 70–120%.

Samples were stored frozen for up to 62 days (fat), 66 days (kidney), 70 days (liver), 63 days (muscle), and 66 days (milk) between collection and analysis. Storage stability was checked at fortification level of 0.05 mg/kg for both dichlobenil and 2,6-dichlorobenzamide. Acceptable storage stability was observed for 2,6-dichlorobenzamide in fat (62 days), kidney (67 days), liver (70 days), muscle (63 days), and milk (71 days), and for dichlobenil in muscle (63 days), fat (62 days), kidney (52 days), and milk (71 days). After 67 days storage, the mean stored recovery in kidney had dropped to 62%, although after correction for concurrent recovery, a corrected recovery of 70% was determined. Stability of dichlobenil in liver was poor, with mean recoveries of 43% after 55 days, and 31% after 70 days.

Residues of dichlobenil were not found above the LOQ (0.01 mg/kg) in any of the control or treated milk or tissue samples. Finite residues were found in tissue samples from all treatment groups, and in milk sample from the mid- and high-dose groups.

	1.6	0.018, 0.029, 0.021 (0.023)
	5.3	0.060, 0.053, 0.065 (0.059)
Fat	0	< 0.01
	0.6	Not analysed.
	1.6	0.010, 0.010, 0.009 (0.010)
	5.3	0.023, 0.017, 0.020 (0.020)

Residues of 2,6-dichlorobenzamide were not found above the LOQ (0.01 mg/kg) in the control milk samples.

Samples of fat and milk from the 1× treatment group were not analysed, as residues were either not detected or only found at the LOQ in samples from the 3× group. Residues of 2,6-dichlorobenzamide in milk peaked at or around day 22 of dosing. A clear linear relationship between feeding level and tissue residue was observed in liver and muscle ($r^2 > 0.95$), while the relationship was less clear for kidney ($r^2 = 0.61$).

Table 51: Relationship between dosing level and maximum tissue residue

Tissue	Regression equation (forced through origin)	r^2 value
Liver	$y = 0.0804x$	0.9974
Kidney	$y = 0.01x$	0.6008
Muscle	$y = 0.0128x$	0.9651

Table 52: Relationship between dosing level and mean tissue residue

Tissue	Regression equation (forced through origin)	r^2 value
Liver	$y = 0.0584x$	0.993
Kidney	$y = 0.0078x$	0.6108
Muscle	$y = 0.0114x$	0.9855

Figure 5 Mean milk residues over time in the 5 ppm feeding group

Poultry

A poultry feeding study was not provided to the Meeting.

APPRAISAL

Dichlobenil is a benzonitrile herbicide for use by soil application in fruit crops, including stone fruit, grapes, and other berry crops. Dichlobenil was scheduled at the Forty-fifth Session of the CCPR in 2013 for evaluation as a new compound by the 2014 JMPR. Data was provided on physicochemical properties, metabolism in food producing animals and plants, environmental fates, methods of analysis, stability of residues in stored analytical samples, GAP information, supervised residue trials, processing studies, and animal feeding studies.

The Meeting received information on processing of oranges, strawberries, onions, lettuce head and peas.

Processing factors calculated for the processed commodities for the above raw agricultural commodities, including previously estimated, are shown in the table below. STMP-Ps was calculated for processed commodities of strawberry, onion and peas for which maximum residue levels were estimated.

Chemical name and structure

The IUPAC name for dichlobenil is 2,6-dichlorobenzonitrile.

The following metabolites are discussed below:

2,6-Dichlorobenzamide (BAM)	
2,6-Dichloro-4-hydroxybenzamide	
4-Chloro-2(3H)benzoxazolone	
6-Chloro-2-methylthiobenzonitrile	

6-Chloro-2-methylsulfonylbenzonitrile	
S-(3-Chloro-2-cyano-6-hydroxyphenyl)-cysteine	
6-Chloro-3-hydroxy-2-thiobenzamide	
6-Chloro-3-hydroxy-2-methylsulfinylbenzamide	
6-Chloro-3-hydroxy-2-methylthiobenzamide	

Animal metabolism

The Meeting received information on the metabolism of ^{14}C -phenyl labelled dichlobenil in rats, lactating goats, and laying hens, and for the metabolism of ^{14}C -phenyl labelled 2,6-dichlorobenzamide (a significant plant metabolite) in lactating goats and laying hens.

Animal metabolism: dichlobenil

In rats, dichlobenil is metabolized via two metabolic pathways: hydroxylation at the 3 or 4 position followed by glucuronidation or sulphation and the second pathway includes substitution of one chlorine atom by glutathione, followed by cleavage and oxidation of the glutathione moiety to cysteine and ultimately thiol and sulfonyl derivatives.

Lactating goats were dosed orally, twice daily, with ^{14}C -phenyl dichlobenil at 10 mg/kg bw/day for three days. Milk was collected twice daily, with blood samples being collected just prior to

and at various intervals after the first and fifth doses. The goats were sacrificed 15 hours after the final dose.

The majority of the administered dose was excreted (39–45% in urine, 24–31% in faeces, 2.9–4.0% in cage wash, and 0.06 to 0.33% in milk). Carcass tissue accounted for 3.2 to 3.4 % of the administered radioactivity, while 1.1–3.3% remained in GI tract tissue, and 0.4–3.3% GI tract contents.

Levels in milk peaked after about 2 days of dosing, at 1.30 mg eq./kg. At sacrifice, total residues of 27 mg eq./kg were found in liver, 4.1 mg eq./kg in kidney, 2.4 mg eq./kg in fat, and 0.42 mg eq./kg in muscle. The proportions of residue extracted were variable, at 65–70% of TRR in milk, 65% in liver, 26% in fat, 13% in muscle, and 28% in kidney.

In muscle, a metabolite tentatively identified as 2-chloro-6-methylthiobenzonitrile predominated, at 11% TRR, with smaller amounts of S-(3-chloro-2-cyano-6-hydroxyphenyl)-cysteine (0.9% TRR) and an unidentified compound (1.3% TRR).

In fat, parent comprised 60% of the identified residue (16% of TRR), with the other 40% 2-chloro-6-methylsulfonylbenzonitrile (10% TRR).

In milk, S-(3-chloro-2-cyano-6-hydroxyphenyl)-cysteine comprised 11–21% TRR, 2-chloro-6-methylsulfonylbenzonitrile 14–38% of TRR, with 3.9–12% of an unidentified component; parent was only present at $\leq 1\%$.

In liver, the majority of residue was present as S-(3-chloro-2-cyano-6-hydroxyphenyl)-cysteine (95% of that identified, or 62% of TRR), with a small amount of 2-chloro-6-methylsulfonylbenzonitrile (3% of TRR).

In kidney, the largest component was 2-chloro-6-methylthiobenzonitrile (23% of TRR), with smaller amounts (1.1–2.5% of TRR) of S-(3-chloro-2-cyano-6-hydroxyphenyl)-cysteine, 2-chloro-6-methylsulfonylbenzonitrile, and an unidentified component.

Laying hens were dosed orally with ^{14}C -phenyl dichlobenil at 9.8–10.2 mg/kg bw/day for three days. The dose was administered twice daily, eggs were collected twice daily, with blood samples being collected just prior to and at various intervals after the first and fifth doses. The hens were sacrificed 15 hours after the final dose.

The majority of the administered dose was excreted, with a mean of 67% recovered in excreta, 4.2% in cage washings, and 6.1% in the GI tract at sacrifice. Eggs accounted for 0.44% of the dose, with levels not reaching a plateau during the study.

The proportions of residue extracted were variable, at 60% of TRR in eggs, 90% in liver, 15% in fat, 8% in muscle, and 39% in kidney.

In fat and eggs, 100% of the extracted residue was unchanged parent compound (15% and 60% of the TRR in fat and eggs, respectively). In muscle, the largest component was the tentatively identified 2-chloro-6-methylthiobenzonitrile (6.4% of TRR), with parent compound comprising 1.6% of TRR. Similar ratios were observed for liver (2-chloro-6-methylthiobenzonitrile; 85% of TRR and parent; 5.4% of TRR). Kidney contained a number of metabolites, the cysteine conjugate of hydroxylated dichlobenil (17% of TRR), parent (9.8% of TRR), 2-chloro-6-methylsulfonylbenzonitrile (5.1% of TRR), and 2-chloro-6-methylthiobenzonitrile (4.3% of TRR), with small amounts (1.2–1.6% of TRR) of two unidentified components.

Metabolism of dichlobenil in goats and hens was similar, although the degree of metabolism appeared to be higher in goats. The chief metabolic pathway was conjugation with cysteine, replacing one of the chlorine atoms, with or without hydroxylation at an adjacent position on the ring. This was followed by cleavage and oxidation of the cysteine moiety to yield methylthio and methylsulfonyl derivatives.

There are strong similarities to the metabolism of dichlobenil in rats, with hydroxylation and glutathione conjugation followed by cleavage of the glutathione moiety taking place in rats, goats and hens.

The only residue of significance in fruit is 2,6-dichlorobenzamide, with no parent being present. Only uses in fruit crops are under consideration at this stage, therefore the Meeting considers the metabolism of dichlobenil in animals to be of secondary importance to the animal metabolism of 2,6-dichlorobenzamide.

Animal metabolism: 2,6-dichlorobenzamide

A lactating goat was dosed orally with ^{14}C -phenyl 2,6-dichlorobenzamide at 13 ppm in feed daily for five days. Milk was sampled twice daily, and the animals were sacrificed 23 hours after the final dose.

The majority of the dose was excreted. In the low dose animal, 62% of the TAR was recovered in urine, 17% in faeces, 3.4% in cage washings, and 0.26% in milk. TRRs in milk reached a plateau of 0.048 mg eq./kg on day 3 of dosing. Total residues in muscle and fat at sacrifice were 0.25 and 0.024 mg eq./kg respectively, with higher residues in the metabolic organs, 9.4 and 1.2 mg eq./kg in liver and kidney respectively.

High proportions of the residue were extracted from the matrices using column extraction methods: > 90% in all cases.

Except for liver, unchanged 2,6-dichlorobenzamide was the most significant residue component, at 0.75 mg eq./kg in kidney (63% of TRR), 0.19 mg eq./kg in muscle (77% of TRR), 0.009 mg eq./kg in fat (40% of TRR), and 0.038 mg eq./kg (80% of TRR) in 72 hour milk.

In kidney, the cysteine conjugate derivatives 6-chloro-3-hydroxy-2-thiobenzamide and 6-chloro-3-hydroxy-2-methylthiobenzamide were also found at 0.25 mg eq./kg (21% of TRR) and 0.23 mg eq./kg (19% of TRR) respectively.

In liver, the most significant residue component was 6-chloro-3-hydroxy-2-thiobenzamide at 6.6 mg eq./kg (70% of TRR), followed by 6-chloro-3-hydroxy-3-methylthiobenzamide at 1.6 mg eq./kg (17% of TRR). Much smaller amounts of 2,6-dichlorobenzamide and 6-chloro-3-hydroxy-2-methylsulfinylbenzamide (0.09–0.16 mg eq./kg, or 0.98–1.7% of TRR) were also found in liver.

Small amounts of a component postulated as dichlobenil only on the basis of retention time comparison with a standard were found in muscle and fat, at 0.01 mg eq./kg (4.4% of TRR) and 0.005 mg eq./kg (24% of TRR) respectively.

The only component found in milk apart from 2,6-dichlorobenzamide was 6-chloro-3-hydroxy-2-thiobenzamide, at 0.006 mg eq./kg (13% of TRR).

Laying hens were dosed orally with ^{14}C -phenyl 2,6-dichlorobenzamide at a mean level of 12 ppm in feed daily for five days. Eggs were sampled twice daily, and the birds were sacrificed 23 hours after the final dose.

Around half the administered dose for the low dose group was excreted, with 49% recovered from excreta and 1.5% from cage washings. In the low dose hens 3.7% of the dose was recovered in eggs, with levels not having peaked over the five day dosing period, reaching 2.4 mg eq./kg in the final day eggs. Total residues of 8.6 mg eq./kg were found in liver and 5.0 mg eq./kg in kidney. Residues were lower in fat, skin and muscle, at 1.3, 1.9 and 1.9 mg eq./kg.

Extraction was essentially quantitative, with > 95% of the TRR extracted from all matrices.

With the exception of muscle and egg, where a single additional unidentified metabolite was found at < 6% of the TRR, the extracted residue in hen matrices comprised only unchanged 2,6-dichlorobenzamide.

While 2,6-dichlorobenzamide is largely unmetabolized by hens, the metabolism of 2,6-dichlorobenzamide in goats is somewhat similar to that of dichlobenil, with the main pathway being cysteine conjugation replacing one of the chlorine atoms, followed by cleavage and oxidation of the cysteine side chain to yield metabolites such as 6-chloro-3-hydroxy-2-thiobenzamide, 6-chloro-3-hydroxy-2-methylthiobenzamide, and 6-chloro-3-hydroxy-2-methylsulfinylbenzamide.

Plant metabolism

The Meeting received information on the metabolism of ^{14}C -phenyl labelled dichlobenil in apples and grapes.

Single outdoor grown apple trees were treated in mid-February at late dormancy with a soil application of a liquid formulation of ^{14}C -phenyl dichlobenil at 6.7 kg ai/ha, the GAP for most fruit crops. Total radioactive residues were determined in soil samples collected at various intervals, as well as in immature apples collected at 77 and 107 days after soil application, and mature fruit collected at harvest (137 days after application).

Total residues in apples were low, at 0.012, 0.028, and 0.042 mg eq/kg at 77, 107, and 137 (mature harvest) days after application, respectively. The majority of the residue in mature apples, 81% of the TRR, or 0.034 mg eq./kg, could be extracted with methanol. The only residue identified in apples was 2,6-dichlorobenzamide, at 0.024 mg eq./kg, or 57% of the TRR. Unidentified components were all < 0.01 mg eq/kg.

Small plots of outdoor grown grapevines were treated in mid-February at late dormancy with a soil application of a liquid formulation of ^{14}C -phenyl dichlobenil at 6.7 kg ai/ha. Total radioactive residues were determined in soil samples collected at various intervals, as well as in immature fruit collected at 159 and 190 days after soil application, and mature grapes collected at harvest (222 days after application).

The total radioactive residues in grapes were similar at the three sampling intervals, 0.32, 0.29, and 0.39 mg eq./kg at 159, 190 and 222 days respectively. Nearly all the residue in mature grapes collected at harvest could be extracted with methanol (99% of TRR, or 0.39 mg eq./kg). The most significant residue component in grapes was by far 2,6-dichlorobenzamide, at 0.34 mg eq./kg, or 87% of the TRR. A second metabolite, 2,6-dichloro-4-hydroxybenzamide was found at < 0.01 mg eq./kg, or 2% of the TRR, while unidentified components totalled 0.06 mg eq./kg, or 15% of the TRR.

The only significant metabolic pathway for dichlobenil in fruits is hydrolysis to give 2,6-dichlorobenzamide.

Environmental fate

As all residue trials considered by the Meeting involve soil application, in accordance with the FAO Manual, data for aerobic soil metabolism, soil surface photolysis, and hydrolysis were evaluated.

Dichlobenil

In an aerobic metabolism study conducted over 50 weeks at 24 °C in sandy loam soil, dichlobenil was principally lost through volatilization of the unchanged parent compound (57% of TAR after 50 weeks), and also by metabolism to 2,6-dichlorobenzamide (13% TAR), formation of bound residue (10% TAR), and mineralization to $^{14}\text{CO}_2$ (< 3%). The DT_{50} for dichlobenil was 13 weeks.

The Meeting noted that dichlobenil has low solubility in water, 14.6 mg/L at 20 °C. Hydrolysis of dichlobenil was insignificant, with no significant degradation in unsterilized aqueous buffer solutions over 150 days.

2,6-Dichlorobenzamide

The DT_{50} values for 2,6-dichlorobenzamide were up to 261 days (37 weeks) in soil. The Meeting noted that 2,6-dichlorobenzamide has a significantly higher water solubility than dichlobenil (2.7 g/L), and is very stable to hydrolysis.

The Meeting concluded that dichlobenil is principally lost from soil through volatilization of the parent compound, with secondary degradation pathways including metabolism to 2,6-dichlorobenzamide, binding to soil, and mineralization to CO_2 . Dichlobenil is relatively persistent, with a DT_{50} in soil of 13 weeks. Hydrolysis is not a significant pathway for degradation.

Residues in succeeding crops

No information on residues of dichlobenil in following crops was received by the Meeting, however such data is not needed given that only uses in permanent crops are under consideration.

Based on the available soil degradation data for 2,6-dichlorobenzamide in soil, the Meeting considers that there is potential for accumulation of soil residues of 2,6-dichlorobenzamide from application in multiple years. Modelling of multiple year soil accumulation using the DT_{50} value of 261 days for 2,6-dichlorobenzamide as a worst case indicates that residues of 2,6-dichlorobenzamide will reach a steady state level of $1.6\times$ the level resulting from a single application.

Methods of analysis

The Meeting received details of analytical methods for dichlobenil and 2,6-dichlorobenzamide residues in plant and animal matrices.

Analyses of dichlobenil in plant commodities involved extraction with ethyl acetate/hexane in the presence of anhydrous sodium sulphate, with clean-up by solid phase extraction using deactivated neutral alumina as the solid phase. Residues were determined by GC-ECD or GC-MS/MS. The method LOQ is 0.01 or 0.02 mg/kg.

Analyses of 2,6-dichlorobenzamide in plant commodities involved extraction with ethyl acetate in the presence of anhydrous sodium sulphate and filter pulp or diatomaceous earth. The extracts were cleaned up by solid phase extraction (neutral alumina), followed by analysis using GC-ECD or GC-MS/MS. The method LOQ is 0.003–0.03 mg/kg.

Mean recoveries in plant matrices were generally within the acceptable range of 70–120%, with the exception of 2,6-dichlorobenzamide fortified in grape juice at 0.003 mg/kg. However, acceptable recoveries were achieved at fortifications of 0.03 and 0.30 mg/kg.

Residues of dichlobenil and 2,6-dichlorobenzamide in animal commodities were determined using a GC-MS method. Fat samples were homogenized with hexane then partitioned into acetonitrile. Kidney, muscle and liver samples were homogenized with water and extracted with ethyl acetate. Residues were transferred into hexane and partitioned into acetonitrile. Milk samples were extracted with ethyl acetate, and the residues transferred into hexane, which was cleaned up by solid phase extraction (Florisol). An LOQ of 0.01 mg/kg was achieved for both analytes in all matrices.

Mean recoveries in animal matrices were within the acceptable range of 70–120%.

Suitable methods are therefore available for determination of both dichlobenil and 2,6-dichlorobenzamide residues in plant and animal commodities with an LOQ of 0.01 mg/kg for each analyte.

Multiresidue methods were not provided to the Meeting. However, the Meeting noted that the USA FDA multiresidue method PAM I has been successfully validated for dichlobenil and 2,6-dichlorobenzamide. The Meeting also noted successful validations of the QuEChERS method for determination of both dichlobenil and 2,6-dichlorobenzamide residues.

Stability of residues in stored analytical samples

Storage stability data for residues of dichlobenil and 2,6-dichlorobenzamide in plant and animal commodities were generated as part of the residue trial and animal feeding studies.

The data showed that residues of dichlobenil and 2,6-dichlorobenzamide were stable in plant samples for at least the period for which the residue trial and animal feeding study samples were stored between collection and analysis (up to 11 months in the case of grapes and grape juice).

Storage stability of 2,6-dichlorobenzamide residues in animal matrices was acceptable over the storage period in the feeding study (up to 71 days), while dichlobenil residues were stable in muscle, fat and milk. Poor stability was observed in liver and kidney, however based on the available metabolism and feeding data, detectable residues of dichlobenil parent compound are not expected in any animal commodities.

Definition of the residue

Plant metabolism studies were available for dichlobenil in fruit crops. In metabolism studies in apples and grapes where radiolabelled compound was applied to the soil, dichlobenil was metabolised almost exclusively to 2,6-dichlorobenzamide, which comprised 57% of the TRR in mature apples, and 86% in mature grapes. No dichlobenil parent compound was found in either apples or grapes, and only one other component, 2,6-dichloro-4-hydroxybenzamide, was found, albeit at a very low level, < 0.01 mg eq./kg, or 2.1% of the TRR, in grapes only. The JMPR considered that this was not of greater toxicological concern than 2,6-dichlorobenzamide and was covered by the toxicological evaluation of 2,6-dichlorobenzamide and dichlobenil.

It is further noted that in residue trials in stone fruit, grapes, and bush berry crops, where both dichlobenil and 2,6-dichlorobenzamide were both analysed, only 2,6-dichlorobenzamide was found at quantifiable levels.

Given that dichlobenil is almost exclusively metabolised to 2,6-dichlorobenzamide in the edible portions of fruit crops, the Meeting proposes that only 2,6-dichlorobenzamide be included in the residue definition for dichlobenil in plant commodities for both compliance with MRLs and dietary risk assessment.

In considering a residue definition for animal commodities, the Meeting noted that livestock are only likely to be exposed to 2,6-dichlorobenzamide residues through feeding, as parent compound is unlikely to be found in feeds, while 2,6-dichlorobenzamide may be present in finite amounts. Therefore, only the livestock metabolism studies for 2,6-dichlorobenzamide are of significance.

In hens, 2,6-dichlorobenzamide was largely unchanged, being the only residue detected in fat, liver and kidney, and the major residue in muscle and eggs. One unidentified component was detected in muscle and eggs but at low levels (< 6% of the TRR). In goats, unchanged 2,6-dichlorobenzamide was the largest residue component in kidney, muscle, fat, and milk. In liver, 6-chloro-3-hydroxy-2-thiobenzamide was the largest component, with 2,6-dichlorobenzamide only being present at low levels. The JMPR considered that this metabolite and others found in lactating goats were not of greater toxicological concern than 2,6-dichlorobenzamide and were covered by the toxicological evaluation of 2,6-dichlorobenzamide and dichlobenil. Given that 2,6-dichlorobenzamide is not significantly metabolised in poultry, and is the most significant residue in the milk and all tissues except liver of goats dosed with the compound, the Meeting proposes that only 2,6-dichlorobenzamide will be included in the residue definition for dichlobenil in animal commodities for both compliance with MRLs and for dietary risk assessment.

The $\log_{10}P_{ow}$ of 2,6-dichlorobenzamide (0.77) indicates low fat solubility. In the goat and hen metabolism studies, residues of 2,6-dichlorobenzamide were higher in muscle than in fat. Similar observations were made in the cattle feeding study. The Meeting concluded that the residues are not fat soluble.

It is noted that 2,6-dichlorobenzamide is not uniquely a metabolite of dichlobenil, as it is also a metabolite of the fungicide fluopicolide, evaluated by JMPR in 2009. A residue definition of *fluopicolide* was established for compliance with the MRLs for plant and animal commodities, and *fluopicolide* and 2,6-dichlorobenzamide, measured separately, for estimation of dietary intake for plant and animal commodities. Fluopicolide parent compound is the major residue resulting from use of fluopicolide. When 2,6-dichlorobenzamide is present in the absence of fluopicolide, it is most likely to have resulted from use of dichlobenil.

The Meeting considered residues of 2,6-dichlorobenzamide resulting from use of both dichlobenil and fluopicolide for establishment of MRLs and for dietary risk assessment.

The Meeting proposed the following definition of the residue (for compliance with the MRL and for dietary risk assessment, for plant and animal commodities): 2,6-dichlorobenzamide.

The residue is not fat soluble.

Residues of supervised residue trials on crops

The Meeting received supervised trial data for soil application of dichlobenil to stone fruit (peaches, cherries and plums) and berry fruit (grapes, raspberries, blackberries, cranberries and blueberries).

The Meeting noted that residues of 2,6-dichlorobenzamide may arise from use of fluopicolide as well as from use of dichlobenil. Therefore, the Meeting has estimated maximum residue levels and STMR and HR values for 2,6-dichlorobenzamide in crops treated with fluopicolide using the data evaluated by the 2009 Meeting.

Stone fruits***Cherries***

The critical GAP for dichlobenil in cherries is in the USA, where soil application at 6.7 kg ai/ha can be made in late autumn (15 November to 15 February) or early spring (up to 1 May). A harvest withholding period is not specified.

In trials on cherries conducted in the USA, $1 \times 7.4\text{--}7.6$ kg ai/ha soil application was made to cherry trees bearing immature fruit, with mature fruit being harvested 28 days later. Residues of 2,6-dichlorobenzamide were < 0.003 (12), and 0.004 (2) mg/kg.

The Meeting noted that most of the trials were conducted with application significantly later than specified on the label (in June or July rather than prior to 1 May), after fruit set. Insufficient trials matching GAP are available. Therefore, the Meeting did not estimate a maximum residue level for cherries.

Peaches

The GAP for dichlobenil in peaches in Canada is soil application at 7 kg ai/ha in late autumn or early spring, with no more than 7 kg ai/ha per season. A harvest withholding period is not specified.

In trials on peaches conducted in the USA, $1 \times 6.8\text{--}7.7$ kg ai/ha soil application was made, with fruit being harvested 20-68 days later. Residues of 2,6-dichlorobenzamide in peaches were < 0.01 , 0.01, 0.02, and 0.04 mg/kg.

The Meeting determined that there were insufficient data for establishment of a maximum residue level in peaches.

Plums

The GAP for dichlobenil in plums in Canada is soil application at 7 kg ai/ha in late autumn or early spring, with no more than 7 kg ai/ha per season. A harvest withholding period is not specified.

In trials on plums conducted in the USA, $1 \times 6.7\text{--}7.9$ kg ai/ha soil application was made, with fruit being harvested 139-154 days later. Residues of 2,6-dichlorobenzamide in plums were < 0.01 and 0.45 mg/kg.

The Meeting determined that there were insufficient data for establishment of a maximum residue level in plums.

Berries and other small fruits***Blueberries***

The GAP in the USA for blueberries involves soil application at 6.7 kg ai/ha, with application in late autumn (15 November to 15 February) or early spring (up to 1 May). No withholding period is specified.

In trials conducted on blueberries, a single soil application of dichlobenil was made in spring at 4.3 kg ai/ha. Residues of 2,6-dichlorobenzamide in blueberries at normal harvest (at a PHI of 51–58 days) were < 0.01 (3), and 0.015 mg/kg.

The Meeting determined that there were insufficient data for establishment of a maximum residue level in blueberries. Further, the Meeting noted that the trials were not conducted at the label rate, and the results were not amenable to the use of proportional scaling given that application was made at below GAP and the majority of the results were <LOQ.

Caneberries

The critical GAP for blackberries and raspberries in the USA is a soil application at 4.5 kg ai/ha made in late autumn (15 November to 15 February) or early spring (up to May 1). No withholding period is specified.

In trials conducted on blackberries and raspberries in the USA, where a single soil application was made at 4.3–4.9 kg ai/ha during spring (between mid-April and mid-May) or early summer (one trial with a mid-June application), residues of 2,6-dichlorobenzamide in mature blackberries and raspberries at normal harvest (44-89 DAT) were < 0.01 (2), 0.01, 0.02, 0.021, 0.031, 0.035, 0.056, and 0.067 mg/kg.

The Meeting noted that although a number of trials were conducted with application after 1 May, there did not appear to be a correlation between the application timing/interval and the residue level, and considered that all the trials were sufficiently robust to provide a realistic estimate of the residues.

The Meeting noted the potential for accumulation of residues of 2,6-dichlorobenzamide from application in successive years and agreed to scale the above values to account for multiple year applications by the factor of 1.6 $\times$ determined from modelling of the multiple year soil accumulation. The resultant scaled data set was: < 0.016 (2), 0.016, 0.032, 0.034, 0.050, 0.056, 0.090, and 0.11 mg/kg.

Based on the above scaled data set, the Meeting estimated a maximum residue level of 0.2 mg/kg for the subgroup caneberries, along with an STMR of 0.034 mg/kg, and an HR of 0.13 mg/kg (the scaled highest residue from an individual sample).

Cranberries

The GAP for cranberries in the USA is soil application at 4.5 kg ai/ha made in late autumn or early spring (no more than 4.5 kg ai/ha in a 12-month period).

In trials conducted on cranberries in the USA, where a single soil application was made during spring at 4.8-5.7 kg ai/ha, residues of 2,6-dichlorobenzamide in cranberries at normal harvest were 0.02 (2) mg/kg.

The Meeting determined that there were insufficient data for establishment of a maximum residue level in cranberries.

Grapes

GAP for grapes in the USA involves soil application at 6.7 kg ai/ha made in early spring, with a harvest withholding period not specified.

In trials conducted in the USA on grapes, where a single soil application was made between the end of dormancy, and the beginning of fruit set, at a rate of 6.7-8.3 kg ai/ha, residues of 2,6-dichlorobenzamide in grapes at normal harvest were 0.004, 0.029, 0.033, 0.042 (2), and 0.058 mg/kg.

The Meeting determined that six trials was insufficient for estimation of a maximum residue level for grapes.

Residues of 2,6-dichlorobenzamide in grapes resulting from use of fluopicolide (2009 evaluation) were: < 0.01 (28), 0.01 (2), 0.013, 0.014, 0.015, 0.02 (2), 0.026, 0.03, 0.037, and 0.04 mg/kg.

Based on the 2,6-dichlorobenzamide residues arising from use of fluopicolide, the Meeting estimated a maximum residue level of 0.05 mg/kg for grapes, together with an STMR of 0.01 mg/kg and an HR of 0.04 mg/kg.

Crops with a fluopicolide use but no dichlobenil use

Bulb vegetables

Residues of 2,6-dichlorobenzamide in bulb onions arising from use of fluopicolide were < 0.01 mg/kg (7). The Meeting estimated a maximum residue level of 0.01* mg/kg for 2,6-dichlorobenzamide in bulb onions, together with STMR and HR values of 0.01 mg/kg.

Residues of 2,6-dichlorobenzamide in Welsh onions arising from use of fluopicolide were < 0.01 (2), and 0.01 mg/kg. The Meeting estimated a maximum residue level of 0.02 mg/kg for 2,6-dichlorobenzamide in Welsh onions, together with STMR and HR value of 0.01 mg/kg.

Brassica vegetables

In the data set for head cabbage (with wrapper leaves) used by the 2009 Meeting for fluopicolide MRL estimation and dietary risk assessment, residues of 2,6-dichlorobenzamide were < 0.01 (6), and 0.02 mg/kg.

Residues of 2,6-dichlorobenzamide in Brussels sprouts arising from use of fluopicolide were < 0.01 (8) mg/kg.

In the USA data set for broccoli used by the 2009 Meeting for MRL estimation and dietary risk assessment for Flowerhead brassicas were < 0.01 (6) mg/kg.

The Meeting noted that 2,6-dichlorobenzamide residues of < 0.01 (6), 0.02, and 0.04 mg/kg were found in head cabbage grown as a rotational crop.

The Meeting agreed to combine the head cabbage dataset for 2,6-dichlorobenzamide residues resulting from in-crop use of fluopicolide with the dataset for residues of 2,6-dichlorobenzamide in head cabbage resulting from use of fluopicolide in a preceding crop:

< 0.01 (12), 0.02 (2), and 0.04 mg/kg

Recognizing that residues of 2,6-dichlorobenzamide could occur in brassica vegetables other than cabbage grown in rotation with a crop treated with fluopicolide, the Meeting decided to estimate a group maximum residue level of 0.05 mg/kg, together with an STMR of 0.01 mg/kg and an HR of 0.04 mg/kg, based on the combined head cabbage dataset.

Fruiting vegetables, Cucurbits

In the dataset for melons used by the 2009 Meeting for estimation of a group MRL for fruiting vegetables, Cucurbits, residues of 2,6-dichlorobenzamide were not detected: < 0.01 (9) mg/kg. It is noted that residues of 2,6-dichlorobenzamide were not detected in other cucurbit crops. The Meeting estimated a group maximum residue level of 0.01* mg/kg for fruiting vegetables, Cucurbits, together with an STMR and an HR of 0.01 mg/kg.

Fruiting vegetables, other than Cucurbits

In the data set in peppers, sweet and peppers, Chilli used by the 2009 Meeting to estimate a group maximum residue level for fruiting vegetables, other than Cucurbits, residues of 2,6-dichlorobenzamide were: < 0.01 (10) mg/kg. It is noted that residues of 2,6-dichlorobenzamide were not detected in other non-cucurbit fruiting vegetable crops. The Meeting estimated a group maximum residue level of 0.01* mg/kg for 2,6-dichlorobenzamide in fruiting vegetables, other than Cucurbits, together with an STMR and an HR of 0.01 mg/kg.

As residues of 2,6-dichlorobenzamide were not detected in chilli peppers treated with fluopicolide in the trials reported by the 2009 JMPR, the Meeting estimated an MRL of 0.01* mg/kg for 2,6-dichlorobenzamide in peppers, Chili, dried, together with an STMR and an HR of 0.01 mg/kg.

Leafy vegetables

The spinach data set was used by the 2009 Meeting to estimate a group MRL for leafy vegetables. Residues of 2,6-dichlorobenzamide in spinach arising from use of fluopicolide were 0.02, 0.03, 0.06, 0.07 (2), 0.09, and 0.19 mg/kg. The Meeting estimated a maximum residue level of 0.3 mg/kg for 2,6-dichlorobenzamide in leafy vegetables, together with an STMR of 0.07 mg/kg and an HR of 0.19 mg/kg.

Celery

In the dataset considered by the 2009 Meeting, residues of 2,6-dichlorobenzamide resulting from use of fluopicolide in celery were < 0.01 (4), 0.01, 0.03 and 0.04 mg/kg. The Meeting estimated a maximum residue level of 0.07 mg/kg for 2,6-dichlorobenzamide in celery, together with an STMR of 0.01 mg/kg and an HR of 0.04 mg/kg.

Rotational crops

Residues arising in rotational brassica crops are covered in the appropriate section above.

Low levels of 2,6-dichlorobenzamide residues were found in rotational pulse and cereal forages and fodders after application of fluopicolide to a preceding crop.

Residues of 2,6-dichlorobenzamide in rotational faba beans were < 0.01 (8) mg/kg.

The Meeting estimated a maximum residue level of 0.01* mg/kg for faba bean (dry), together with an STMR and an HR of 0.01 mg/kg. The Meeting agreed to extrapolate these values to establish a group maximum residue level for pulses.

Residues of 2,6-dichlorobenzamide in faba bean forage were < 0.01 (3), 0.01, 0.03, 0.06 (2), and 0.10 mg/kg (as received).

The Meeting estimated a median residue of 0.02 mg/kg, and a highest residue of 0.10 mg/kg for bean forage on an as received basis. The Meeting agreed to extrapolate these values to legume animal feeds.

Residues of 2,6-dichlorobenzamide in rotational wheat were < 0.01 (9) mg/kg.

The Meeting estimated a maximum residue level of 0.01* mg/kg for wheat, together with STMR and HR values of 0.01 mg/kg. The Meeting agreed to extrapolate these values to estimate a group maximum residue level and STMR/HR values for cereal grains.

Residues of 2,6-dichlorobenzamide in rotational wheat forage were < 0.01 (6), 0.01 (2), and 0.02 mg/kg (as received basis).

The Meeting estimated a median residue of 0.01 mg/kg and a highest residue of 0.02 mg/kg for wheat forage on an as received basis. The Meeting agreed to extrapolate these figures to cereal forage.

Residues of 2,6-dichlorobenzamide in rotational wheat hay (stalks and/or ears) were < 0.01 (6), 0.01, 0.03, and 0.06 mg/kg (as received).

As it was not clear that the samples had been dried, these values were converted to a dry weight basis assuming the 25% dry matter content for wheat forage: < 0.04 (6), 0.04, 0.12, and 0.24 mg/kg.

Residues of 2,6-dichlorobenzamide in rotational wheat straw were < 0.01 (7), 0.01, and 0.03 mg/kg on an as received basis.

Based on the hay data, the Meeting estimated a maximum residue level of 0.4 mg/kg for wheat straw and fodder, dry. The Meeting agreed to extrapolate this to straw and fodder (dry) of cereal grains.

The Meeting estimated a median residue of 0.04 mg/kg and a highest residue of 0.24 mg/kg for cereal hays based on the wheat hay data set and a median residue of 0.01 mg/kg and a highest residue of 0.03 mg/kg for cereal straws based on the wheat straw data set.

Fate of residues during processing

Plums

A processing study was provided for plums but as there was insufficient data to estimate a maximum residue level in plums, it will not be considered further.

Grapes

A processing study in grapes was provided. Grapes from a plot treated with dichlobenil at a target rate of 8.74 kg ai/ha were processed into juice and raisins, and processing factors of 1.4 and 2.8 respectively were determined for 2,6-dichlorobenzamide.

Based on the processing factor of 2.8 and the grape MRL of 0.05 mg/kg, the Meeting estimated a maximum residue level of 0.15 mg/kg for dried grapes. Based on the STMR and HR of 0.01 and 0.04 mg/kg respectively for grapes, the Meeting estimated an STMR-P of 0.028 mg/kg, and an HR-P of 0.11 mg/kg for dried grapes.

Based on the processing factor of 1.4, and the grape MRL of 0.05 mg/kg, the Meeting estimated a maximum residue level of 0.07 mg/kg for grape juice. Based on the STMR and HR values for grapes, the Meeting estimated an STMR-P of 0.014 mg/kg and an HR-P of 0.056 mg/kg.

Grape pomace is used as a feed for cattle. However, the processing study did not include results for pomace. Given that pomace consists of the dry matter remaining after manufacture of juice or wine, the Meeting estimated an STMR-P value of 0.028 mg/kg for grape pomace, dry, based on the processing data for raisins.

Tomatoes

As residues of 2,6-dichlorobenzamide were not detected in tomatoes, the Meeting confirmed the median residues and STMRs of 0.01 mg/kg estimated by the 2009 Meeting for tomato pomace, juice, paste and ketchup.

Residues in animal commodities

Feeding studies

A feeding study for 2,6-dichlorobenzamide in lactating dairy cattle was provided to the Meeting.

Lactating Holstein dairy cow were dosed daily by capsule with 2,6-dichlorobenzamide at the equivalent of 0.6, 1.6 and 5.3 ppm in the dry weight diet for 28 consecutive days. Milk was collected throughout, and the cattle were slaughtered within 6 hours of the final dose for tissue sampling. 2,6-Dichlorobenzamide residues were found at 0.011 mg/kg in milk from the 1.6 ppm group, and at 0.031 mg/kg in milk from the 5.3 ppm group. Residues of 2,6-dichlorobenzamide were found in most tissues at all feeding levels, except for fat. The relationships between dose and residues of 2,6-dichlorobenzamide in muscle, kidney and liver were linear.

Farm animal dietary burden

Dietary burden calculations incorporating all commodities considered by the current and 2003 Meetings for beef cattle, dairy cattle, broilers and laying poultry are presented in Annex 6. The

calculations are made according to the livestock diets of the USA/Canada, the European Union, Australia and Japan as laid out in the OECD table.

	US/CAN		EU		AU		Japan	
	Max.	Mean	Max.	Mean	Max.	Mean	Max.	Mean
Beef cattle	0.064	0.010	0.31	0.063	0.38	0.077	0.019	0.002
Dairy cattle	0.25	0.054	0.091	0.031	0.39	0.075	0.031	0.013
Poultry – broiler	0.009	0	0.01	0	0.012	0	0.022	0.029
Poultry – layer	0.009	0	0.096	0.017	0.012	0	0.006	0

Animal commodity maximum residue levels

The highest dietary burden for cattle is for Australia (maximum of 0.39 ppm for both beef and dairy cattle and mean values of 0.077 mg/kg for beef cattle and 0.075 mg/kg for dairy cattle).

Scaling the residues observed in milk at a feeding level of 1.6 ppm for the expected Maximum Feeding Level of 0.39 ppm shows that residues are not expected to be found above the LOQ in milk. The Meeting estimated a maximum residue level of 0.01* mg/kg for milk, together with an STMR of 0.01 mg/kg.

The calculated maximum residues for muscle, liver and kidney are tabulated below.

Tissue	Regression equation (forced through origin)	Calculated residue for 0.39 ppm residues of 2,6-dichlorobenzamide in feed (mg/kg)
Liver	$y = 0.0804x$	0.031
Kidney	$y = 0.01x$	0.004
Muscle	$y = 0.0128x$	0.005
Fat	Scaled from residue at LOQ (0.01 mg/kg) at 1.6 ppm feeding level	0.002

The calculated mean residues for muscle, liver and kidney are tabulated below.

Tissue	Regression equation (forced through origin)	Calculated residue for 0.075 ppm residues of 2,6-dichlorobenzamide in feed (mg/kg)
Liver	$y = 0.0584x$	0.004
Kidney	$y = 0.0078x$	0.0006
Muscle	$y = 0.0114x$	0.0009
Fat	Scaled from residue at LOQ (0.01 mg/kg) at 1.6 ppm feeding level	0.0004

Based on the calculated residues, the Meeting estimated a maximum residue level of 0.04 mg/kg for edible offal, mammalian, together with an STMR of 0.01 mg/kg and an HR of 0.031 mg/kg. The Meeting estimated maximum residue levels of 0.01* mg/kg for meat (mammalian, except marine mammals) and mammalian fats, together with STMR and HR values of 0.01 mg/kg.

Poultry

The highest dietary burden for poultry is for European laying hens (mean of 0.017 ppm and maximum of 0.096 ppm).

A poultry feeding study was not provided to the Meeting. In a metabolism study for 2,6-dichlorobenzamide in laying hens, after dosing at 10 ppm daily for five days, residues of 2,6-dichlorobenzamide were 8.5 mg/kg in liver, 4.8 mg/kg in kidney, 1.8 mg/kg in skin, 1.9 mg/kg in muscle, 1.3 mg/kg in fat, and 2.0 mg/kg in eggs.

Scaling the residues in hen matrices for the expected maximum and mean feeding levels in poultry, the following median and highest residues were calculated.

Tissue	Maximum residue	Median residue
Liver	0.081	0.014
Kidney	0.046	0.008
Muscle	0.018	0.003
Fat	0.012	0.002
Eggs	0.019	0.003

Based on the calculations for eggs, the Meeting estimated a maximum residue level of 0.03 mg/kg for eggs, together with an STMR of 0.01 mg/kg and an HR of 0.019 mg/kg.

Based on the calculations for liver, the Meeting estimated a maximum residue level of 0.1 mg/kg for poultry edible offal, together with an STMR of 0.014 mg/kg and an HR of 0.081 mg/kg.

Based on the calculations for muscle, the Meeting estimated an MRL of 0.03 mg/kg for poultry meat, together with an STMR of 0.01 mg/kg and an HR of 0.018 mg/kg.

Based on the calculations for fat, the Meeting estimated an MRL of 0.02 mg/kg for poultry fats, together with an STMR of 0.01 mg/kg and an HR value of 0.012 mg/kg.

RECOMMENDATIONS

Definition of the residue (for compliance with the MRL and for estimation of dietary intake for plant and animal commodities): *2,6-Dichlorobenzamide*.

The residue is not fat soluble.

The Meeting estimated the maximum residue levels, STMR and HR values below:

CCN	Commodity name	Recommended maximum residue level, mg/kg		STMR (P), mg/kg	HR (P), mg/kg
		New	Previous

FL = indicates values estimated to accommodate residues of 2,6-dichlorobenzamide arising from fluopicolide use.

DIETARY RISK ASSESSMENT

Long-term intake

The ADI for dichlobenil is 0–0.01 mg/kg bw. Finite residues of dichlobenil parent compound are not expected to be found in edible commodities, and parent compound has not been recommended for inclusion in the residue definition for dietary risk assessment. The Meeting concluded that the long-term intake of residues of dichlobenil when used in ways that have been considered by the JMPR is unlikely to present a public health concern.

The ADI for 2,6-dichlorobenzamide is 0–0.05 mg/kg bw. The International Estimated Dietary Intakes (IEDIs) for 2,6-dichlorobenzamide arising from both dichlobenil and fluopicolide were calculated for the 17 GEMS/food cluster diets using STMRs/STMR-Ps estimated by the current Meeting (see Annex 3 of the 2014 JMPR Report). The calculated IEDIs were 0–1% of the maximum ADI (0.05 mg/kg bw). The Meeting concluded that the long-term intakes of residues of 2,6-dichlorobenzamide, resulting from the uses of dichlobenil considered by the current Meeting and from the uses of fluopicolide considered by the 2009 Meeting are unlikely to present a public health concern.

Short-term intake

The ARfD for dichlobenil is 0.5 mg/kg bw (for women of childbearing age only). Finite residues of dichlobenil parent compound are not expected to be found in edible commodities, and parent compound has not been recommended for inclusion in the residue definition for dietary risk assessment. The Meeting concluded that the short-term intake of residues of dichlobenil when used in ways that have been considered by the JMPR is unlikely to present a public health concern.

The ARfD for 2,6-dichlorobenzamide is 0.3 mg/kg bw (for women of childbearing age only). The International Estimated Short-Term Intakes (IESTIs) for 2,6-dichlorobenzamide arising from dichlobenil and fluopicolide were calculated for food commodities and their processed commodities using HRs/HR-Ps or STMRs/STMR-Ps estimated by the current Meeting and by the 2009 Meeting as part of the evaluation of fluopicolide (see Annex 4 of the 2014 JMPR Report). The calculated IESTIs were 0–2% of the ARfD for all commodities. The Meeting concluded that the short-term intake of residues of 2,6-dichlorobenzamide, when dichlobenil and fluopicolide are used in ways that have been considered by the JMPR, is unlikely to present a public health concern.

DIMETHOMORPH (225)

First draft was prepared by Dr Anita Stromberg, National Food Agency, Uppsala, Sweden

EXPLANATION

Dimethomorph, a cinnamic acid derivative, is a member of the morpholine group of fungicides and consists of a mixture of the E and Z isomers in approximately equal proportions. Its mode of action is through the disruption of fungal cell wall formation. When applied as a foliar spray dimethomorph penetrates the leaf surface and is translocated within the leaf to provide protectant action against plant pathogens belonging to class Oomycetes order Peronosporales. The fungicide is selective for downy mildews and members of the genus *Phytophthora*. Dimethomorph was evaluated for the first time by the JMPR in 2007. The 2007 meeting established an acceptable daily intake (ADI) of 0–0.2 mg/kg bw and an acute reference dose (ARfD) of 0.6 mg/kg bw. The residue (for compliance with the MRL and for estimation of dietary intake) for plant and animal commodities was defined as dimethomorph (sum of isomers). Maximum residues levels for 20 commodities were proposed by JMPR 2007.

Dimethomorph was listed by the Forty-fifth Session of the CCPR (2013) for evaluation of additional MRLs. The 2014 Meeting received GAP information and residue trial data from uses as foliar spray, soil drench or drip irrigation in oranges, strawberries, grapes, papaya, bulb onions, leek, spring onions, head cabbage, broccoli, pepper, lettuce leaf, spinach, lettuce head, taro, green peas, vining peas, lima beans, artichoke, and celery. An analytical method for animal matrices was provided as well as validation data for an analytical method in oranges. Processing studies in oranges, strawberry, onion, lettuce head and peas were also provided.

ANALYTICAL METHODS

The Meeting received a summary of validation data for the method Agriquem PE-804 which was developed for determination of dimethomorph residues in citrus fruits (doc. code 2010/1089351). The method (extraction method and extraction efficiency) was already reviewed by the JMPR in 2007. The method validation data for citrus was carried out concurrently with the analysis of the residue trials and not carried out as a separate project. The recoveries obtained as part of method validation for the parent dimethomorph (sum of isomers) in citrus fruit are presented in Table 1.

Table 1 Recovery data for the method Agriquem PE-804 for dimethomorph in citrus

Matrix	reported LOQ mg/kg	spike level	n	% recovery		RSD	Trial references
				mean	range		
Orange pulp	0.01	0.025	8	101.0	96–108	5.9	2006/1015077
		0.05	8	110.8	92–110	6.5	2005/1034175 2006/1015076
		0.1	8	81.6	73–88	6.0	2006/1015076
		0.2	4	97.3	94–104	4.9	2005/1034175
Orange whole fruit	0.01	0.05	8	88.5	78–106	9.9	2006/1015076 2006/1015076
		0.075	4	91.0	84–106.67	15.8	2005/1034175
		0.1	4	95.5	88–106.0	9.4	2006/1015076
		0.15	8	88.4	81.33–109.33	10.9	2006/1015076
		0.3	4	81.3	81.0–81.67	0.4	2005/1034175
Orange peel	0.01	0.075	6	87.1	72–104	14.4	2006/1015076
		0.1	4	91.0	87.0–95.0	4.5	2005/1034175
		0.15	6	75.3	71.33–78.67	3.9	2006/1015076
		0.2	4	100.4	92.0–106.5	6.1	2006/1015076
		0.25	4	87.0	77.2–79.2	12.2	2006/1015077
		0.4	4	86.7	73.0–93.25	10.7	2005/1034175

The recovery in all the matrices and fortification levels was in the acceptable range 70–110%. The relative standard deviation for all matrices was within the adequate level below 20%.

A new analytical method for animal matrices was submitted to the 2014 Meeting. In this method dimethomorph is extracted with methanol/water/hydrochloric acid. The extract is partitioned against cyclohexane at alkaline conditions and then evaporated to dryness and dissolved in a methanol/water mixture. The final determination of dimethomorph is performed by HPLC-MS/MS at two transitions. Transition m/z 388 $\rightarrow$ 301 is proposed as target transition for quantification and transition m/z 388 $\rightarrow$ 165 for confirmatory purposes. The limit of quantification is 0.01 mg/kg for dimethomorph in milk, egg, muscle and liver.

Table 2 Recovery result of dimethomorph residues using method LO138/01 in different animal tissues

Sample Matrix	Dimethomorph	Fortification level	Average recovery%	RSD%	No of analysis
Egg	Dimethomorph m/z 388-301	0.01	100.4	1.9	5
		0.1	100.9	2.3	5
	Dimethomorph m/z 388-165	0.01	97.8	1.9	5
		0.1	100.9	1.6	5
Fat	Dimethomorph m/z 388-301	0.01	95.1	0.9	5
		0.1	105.2	2.5	5
	Dimethomorph m/z 388-165	0.01	96.7	2.6	5
		0.1	104.8	1.8	5
Kidney	Dimethomorph m/z 388-301	0.01	99.5	3.9	5
		0.1	98.1	2.6	5

The method was independently validated with recoveries in milk, egg, muscle and liver in the range of 70–110% and a RSD of $\leq 20\%$.

USE PATTERN

Dimethomorph is a morpholine fungicide with protective action against plant pathogenic Phytophthora species and a number of downy mildew diseases on fruit, vegetables and potato.

The fungicide is registered in around 100 countries worldwide. Information on registered uses together with labels for dimethomorph was provided to the Meeting by one manufacturer. The representative uses relating to the crops under consideration for additional MRLs and revising some of the existing CODEX MRLs are summarized in the following tables.

Table 3 Selected representative uses of dimethomorph on berries and other small fruit as well as fruit and assorted and sub-tropical fruits crops and bulb vegetables (from labels provided)

* Trials were evaluated by JMPR 2007. See Evaluation report for dimethomorph, Table 48

Conditions of the supervised residue trials were generally well reported in detailed field reports. In most trials treated plots were not replicated but where results were reported from replicate plots, these are presented as individual values. Field reports provided data on the sprayers used and their calibration, plot size, residue sample size and sampling date. Although trials included control plots, no control data are recorded in the tables except where residues in control samples exceeded the LOQ. Residue data are recorded unadjusted for % recovery. When residues were not detected they are shown as below the LOQ (e.g. < 0.01 mg/kg). Laboratory reports included methods validation with procedural recoveries from spiking at residue levels similar to those occurring in samples from the supervised trials. Data on duration of residue sample under storage were also provided. Residues and application rates have generally been rounded to two significant figures or, for residues near the LOQ, to one significant figure. Where trials have involved two or more applications, the mean target application rate has been recorded unless the individual rates differ by more than 10%.

Residues values from trials conducted according to a maximum registered GAP with supporting trials have been used for the estimation of maximum residue levels. The results included in the evaluation of the MRL, STMR and HR is underlined.

Oranges

Eight outdoor trials performed during growing season 2004–2005 in Spain were presented to the 2007 and 2014 Meeting. Two broadcast spray applications of dimethomorph at 0.41 kg ai/ha were made at 15 day intervals 28 ± 1 and 14 ± 1 days before harvest.

Mature fruit were sampled and both the whole fruit and the pulp were analysed separately by LC-MS/MS, using Method PE 804 approved at this Meeting (see chapter analytical method). The limit of quantification was 0.01 mg/kg for and the mean recovery was 73–104.5.2% at fortification levels of 0.05–0.3 mg/kg for pulp, whole fruit and peel. The results of the residues from dimethomorph are summarized in Table 7.

Grapes

During growing season 2008 eight outdoor trials on grapes were conducted in the USA. Dimethomorph was applied four times as a foliar spray using a 6–8 days interval. The applications of the concentrate (0.04–0.06 kg ai/hL) and the dilute (0.009–0.02 kg ai/hL) were made to side by side plots. The timing of the applications was from BBCH 7 (developing of fruits) until BBCH 8 (ripening of fruits).

The samplings of fresh grape fruits were analysed using HPLC-MS/MS Method 575/0. The limit of quantification was 0.01 mg/kg and the mean recovery was 71–115% at fortification levels of 0.01–5.0 mg/kg. The results are summarized in Table 8.

Strawberries

Twenty one additional (protected and outdoor) trials where dimethomorph was applied as root drench or drip irrigation and four additional (outdoor) trials where dimethomorph was applied as a foliar spray, were presented.

Root drench /drip application

In eight protected trials performed 2004 and 2007 on strawberries in three cultivars in Europe (Belgium, the Netherlands, Germany, Denmark, and northern France) dimethomorph was applied once as a root drench (green house) or (plastic tunnel) at planting/transplanting. The trials from 2004 included in addition to the treatment 0.125 g ai/plant, the treatment 0.0625 g ai/plant. The PHI was 34–46 days. The results are summarized in Table 9.

In two greenhouse trials on strawberries in Spain and south of France during growing season 2007 dimethomorph was added twice with a 14 days interval to the drip irrigation system in an amount of 0.75 kg ai/ha. The residue decline was measured 0, 1, 3 ± 1 and 7 ± 1 days after treatment. The results are summarized in Table 10.

In three outdoor trials on strawberries in Europe 2004 (Belgium, Germany and the Netherlands) dimethomorph was applied once as a root drench at planting/transplanting. The trials from 2004 included in addition to the treatment 0.125 g ai/plant, the treatment 0.0625 g ai/plant. The PHI was 43 ± day. The results are summarized in Table 11.

In eight outdoor strawberry trials in Spain dimethomorph) was added twice to the drip irrigation system in an amount of 0.75 kg ai/ha 15 ± 1 day before harvest. Duplicate samples of strawberry fruits were sampled 0, 3, 7, 21 and 28 days after last application. PHI was one day. The results are summarized in Table 12.

Foliar spray application

In four independent outdoor strawberry trials (four cultivars) from northern Europe (Belgium, Germany, the Netherlands and United Kingdom) dimethomorph was applied once as a foliar spray at 1.5 kg ai/ha, the PHI was 35 days. The results are summarized in Table 13.

Analytical methodology

Mature fruit were sampled. In the trials reported from 2004 the strawberry fruits were analysed using GC-NDP and an extended version of the DFG S19 method reviewed by JMPR 2007. The mean recovery rate for the revised method was 90.5–111.5% at fortification levels of 0.01–1 mg/kg. The limit of quantification was 0.01 mg/kg.

In outdoor drip irrigations trials from Spain the analytical was LC-MS method PE 804 with a limit of quantification of 0.01 mg/kg, and the mean recovery rates were 89–99.2% at fortification levels of 0.015–0.3 mg/kg. The analytical method 575/0 using HPLC-MS/MS were used in the trials reported from 2008 and onwards. The limit of quantification for this method was 0.01 mg/kg and the mean recovery rates were 92–106% at fortification levels of 0.01–1 mg/kg.

^c Residues taken from specimen labelled as untreated. The corresponding treated specimen had residue levels < 0.01 mg/kg. It is assumed that there has been a mistake at the labelling either in the field or in the analytical phase.

Papaya

Four field trials were conducted 2011 in Brazil. Dimethomorph was applied four times as a foliar spray from the beginning of ripening until full maturity of the fruits with a 6–8 days interval.

Samples of mature whole fruit (peel and pulp) was analysed with LC/MS/MS/ using Method 535/1, The limit of quantification was 0.01 mg/kg and the mean recovery was 95–92% at fortification levels of 0.01–1.0 mg/kg. The results are summarized in Table 14 below.

^a with 1000 L water/ha^b During conduction of this trial ripe fruit were discarded, therefore a decrease in BBCH is observed.

Bulb onions

Ten residue decline trials were conducted in the USA and Canada during growing season 2008. Three broadcast spray applications of dimethomorph were done at a 4–8 days interval. The growth stage for the applications varied from BBCH 19 (vegetative) until BBCH 81 (mature bulbs). Duplicate samples of onion bulb were analysed using HPLC-MS/MS Method 575/0. The limit of quantification was 0.01 mg/kg and the mean recovery was $85.9 \pm 11.8\%$ at fortification levels of 0.01–1.0 mg/kg. The results are summarized in Table 15.

Eight residue trials were performed in the USA during growing season 1999. Seven foliar directed applications were done with a 6–8 days interval. The growth stage of the applications varied from vegetative to mature bulbs. Duplicated samples were analysed using HPLV/UV Method FAMS 002/004 approved grapes at the 2007 Meeting. The limit of quantification was 0.01 mg/kg and the recovery was 70–120% at fortification levels of 0.01–0.1 mg/kg. The results are summarized in Table 15.

Leek

Nineteen residue decline trials were conducted in Europe during growing seasons 1999 and 2006. Dimethomorph was applied three times as a foliar spray. The applications were made 34–14 ± 1 days before harvest with a spray interval of 10–11 days.

Samples of leek stems were analysed using LC/MS/MS Method 575/0. The limit of quantification was 0.01–0.02 mg/kg and the recovery was 74–103%. The results are summarized in Table 16.

^a Spray volumes of 372–600 L/ha

Spring onions

During growing season 2011 three outdoor trials were conducted in the USA. Three broadcast spray applications of dimethomorph were made at a 5–6 days interval. The growth stage for the applications varied within BBCH 41–49 (development of harvestable vegetative plant parts).

Three outdoor residue decline trials were conducted in USA 2008. Three broad cast spray applications of dimethomorph were made at a 4–8 days interval. The growth stage for the applications varied from 12 days before first sampling until growth complete.

Duplicate samples from treated plots were analysed with LC/MS/MS using Method 575/0. The limit of quantification was 0.01 mg/kg and the mean recovery was 76–114% and 74–93% for the trials from 2011 and 2008 respectively at fortification levels of 0.01–10.0 mg/kg. The results are summarized in Table 17.

During growing season 1999 four trials were performed on spring onions in the USA. Seven to eight foliar directed spray applications of dimethomorph formulation were made at 5–8 days interval. The growth stage for applications varied within growth stage development of harvestable vegetative plant parts (BBCH 41–49) from vegetative until vegetative (mature).

Duplicate samples (whole vegetable) from treated plots were sampled on the day of seventh application. The samples were analysed with LC/MS/MD using Method 575/0. The limit of quantification was 0.05 mg/kg and the mean recovery was 92–114% at fortification levels of 0.05–5.0 mg/kg. The results are summarized in Table 18.

Pepper (bell and non-bell)

Twelve outdoor trials on bell peppers and non-bell peppers were conducted in the USA during growing seasons 1998 and 1999. Seven foliar broadcast applications of dimethomorph were made with a 4–15 days interval. The growth stage for the applications was from vegetative (5–16 cm) to mature heads. Three of the trials were decline trials.

Duplicate samples were analysed using GC-ECD method FAMS 002-04. The average procedural recovery range for dimethomorph was (95–119%) at the fortification level of 0.025–5 mg/kg and the limit of quantification was 0.025 mg/kg. The results are summarized in Table 21.

Lettuce, head

Eight outdoor residue decline trials from the USA (seven) and Canada (one) in lettuce head were conducted during growing season 2008. Dimethomorph was applied three times as a foliar broadcast spray and a spray interval of 4–8 days. The timing of the applications was from head development until mature heads. Duplicate samples (fresh heads with wrappers leaves) were analysed with HPLC-MS/MS using Method 575/0. The limit of quantification was 0.01 mg/kg and the mean recovery 75% at fortification levels from 0.01–20.0 mg/kg. The results are summarized in Table 23.

In six similar trials from the USA made in during the growing season of 1998, dimethomorph was applied seven to eight times as foliar spray with a spray interval of 5 to 11 days. Mature heads were analysed using GC-ECD and Method FAMS 002-04. The limit of quantification was 0.025 mg/kg and the mean recovery 101 ± 15 fortification level from 0.025–10 mg/kg. The results are summarized in Table 24.

Lettuce, leaf

Nine field trials were conducted in USA in during growing season 2008. Dimethomorph was applied three times as a foliar broadcast spray and intervals of 4–8 days. The growth stage for the applications varied from vegetative stage until BBCH 49. Duplicate samples of mature leaves were sampled and analysed with HPLC-MS/MS using Method 575/0. The limit of quantification was 0.01 mg/kg and the mean recovery 75% at fortification levels from 0.01–20.0 mg/kg. The results are summarized in Table 25.

Nine field trials were conducted in the USA during growing season 1998. Dimethomorph was applied seven times as foliar spray at 0.2 kg ai/ha and spray interval of 3–6 days. Duplicate samples of leaves were analysed with GC-ECD using Method FAMS 002-04. The limit of quantification was 0.1 mg/kg and the mean recovery 98 ± 8 fortification level from 0.1–10 mg/kg. The results are summarized in Table 25.

Taro, leaf

Three field trials on taro were conducted in Hawai during growing season 2000. Dimethomorph was applied seven times as a foliar spray (spray interval of 7 to 8 days) or drip irrigation.

Duplicate samples of leaves were analysed using GC-ECD and Method FAMS 002-04. The limit of quantification was 0.01 mg/kg and the recovery 76–119% at fortification level 0.01–10 mg/kg for leaves. The results are summarized in Table 27.

*Legume vegetables**Pea, Shelled, (succulent seed)*

Two field trials were conducted in France and Germany during the growing season of 2005. Dimethomorph was applied as foliar broadcast application two times 29 and 21± 1 day before harvest. Samples of peas were analysed by LC-MS/MS using Method 575/0. The limit of quantification was 0.01 mg/kg and recovery 79–89% for peas with pods and 83–96% for rest of plants without roots at fortification level 0.01–10 mg/kg. The results are summarized in Table 28.

During the growing season of 2006 ten field trials were conducted on green peas in Spain, France (north and south), Germany, the Netherlands and Denmark. Dimethomorph was applied as foliar broadcast application two times 29 and 21± 1 day before harvest. Samples were analysed using LC-MS/MS and Method 575/0. The limit of quantification was 0.01 mg/kg and recovery 83–95% for peas with pods and 80–97% for rest of plants without roots at fortification level 0.01–10 mg/kg. The results are summarized in Table 28.

Vining peas

During the growing season of 2008 four field trials were conducted on vining peas in Northern France, Germany and the Netherlands. Dimethomorph was applied as a foliar broad cast application two times 29 ± 1 and 21 ± 1 days before harvest. Samples (peas with pods and rest of plant w/o roots) were collected directly after the second application. Samples of pods and seed were taken at and 20 ± 1 day after the last treatment. Pea seeds were analysed using LC-MS/MS and the Method 535/1. The limit of quantification was 0.01 mg/kg and the recovery 72–110% for the different samples (n2) at fortification levels 0.01–10 mg/kg. The results are summarized in Table 29.

Lima Beans

During the 2002 and 2003 growing season seven field trials on Lima beans were conducted in the USA. Dimethomorph was applied as a foliar broad cast spray seven times with an interval of 5–11 days. Duplicate samples were analysed using GC-MSD and the Method FAMS 002-04 approved for grapes the 2007 Meeting. The limit of quantification was 0.01 mg/kg and the recovery 71–123% for the different samples at fortification levels 0.01–1 mg/kg. The results are summarized in Table 27.

During the growing season 2010 three field trials on Lima Beans was conducted in the USA. Dimethomorph was applied as foliar broad cast spray five to six times with an interval of 6–8 days. Duplicate samples were collected (pods) at the same day as the last application and frozen within 30 minutes. The lima beans were analysed with GC-MSD using Method FAMS 002-04. The limit of quantification was 0.01 mg/kg and the recovery 85–102% for the different samples at fortification levels 0.01–1 mg/kg. The results are summarized in Table 30.

*Root and vegetable crop**Ginseng*

Four outdoor trials were conducted in the USA during growing season 2004. Dimethomorph was applied seven times from blooming until berries dropping. In three trials dimethomorph was applied as a broadcast foliar spray and in one trial via drip application.

Duplicate samples were analysed using Method FAMS 073-03 to measure dimethomorph residues in ginseng roots. The limit of quantification of this method was 0.08 mg/kg and the mean recovery was 87.3–96.9% at fortification levels of 0.05–5 mg/kg. The results are summarized in Table 31.

*Stalk and stem vegetable**Globe artichoke*

Ten outdoor trials on globe artichoke from Germany, northern and southern France, the Netherlands, Spain and Italy conducted during the growing season 2006 and 2007. Dimethomorph was applied three times by foliar broadcast spray in intervals of 7 ± 1 day. The timing of the applications was from 17 until $3 \pm$ days before harvest.

Samples (artichoke heads) were analysed by HPLC-MS/MS using method 575/0. The limit of quantification of this method was 0.01 mg/kg and the recovery was 70–110% at fortification levels of 0.01 and 1.0 mg/kg. The results are summarized in Table 32.

^a Spray volumes of 400 L/ha*Celery*

Nine outdoor residue decline trials on celery from the USA and Canada performed during growing season 2008. Dimethomorph was applied three times as a foliar broadcast spray with and spray intervals of 4–6 days. The timing of the applications was from vegetative stage (35–40 cm) until stalk elongation.

Duplicate samples were analysed by HPLC-MS/MS using Method 575/0. The limit of quantification was 0.01 mg/kg and the mean recovery $78 \pm 8\%$ at fortification levels from 0.01–10.0 mg/kg. The results are summarized in Table 33.

Taro corm (root)

Three field trials on taro were conducted in Hawai during growing season 2000. Meeting. Dimethomorph was applied seven times as a foliar spray or drip irrigation. Dimethomorph was applied with a spray interval of 7 to 8 days to the vegetative stage (growth height 1.2 m to 1.7 m).

The cormes were analysed using GC-ECD and Method FAMS 002-04. The limit of quantification was 0.01 mg/kg and the recovery 76–119% at fortification level 0.01–10 mg/kg for leaves. The results are summarized in Table 34.

Fate of residues in storage and processing

Oranges

During the 2011 growing season four independent field trials were conducted in oranges (sweet) in Spain to determine the potential for concentration of residues in juice, marmalade, pulp, pomace, pulp and oil after processing to these commodities. Treated plots received two foliar applications of dimethomorph (DC formulation) at a rate of 1.22 kg ai/ha 28 and 14 days before harvest. Samples of whole fruits were taken on the day of the last application (BBCH 83–85) and 14 ± 1 day later (BBCH 89).

The processing of oranges was conducted with samples taken at the last sampling using simulated commercial processing procedures according to the flowchart below. During processing, nine different fractions of orange products or intermediates were collected for analysis specifically; juice, wet pomace, dried pomace, marmalade, peel after oil extraction, pulp, peel, dried pulp and oil.

Strawberry (doc. code 2012/1002401)

During the 2007 growing season four independent field trials in strawberries were conducted in Germany to study the potential of concentration of residues in jam and canned fruit after processing to these commodities. Dimethomorph (WP formulation) was applied once at (0.375 g ai/plant) which are 2–3 times maximum label rate for foliar and soil drench applications respectively. Samples of strawberries were collected 35 days after last application according to critical GAP.

The samples were processed into washed fruit, jam and canned fruit. During processing using simulated commercial processing procedures according to flow diagram in flowchart below different fractions of strawberry intermediates were collected for analysis; specifically washed strawberries, wash water, jam before cooking, jam after cooking, canned strawberries and vegetable stock.

^a Transfer factor = residue in processed fraction (PF)/ residue in RAC^b Trial 1: FR 24/07/50, Trial 2: FR 24/07/70, Trial 3: 24/07/30, Trial 4: 24/07/75. These trials are not reported in details here*Onion (doc. code 2010/1093126)*

During the 2009 growing season four independent trials in bulb onions (*Allium cepa*) were conducted in Germany to study the potential of concentration residues in dried onion, peeled onions and in peel after processing to these commodities. Dimethomorph was applied two times 28 and 14 days before harvest at 0.54 kg ai/ha which is two times the label rate but one time less than maximum number of applications. Samples of onions bulbs were collected on the day of last application and 7±1 days later. The processing of onions was conducted with samples taken at the last sampling which is 7 days later than in cGAP.

Onion bulbs were washed (3 min) with cold tap water immediately before processing. The green leaves were cut off followed by peeling using a knife. The peeled onions were cut into slices and dried in an oven in cycles from 90 °C 20 minutes, 60 °C 20 minutes and 50 °C until the dry weight of 4–6% was reached. After processing four different fractions on onion products or intermediates were collected for analysis, specifically onion bulbs, dried onions, peeled onions and peel.

Residues of dimethomorph were determined by LC-MS/MS using method No. 575/0. The limit of quantitation was 0.01 mg/kg and the mean recovery rate from 84–99% at fortification levels of 0.01–10 mg/kg in the different matrices. The results are summarized in Table 38..

^a Transfer factor = residue in processed fraction (PF)/ residue in RAC^b Trial 1: L090306, Trial 2: L090307, Trial 3: L090308, Trial 4: L090309. These trials are not reported in details here^c At processing start^d For calculation purposes < 0.01 is set 0.01*Lettuce (doc. code 2008/1004853)*

During the growing season 2007, four independent field trials were conducted in Northern France, Germany, Spain and Italy to determine the residue levels of dimethomorph in lettuce head (open and closed head cultivars) and its processed parts. The trials were treated three times with a dose rate of 0.18 kg ai/ha which generally is according to label rates for outdoor lettuce head and leaf, but below (70%) label rates for protected cultivation of lettuce in the Netherlands.

Samples of lettuce heads were collected 0, 7, 14 and 21 days after the last application for analysis of the raw agricultural commodity. The samples for processing were taken 7 days after last treatment which is 7 days later than in cGAP. The processing procedure included dividing lettuce heads into inner and outer leaves and washing of the leaves.

Residues of dimethomorph were determined by LC-MS/MS using method No. 575/0. The limit of quantitation was 0.01 mg/kg and the mean recovery rate from 71–106% at fortification levels of 0.01–20 mg/kg in the different matrices. The result are summarized in Table 39.

Pea (doc. code 2007/1044681)

During the 2006 growing season four independent trials were conducted on fresh peas (*Pisum sativum*) in Germany to study the potential of residues its processed products cooked and canned peas. Dimethomorph (WG formulation) was applied as a foliar spray two times 29 and 21 days $\pm$ 1 day prior to harvest, at 0.51–0.53 kg ai/ha which is more than two times the label rate. Samples (plants without pods and whole pods) were collected on the day of last application and 21 $\pm$ 1 days after last application.

The processing of peas was performed with green seeds taken at the last sampling which is according to cGAP. The green seeds were first washed in tap water for three minutes and then boiled in a saucepan covered with water added with salt 2 g/100 mL until the peas were cooked through. For preserving procedure the peas was blanched by staying 2 minutes $<$ 85 °C. After blanching the peas were put in tins covered with 2% NaCL-solution. The tins with the peas were sterilized at 120 °C in an autoclave for 20 minutes. During processing different fractions from pea products or intermediates were collected for analysis, specifically washed peas, cooked peas, blanched seed and canned peas.

Residues in animal commodities

New residue data on residues of dimethomorph in animal feed have been provided to the 2014 Meeting. A new livestock dietary burden calculation has therefore been performed (Annex 6 to the 2014 Report).

The new estimation did not result in significant change of the dietary burdens of farm animals, please see Appraisal.

APPRAISAL

Dimethomorph is a fungicide with protective action against plant pathogenic *Phytophthora* species and a number of downy mildew diseases of fruit, vegetables and potatoes. It consists of a mixture of an E and Z isomers in approximately equal proportions. Its mode of action is through disruption of fungal cell wall formation.

Dimethomorph was evaluated for the first time by the JMPR in 2007 and the Meeting established an acceptable daily intake (ADI) of 0–0.2 mg/kg bw and an acute reference dose (ARfD) of 0.6 mg/kg bw. The residue (for compliance with the MRL and for the estimation of dietary intake) for plant and animal commodities was defined as dimethomorph (sum of isomers). Maximum residues levels for 20 commodities were proposed by the JMPR in 2007.

The current Meeting received information on supervised residue trial for dimethomorph in oranges, strawberries, grapes, papaya, bulb onions, leek, spring onions, head cabbage, broccoli, pepper, lettuce leaf, spinach, lettuce head, taro, green peas, vining peas, lima beans, artichoke, and celery. An analytical method for determination of dimethomorph in animal matrices were provided as well as validation data for an analytical method in oranges and processing studies in oranges, strawberry, onion, lettuce head, and peas.

Methods of analysis

The 2007 Meeting evaluated methods of analysis for dimethomorph in different plant and animal matrices with a LOQ of 0.01 mg/kg (LC-MS/MS or GC-NDP), LOQ of 0.02 mg/kg (GC-NDP or GC-MS) based on the multi-residue method DFG-S19.

The current Meeting received information on a new analytical method LO138/01 for dimethomorph in animal matrices. In this method dimethomorph is extracted with methanol/water/hydrochloric acid. The final determination of dimethomorph is performed by HPLC-MS/MS at two transitions. Transition m/z 388 → 301 is the target transition for quantification and transition m/z 388 → 165 for confirmatory purposes. The method is suitable for measuring residues of 0.01 mg/kg for dimethomorph in milk, egg, muscle and liver.

Stability of pesticide residues in stored analytical samples

In 2007 the Meeting concluded that dimethomorph is stable (less than 10% loss of residues) under frozen conditions in stored samples in most crops and animal commodities if stored under frozen conditions at 18-24 months and 16 months, respectively.

Results of supervised residue trials on crops

Oranges

Data from supervised trials on oranges from Spain were presented to the Meeting. However, no registered GAP from Spain was available for oranges. As a result no estimation of a maximum residue level was made.

Grapes

Data from supervised trials on grapes from the USA were presented to the Meeting. The registered critical GAP in the USA is four foliar applications of 0.219 kg ai/ha and PHI of 14 days.

In twelve independent residue trials from USA matching the cGAP the residues of dimethomorph in grapes were (n=12): 0.11, 0.26, 0.41, 0.46, 0.49, 0.55, 0.65, 0.71, 0.75, 0.92, 1.77, 1.86 mg/kg.

The Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph in grapes of 3 mg/kg, 0.60 mg/kg and 1.9 mg/kg, respectively. The Meeting replaces its previous recommendation of 2 mg/kg for a maximum residue level for grapes.

Strawberry

Data from supervised trials on strawberries were presented to the Meeting.

The critical GAP is from Belgium (protected and outdoor) with three successive root drench applications of 0.05 g ai/plant and a PHI of 35 days. No trials supporting the GAP were provided.

In Ireland the GAP (protected and outdoor) is one root drench application of 0.05 g ai/plant with a PHI of 35 days. A dataset on protected strawberries was submitted consisting of four trials with replicate plots treated either at 0.0625 g ai/plant or 0.125 g ai/plant and with four additional trials solely treated at 0.125 g ai/plant.

In four GAP compliant plots conducted at 0.0625 g ai/plant residues in strawberry fruits were (n=4): 0.03, 0.18, 0.26, 0.3 mg/kg.

In four additional trials solely conducted at 0.125 g ai/plant residues in strawberry fruits were (n=4): 0.04 (2), 0.05 and 0.21 mg/kg.

Since the four trials provided according to GAP are insufficient for an evaluation of residues in strawberries, the Meeting decided to extend the dataset by applying the proportionality approach. In accordance to the general principles outlined in the 2012 JMPR report, all residue values within and above 25% deviation from GAP were scaled to match the application rate of 0.05 g ai/plant. From

replicated plots conducted at different application rates, the higher scaled residue was selected for the assessment. Scaled residues in strawberry fruits were: 0.024, 0.14, 0.21, 0.24 mg/kg (factor 0.8, based on 0.0625 g ai/plant → 0.05 g ai/plant and 0.016, 0.016, 0.02, 0.084 mg/kg (factor 0.4, based on 0.125 g ai/plant → 0.05 g ai/plant).

The combined scaled dataset is (n=8) 0.016, 0.016, 0.02, 0.024, 0.084, 0.14, 0.21 and 0.24 mg/kg.

Three similar outdoor trials with a PHI of 43 days from Belgium, the Netherlands and Germany were also available. The residues in these trials were for 0.125 g ai/plant (n=3) 0.01, 0.02 and 0.04 mg/kg.

For drip irrigation eight trials from Spain using 2×0.75 kg ai/ha with a PHI of one day were presented to the Meeting. No registered GAP from Spain was available for strawberries.

In the United Kingdom the registered GAP for outdoor is one foliar spray at 1.5 kg ai/ha applied just after planting/transplanting with a PHI of 35 days. Eight trials presented to JMPR 2007 from the Netherlands and four trials from northern Europe presented to the current Meeting match this GAP and could be combined. The residues found in these combined trials are (n=12) < 0.01 mg/kg (9), 0.01, 0.02 and 0.03 mg/kg.

The highest residues came from the protected root drench treatment. Based on the combined scaled dataset from protected root drench trials for strawberries in Ireland, the Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph for strawberries of 0.5 mg/kg, 0.05 mg/kg and 0.24 mg/kg, respectively. The Meeting replaces its previous recommendation of 0.05 mg/kg for maximum residue level for strawberry.

Papaya

Data from supervised trials on papaya from Brazil were presented to the Meeting. No registered GAP from Brazil was available for papaya. As a result no maximum residue level estimation was made.

Bulb vegetables

Bulb onion

The Meeting received results from supervised trials with dimethomorph on bulb onions. The critical GAP is for Bulb Vegetables (Garlic, Garlic great headed, Leek, Onion dry bulb, Onion green, Onion Welsh Shallot) in the USA and Canada with three foliar applications of 0.21 kg ai/ha and PHI of 0 days.

Ten independent residue trials from the USA (nine) and Canada (one) were presented on bulb onions matching the cGAP. Residues of dimethomorph in bulb onions were (n=10) 0.06, 0.08, 0.10, 0.12, 0.16, 0.18 (2), 0.23, 0.28 and 0.38 mg/kg. The highest residue of 0.40 mg/kg was measured in individual onion samples.

The Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph in bulb onions of 0.6 mg/kg, 0.17 mg/kg and 0.40 mg/kg, respectively. The Meeting also agreed to extrapolate these estimations to shallot and garlic.

Leek

Data from supervised trials on leek were presented to the Meeting. The critical GAP is in France with two foliar applications of 0.18 kg ai/ha and a PHI of 14 days.

Eighteen independent trials from Belgium, Germany, Greece, Italy, France, the Netherlands, Spain, and the UK matching this GAP were presented. The dimethomorph residue from trials on leek was in south EU (n=4) 0.06, 0.08, 0.3 and 0.69 mg/kg and north EU (n=14) 0.01 (2), < 0.02 (2), 0.03, 0.04 (2), 0.07, 0.08 (2), 0.10 (2), 0.11, 0.13.

The combined data set is (n= 18) 0.01 < 0.02 (2), 0.03 0.04 (2), 0.05, 0.06, 0.07, 0.08 (3), 0.10 (2), 0.11, 0.13, 0.30 and 0.69 mg/kg.

The Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph in leek of 0.8 mg/kg, 0.08 mg/kg and 0.69 mg/kg, respectively.

Spring onion

Data from supervised trials on spring onion were presented to the Meeting. The critical GAP is for Bulb Vegetables (Garlic, Garlic great headed, Leek, Onion dry bulb, Onion green, Onion Welsh Shallot) in USA and Canada with three foliar applications of 0.21 kg ai/ha and a PHI of 0 days.

Six independent residue trials from the USA matched the cGAP. Residue of dimethomorph in whole plant were (n=6) 1.27, 1.56, 1.79, 2.35, 2.45 and 5.36 mg/kg. The highest residue of 6.6 mg/kg was measured in individual spring onion samples.

The Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph in spring onion of 9 mg/kg, 2.1 mg/kg and 6.6 mg/kg, respectively. The Meeting also agreed to extrapolate this estimation to Onion, Welsh.

Brassica vegetables

Head cabbage

The Meeting received results from supervised trials with dimethomorph on head cabbage. The critical GAP is in USA with three foliar applications of 0.21 kg ai/ha and a PHI of 0 days.

Ten independent residue trials from USA matched the cGAP. Residue from dimethomorph in cabbage heads were (n=10) 0.17, 0.45, 0.46, 0.86, 1.08 (2), 1.22, 1.37 1.51 and 4.26 mg/kg. The highest residue of 4.6 mg/kg was measured in individual head cabbage samples.

The Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph in head cabbage of 6 mg/kg, 1.1 mg/kg and 4.6 mg/kg, respectively. The Meeting replaces its previous recommendation of 2 mg/kg for maximum residue level for head cabbage.

Broccoli

Data from supervised trials on broccoli were presented to the Meeting. The critical GAP is from the USA which consists of three foliar applications of 0.21 kg ai/ha and a PHI of 0 days.

Ten independent residue trials performed in USA match the US GAP. Residues for dimethomorph in broccoli were (n=10): 0.25, 0.68, 0.74, 0.90, 0.95, 1.49, 1.62, 1.75, 1.88 and 2.33 mg/kg. The highest residue of 2.6 mg/kg was measured in an individual broccoli sample.

The Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph in broccoli of 4 mg/kg, 1.3 mg/kg and 2.6 mg/kg, respectively. The Meeting replaces its previous recommendation of 1 mg/kg for a maximum residue level for broccoli.

Fruiting vegetables, other than cucurbits

Peppers

Data from supervised trials on pepper were presented to the Meeting. The GAP in Canada for Fruiting vegetables (tomato, eggplant, ground cherry, peppers (all varieties), pepino and tomatillo) is five foliar applications of 0.225 kg ai/ha and a PHI of 0 days.

In eleven outdoor independent residue trials in USA matching the Canadian GAP the residues of dimethomorph in peppers were (n= 11): 0.04, 0.06, 0.08, 0.11, 0.13(2), 0.14, 0.25, 0.7, 0.84 and 1.05 mg/kg.

Tomato

Data from supervised trials on tomato were presented to the 2007 Meeting. The critical GAP is from Canada for Fruiting vegetable with five foliar applications of 0.225 kg ai/ha and PHI of 0 day.

In twelve outdoor independent residue trials on tomato from the USA matching the cGAP the residue of dimethomorph in tomato fruit were (n= 12): 0.05(2), 0.06(2), 0.07, 0.11, 0.14, 0.21, 0.3, and 0.38, 0.41 and 0.51 mg/kg.

The Meeting noted that the GAP in Canada was for fruiting vegetables, other than cucurbits, the medians of the data sets for peppers and tomatoes differed by less than 5-fold and that the residue populations were statistically similar. The Meeting therefore decided to consider recommending a crop group maximum residue level. The combined data set matching the Canadian GAP is (n= 23) 0.04, 0.05(2) 0.06(3), 0.07, 0.08, 0.11(2), 0.13(2), 0.14(2), 0.21, 0.25, 0.30, 0.38, 0.41, 0.51 0.70, 0.84 and 1.05 mg/kg. The highest residue of 1.2 mg/kg was measured in an individual pepper sample.

The Meeting estimated a group maximum residue level, an STMR value and an HR value for dimethomorph in fruiting vegetables, other than cucurbits except mushrooms and sweet corn of 1.5 mg/kg, 0.13 mg/kg and 1.2 mg/kg, respectively.

The Meeting withdraws its previous recommendation of 1 mg/kg for fruiting vegetable, other than cucurbits except mushrooms and sweet corn.

*Leafy vegetables**Lettuce, Head*

Data from supervised field trials on head lettuce were presented to the Meeting. The critical GAP is from USA for Leafy vegetables, except brassica vegetables, consisting of three foliar applications at 0.19 kg/ha and a PHI of 0 days.

In fourteen independent trials from the USA matching the cGAP the residues from dimethomorph in head lettuce were (n= 14): 1.08, 1.21, 1.36, 1.42, 1.46, 1.68, 1.72, 2.06, 2.3, 2.82, 3.63, 4.1, 4.37 and 6.45 mg/kg.

The Meeting noted that the US trials reported by the 2007 JMPR resulted in higher residues. The Meeting therefore, confirmed the previous recommendations made by the 2007 JMPR.

Lettuce, Leaf

Data from supervised trials on leaf lettuce were presented to the Meeting. The critical GAP is from USA for Leafy vegetables, except brassica vegetables with three foliar applications 0.19 kg/ha and a PHI of 0 days.

In nine independent trials from the USA matching the cGAP the residues from dimethomorph in lettuce leaf were (n= 9) 2.09, 3.37, 3.68, 4.61, 5.19, 5.38, 5.83, 9.77 and 9.88 mg/kg. The highest residue of 10.5 mg/kg was measured in an individual lettuce sample.

The Meeting estimated a maximum residue level, an STMR value and a HR value for dimethomorph in leaf lettuce of 20 mg/kg, 5.2 mg/kg and 10.5 mg/kg.

Short-term intake assessment showed that residues in leaf lettuce exceeded the acute reference dose of 0.6 mg/kg bw by 110% for children.

Spinach

Data from supervised trials on spinach were presented to the Meeting. The critical GAP is from USA for Leafy vegetables, except brassica vegetables with three foliar applications 0.19 kg/ha and a PHI of 0 days.

In eight independent trials from the USA matching the cGAP the residues from dimethomorph in spinach leaves were (n= 8) 4.69, 5.30, 5.91, 8.21, 8.35, 8.48, 10.18 and 11.26 mg/kg. The highest residue of 11.5 mg/kg was measured in individual spinach samples.

The Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph in spinach of 30 mg/kg, 8.3 mg/kg and 11.5 mg/kg, respectively.

Taro leaves

Data from supervised trials on taro leaves from USA were presented to the Meeting. The critical GAP is five foliar applications of 0.19 kg ai/ha and PHI 7 days for use in USA except California.

Dimethomorph was applied seven times to taro at the rate of 0.225 kg ai/ha with an interval of 7–8 days. Presented residue trials from head lettuce, leaf lettuce and spinach show that residues of dimethomorph decline significantly three days after application. The Meeting, therefore, concluded that the first two applications would not contribute significantly to the residues in leaves at harvest.

In three independent trials from USA matching the cGAP residues in taro leaves were (n=3): 1.44, 1.64 and 4.53 mg/kg. The highest residue of 5.4 mg/kg was measured in an individual taro sample.

The Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph in taro leaves of 10 mg/kg, 1.64 mg/kg and 5.4 mg/kg, respectively.

Legume vegetable

Peas, shelled (succulent seed)

Data on supervised trials on peas were presented to the Meeting. The critical GAP is from France with two foliar applications at 0.18 kg ai/ha and a PHI of 21 days.

In twelve independent trials from north (eight) and south (four) Europe matching the cGAP residues of dimethomorph in fresh peas without pods were (n= 12) < 0.01 (8), 0.016, 0.044 and 0.063 mg/kg.

The Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph in peas without pods of 0.15 mg/kg, of 0.01 mg/kg and 0.063 mg/kg, respectively.

Lima bean

Data from supervised trials on Lima bean were presented to the Meeting. The critical GAP is from the USA with five applications at 0.19 kg ai/ha and a PHI of 0 days.

Ten independent trials matching the cGAP were conducted on Lima bean in USA. Residues of dimethomorph in beans (succulent seed without pods) (n=10) were 0.01, 0.03(4), 0.05, 0.06, 0.08, 0.1, 0.21 and 0.47 mg/kg. The highest residue of 0.48 mg/kg was measured in an individual Lima bean sample.

The Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph in Lima bean of 0.7 mg/kg, 0.055 mg/kg and 0.48 mg/kg, respectively.

Root and tuber vegetables

Ginseng

Data from supervised trials on ginseng were presented to the Meeting. The critical GAP from the USA, except California, is five applications of 0.19 kg ai/ha and a PHI of 14 days. Four trials were presented where dimethomorph was applied seven times at 0.225 kg ai/ha. Residue decline trials were not provided for any root and tuber vegetable to support that the first two applications did not contribute to the residues at harvest. Consequently, no maximum residue level estimation was made.

Taro root

Data on supervised trials on taro corms from Hawaii were presented to the Meeting. The critical GAP is five applications of 0.19 kg ai/ha and a PHI of 30 days in the USA, except California. Three trials were presented where dimethomorph was applied seven times at 0.225 kg ai/ha. Residue decline trials were not presented for any root and tuber vegetable to support that the first two applications not contribute to the residues at harvest. Consequently, no maximum residue level estimation was made.

*Stalk and stem vegetables**Globe artichoke*

Data from supervised trials on globe artichoke were presented to the Meeting. The critical GAP from France is three foliar applications of 0.18 kg ai/ha and PHI of 3 days.

In ten independent trials from Europe matching the French GAP residues of dimethomorph in artichoke heads were in North Europe (n=5) 0.11, 0.24, 0.26, 0.55 and 0.75 mg/kg and in South EU (n=5) 0.06, 0.09, 0.14, 0.32 and 1.14 mg/kg.

The combined data set was (n=10): 0.06, 0.09, 0.11, 0.14, 0.24, 0.26, 0.32, 0.55, 0.75 and 1.14 mg/kg.

The Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph in globe artichoke of 2 mg/kg, 0.25 mg/kg and 1.14 mg/kg, respectively.

Celery

Data from supervised trials on celery were presented to the Meeting. The critical GAP is from the USA with three foliar applications of 0.21 g ai/ha and a PHI of 0 days.

In nine independent trials from Canada (two) and from USA (seven) matching the cGAP residues of dimethomorph in leaf stalks were (n=9): 1.27, 1.55, 1.85, 1.91, 2.44, 3.27, 4.02, 5.54 and 8.21 mg/kg.

The highest residue of 8.8 mg/kg was measured from an individual celery sample.

The Meeting estimated a maximum residue level, an STMR value and an HR value for dimethomorph in celery of 15 mg/kg, 2.44 mg/kg and 8.8 mg/kg, respectively.

*Animal feeds**Pea forage*

Data on supervised trials on peas were presented to the Meeting. The critical GAP is from France with two foliar applications at 0.18 kg ai/ha and a PHI of 21 days. However, the residues (10) 28 days after the second treatment were found to be higher and were used for animal burden calculation: 0.42, 0.59, 1.57, 1.59, 1.88, 2.40, 4.60, 4.97, 5.45 and 9.58 mg/kg.

The Meeting estimated in pea forage a median residue of 2.14 mg/kg (fresh weight) and a highest residue of 9.58 mg/kg (fresh weight).

Fate of residue during processing

The Meeting received information on processing of oranges, strawberries, onions, lettuce head and peas.

Processing factors calculated for the processed commodities for the above raw agricultural commodities, including previously estimated, are shown in the table below. STMP-Ps was calculated for processed commodities of strawberry, onion and peas for which maximum residue levels were estimated.

Processed commodity	Processing factor	PF (Best estimate)	STMR-P	HR-P
Strawberry, jam	0.24, 0.43, 0.44, 0.54	0.435	0.02	
Strawberry, canned	0.57, 1, 1.21, 1.52	1.11	0.0555	
Onions, raw without skin	0.02, 0.04, 0.12, 0.34	0.08	0.014	0.032
Dried onion	0.03, 0.12, 0.04, 0.34	0.13	0.022	0.053
Peas (cooked)	0.08, 0.17, 0.24, 0.26	0.21	0.002	
Peas (canned)	0.06, 0.08, 0.20, 0.24	0.14	0.0014	

*estimated by 2007JMPR Meeting

** PF =processing factor

^b Data from a 5-week special neurotoxicity study, using a limited number of dogs.

The Meeting confirmed its previous maximum residue level estimation of 5 mg/kg for dried grapes.

Residues in animal commodities

Farm animal dietary burden

Dietary burden calculation for beef cattle, dairy cattle, broilers and laying poultry based on feed items evaluated by JMPR in 2007 and 2014 are provided in table below. The calculations were made according to the livestock diets from US-Canada, EU, Australia and Japan according to OECD feeding table. Noting that fresh forage commodities are not significant in international trade, the Meeting only included the burden contributions from the pea forages in the European dietary burden calculation, as dimethomorph is not authorised for use on peas in US-Canada, Australia or Japan.

Dietary burden calculations for beef cattle, dairy cattle, broilers and laying poultry are presented in Annex 6 and are summarised below.

Estimated maximum and mean dietary burden of farm animals Summary (ppm of dry matter diet)

	US-Canada		EU		Australia		Japan	
	max	mean	max	mean	max	mean	max	mean
Beef cattle	0.4	0.3	14.2 ^a	3.6 ^c	2.6	2.6	0.007	0.007
Dairy cow	0.1	0.1	14.1 ^b	3.5 ^d	2.6	2.6	0.01	0.01
Poultry-broiler	0.002	0.002	0.06	0.05	0.04	0.04	0.002	0.002
Poultry layer	0.002	0.002	5.4 ^{e g}	1.27 ^{f h}	0.04	0.04	0.007	0.007

^a Highest maximum beef or dairy cattle dietary burden suitable for MRL estimates for mammalian tissues

^b Highest maximum dairy cattle dietary burden suitable for MRL estimates for mammalian milk

^c Highest mean beef or dairy cattle dietary burden suitable for STMR estimates for mammalian tissues.

^d Highest mean dairy cattle dietary burden suitable for STMR estimates for milk.

^e Highest maximum poultry dietary burden suitable for MRL estimates for poultry tissues.

^f Highest mean poultry dietary burden suitable for STMR estimates for poultry tissues.

^g Highest maximum poultry dietary burden suitable for MRL estimates for poultry eggs.

^h Highest mean poultry dietary burden suitable for STMR estimates for poultry eggs

For beef and dairy cattle, the calculated maximum dietary burdens suitable for estimating maximum residue levels in mammalian tissues and milk are 14.2 and 14.1 ppm dry weight of feed respectively.

The calculated mean dietary burden, suitable for estimating STMRs in mammalian tissues and in milk is 3.6 and 3.5 ppm, dry weight of feed, respectively.

In the cattle feeding study evaluated by JMPR in 2007 where lactating cows were dosed at 37.5 ppm (approximately 40% higher than estimated maximum burden) no residues of parent dimethomorph were detected in edible tissue or milk. Therefore the Meeting concluded that no residues are to be expected at the maximum calculated dietary burden for ruminants.

The calculated maximum dietary burden suitable for estimating maximum residue levels in poultry tissues and eggs is 5.4 ppm dry weight of feed and the calculated mean dietary burden, suitable for estimating STMRs in poultry tissues and in eggs is 1 ppm dry weight of feed.

In the metabolism study where laying hens were fed the equivalent of 40 ppm in the feed for seven days, dimethomorph residues in fat and skin were < 0.02 mg/kg and were not detected in tissue or eggs. On the basis that the maximum calculated dietary burden is eight times lower than the dose rate in the metabolism study the Meeting concluded that no residues of dimethomorph are to be expected at the maximum calculated dietary burden for poultry.

The Meeting confirmed the previous recommendations for animal commodities.

RECOMMENDATIONS

On the basis of the data from supervised residue trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for the IEDI and IESTI assessment.

Definition of the residue (for compliance with the MRL and for estimation of dietary intake) for plant and animal commodities: dimethomorph (sum of isomers).

The residue is not fat soluble.

MRL recommendations and dietary intake

^a recommendations from the 2007 Meeting

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Daily Intakes (IEDI) of dimethomorph, based on the STMRs estimated for 30 commodities, for the 17 cluster diets were in the range of 0–2% of maximum ADI (0.2 mg/kg bw), see Annex 3. The Meeting concluded that the long-term intake of residues of dimethomorph resulting from its uses that have been considered by JMPR is unlikely to present a health concern.

Short-term intake

The WHO Panel of the 2007 JMPR established an Acute Reference Dose (ARfD) of 0.6 mg/kg bw for dimethomorph.

The International Estimated Short Intake (IESTI) for dimethomorph was calculated for new food commodities and their processed fractions for which maximum residue levels were estimated and for which consumption data were available, see Annex 4.

For lettuce leaf, the IESTI represented 110% of the ARfD of 0.6 mg/kg bw. On the basis of the information provided to the JMPR it was not possible to conclude that the estimate of the short-term intake of dimethomorph, from the consumption of lettuce leaf, was less than the ARfD. The Meeting noted that an alternative GAP for lettuce leaf was not available.

For the other commodities the IESTI for dimethomorph calculated on the basis of recommendations made by the JMPR represented 0-90% of the ARfD (0.6 mg/kg bw) for children and 0-30% for the general population.

The Meeting concluded that except for lettuce leaf, the short-term intake of residues of dimethomorph, when used in ways that have been considered by the JMPR is unlikely to present a public concern.

DITHIOCARBAMATES (105) - MANCOZEB (050)

The first draft was prepared by Professor Mi-Gyung Lee, Andong National University, Republic of Korea

EXPLANATION

Mancozeb was evaluated in 1993 in the CCPR periodic review programme. Since then, in 2012, the Meeting evaluated residue data on mancozeb and maneb, however, made no recommendation for MRLs. Currently, a number of MRLs for dithiocarbamates are established based on the residue data derived from use of mancozeb, maneb, metiram, thiram, ziram and propineb.

The 1993 JMPR evaluated several dithiocarbamate fungicides for toxicology and residues when the Meeting established an ADI of 0–0.03 mg/kg bw (group or in any combination) for ethylene-bis-dithiocarbamates (EBDCs: mancozeb, maneb, metiram and zineb). In addition, for their metabolite ethylenethiourea (ETU), the Meeting established an ADI of 0–0.004 mg/kg bw. At present, there are no ARfDs established by the JMPR for ethylene-bis-dithiocarbamates or ETU.

The mancozeb residue is defined as total dithiocarbamates, determined as CS₂, evolved during acid digestion and expressed as mg CS₂/kg, for compliance with MRLs in plant and animal commodities. Dithiocarbamate residues are not fat soluble.

Dithiocarbamates-Mancozeb was listed by the Forty-fifth Session of the CCPR (2013) for the evaluation of additional MRL in 2014 JMPR. Further, it was requested by the Session that 2014 JMPR evaluate monitoring data on spices produced by India for additional MRLs. The Meeting received supervised residue trial data from Thailand (chili pepper) and the Republic of Korea (ginseng and the processed products). From India, monitoring data on spices (cardamom, coriander, cumin, fennel and black pepper) were submitted.

RESIDUE ANALYSIS*Analytical methods*

The analytical method used for determination of dithiocarbamates in chili pepper was based on the Dutch manual of analytical methods (Ministry of Welfare, Health and Cultural Affairs, 1988), which was reviewed in 1995 by JMPR: dithiocarbamates are converted to CS₂ by treatment with hydrochloric acid in the presence of stannous chloride. The CS₂ in the head-space is determined by GC with either ECD or FPD. For analysis of dithiocarbamates in chili pepper, ECD was used. The limit of quantification was 0.05 mg/kg as CS₂. Recovery tests were performed at five levels of 0.05–5.0 mg CS₂/kg (n=3 at each level). The average recoveries were in the range of 71–101%. In procedural recovery tests conducted at a fortified level of 0.1 mg CS₂/kg, the average recoveries (n=3) were 81–100% with an acceptable RSDs. ETU residue was not analysed.

Information on an analytical method ABY0064 with a validation study was submitted, for the analysis of mancozeb in ginseng and the processed products. This method is based on the direct determination, by HPLC-MS/MS, of a derivatized EBDC (EBDC-dimethyl produced by S-methylation). In the mass analysis, individual EBDCs are distinguished using compound-specific transition ions.

The validation study was performed with orange, olive and their products. An aliquot of extracting solvent and iodomethane were added to sample (2 g). The extracting solvent was a mixture of disodium EDTA (ethylenediaminetetraacetic acid), NaOH, L-cysteine, water and methanol. The sample extract was cleaned up using C₁₈ SPE cartridge with an eluting solvent of water:methanol (40:60, v:v). Residues were quantified with by HPLC-MS/MS (MRM *m/z* 241 > 134). The responses of the HPLC/MS/MS systems were linear over the range 0.1 to 5 ng/mL (*r*², > 0.99). At the fortification levels of 0.01 and 0.1 mg/kg of mancozeb, individual recoveries were in the range of 70% to 108% (RSD, < 15%). The limit of quantification was 0.01 mg/kg in all matrices (Table 1).

In the validation study, additionally, a method for ETU analysis was tested for its performance. The method involved extraction with dichloromethane, clean-up by liquid-liquid partition with hexane and quantification by HPLC-MS/MS (MRM m/z 103 > 44 for ETU; MRM m/z 107 > 48 for internal standard, ETU D4). The linearity was over the range 2.5 to 100 ng/mL. At the fortification levels of 0.01 and 0.1 mg/kg of ETU, individual recoveries were in the range of 79% and 109% (CV, < 12%). The limit of quantification was 0.01 mg/kg in the all matrices (Table 2).

The control sample extracts from all matrices (oranges, olives and their by-products) were fortified with mancozeb (as the methylated derivative) or ETU, the residues in the final extracts were stable for seven days stored at approximately -20 °C. The storage period was sufficient to cover the maximum storage period of the extracts from this validation study.

Table 1 Recoveries of mancozeb in orange, olive and the processed products using the method ABY0064

Matrix	Fortification, mg/kg	No.	Range of recoveries, %	Mean recovery, %	CV, %
Orange pulp	0.01	5	73-98	82	12.5
	0.1	5	71-76	73	2.6
Orange peel	0.01	5	96-101	97	2.3
	0.1	5	96-104	101	3.6
Orange juice	0.01	5	85-95	90	4.4
	0.1	5	75-78	77	2.0
Orange oil	0.01	5	97-103	94	14.7
	0.1	5	98-108	101	4.4
Orange wet pomace	0.01	5	80-100	90	7.9
	0.1	5	80-93	88	5.9
Orange dry pomace	0.01	5	70-84	74	7.8
	0.1	5	71-81	76	6.8
Olive oil	0.01	5	72-85	78	7.0
	0.1	5	70-86	78	9.6

Mancozeb was not detected (< 0.01 mg/kg) in control samples.

Table 2 Recoveries of ETU from oranges, olives and the processed by-products

Matrix	Fortification, mg/kg	No.	Range of recoveries, %	Mean recovery, %	CV, %
Orange whole fruit	0.01	5	79-98	88	9.5
	0.1	5	94-106	100	4.4
Orange pulp	0.01	5	94-107	103	5.0
	0.1	5	97-107	102	3.7
Orange peel	0.01	5	88-104	97	7.0
	0.1	5	89-95	92	2.4
Orange juice	0.01	5	80-103	89	12.4
	0.1	5	96-109	104	5.0
Orange oil	0.01	5	88-93	89	5.4
	0.1	5	80-92	87	5.4
Orange wet pomace	0.01	5	91-100	96	3.5
	0.1	5	99-104	102	2.3
Orange dry pomace	0.01	5	90-109	98	7.7
	0.1	5	100-106	103	2.5
Olive whole fruit	0.01	5	79-109	98	12.3
	0.1	5	95-108	103	5.4

Matrix	Fortification, mg/kg	No.	Range of recoveries, %	Mean recovery, %	CV, %
Olive oil	0.01	5	85-94	91	4.7
	0.1	5	89-98	94	3.7

ETU was not detected (< 0.01 mg/kg) in control samples.

Analyses of mancozeb and ETU in ginseng and the processed products were conducted by the analytical methods mentioned above, except minor modifications in certain trials, e.g., use of HPL SPE instead of C18 SPE or without involvement of internal standard in ETU analysis. LOQ of mancozeb in fresh ginseng by HPLC-MS/MS was 0.01 mg/kg and 0.02 mg/kg for the other matrices (dried ginseng, red ginseng, water extract of dried ginseng and water extract of red ginseng). For ETU, the LOQs were 0.01mg/kg or 0.02 mg/kg in fresh ginseng and 0.02 mg/kg in dried and red ginseng. In the ginseng matrices (fresh and processed), individual procedural recoveries (n=3 or 5) for mancozeb and ETU were between 70% and 120% (RSD, <20%) at the various fortification levels (0.01–1.0 mg/kg in mancozeb; 0.02–1.0 mg/kg in ETU).

In the analysis of dithiocarbamates in spices employed in monitoring, spectrometry was used. The samples (10–20 g) were hydrolysed with hydrochloric acid and stannous chloride solution at elevated temperature, and the evolved carbon disulphide (CS₂) passed through two gas washing tubes in series containing lead acetate and sodium hydroxide solutions and an absorption tube containing an ethanolic solution of cupric acetate and diethanol amine. Formed two cupric complexes of N,N-bis (2-hydroxyethyl) dithiocarbamic acid were measured by spectrometry at 453 nm (Kepple G.E. J AOAC 54, 528-532, 1971). LOQs of dithiocarbamates in spices (cardamom, coriander, cumin, fennel and pepper) were 0.1 mg CS₂/kg. At fortification levels of 0.1–1.0 mg CS₂/kg, recoveries were 90–110% in cumin, coriander and fennel and 88-107% in cardamom and black pepper.

Stability of residues in stored analytical samples

In ginseng trials, fortified control samples were concurrently treated with the field trial samples during storage and analysis. The ginseng samples (fresh and processed) fortified with mancozeb and ETU were stored together with the field trial samples at -20 °C or below until analysis. Recoveries of mancozeb in fresh ginseng were 81–92% (0.1 mg/kg, n=5) at 56 days or 86–94% (0.1–0.5 mg/kg, n=6) at 103 days. In the processed ginseng, recoveries of mancozeb were 81–117% (0.2 mg/kg, n=20 for all processed types) at 11–56 days or 78–94% (0.2–1.0 mg/kg, n=6 for dried ginseng) at 100 days. For ETU, the recoveries in fresh ginseng were 84–92% (0.2 mg/kg, n=5) at 71 days or 85–96% (0.1–0.5 mg/kg, n=6) at 103 days; in the processed, 83–96% (0.2 mg/kg, n=10 for dried and red ginseng) at 55–62 days or 90–96% (0.2–1.0 mg/kg, n=6 for dried ginseng) at 100 days. The days refer to mean storage days of fortified samples and covered the actual storage days of the samples, except for two cases in fresh ginseng, analysis of mancozeb (max. actual storage 76 days over test 56 days,) and analysis of ETU (max. actual storage 92 days over test 71 days). Based on the results, it is considered that the residues were stable during the study period.

As the analysis of mancozeb residues in chili peppers was undertaken on the day of harvest, storage stability tests were not conducted.

USE PATTERN

Mancozeb is a protective fungicide effective against a wide range of foliar fungal diseases. The registered uses on ginseng, chili pepper, cumin and black pepper are summarized in Table 3.

Table 3 Registered uses of mancozeb submitted for evaluation

Chili pepper: Capsicum annuum Linn. var. *acuminatum* Fingerh

WP 80% formulation was used.

Portion analysed: whole fruit without stem

^a The residue value is an average of analytical results for three harvested samples.

Root and tuber vegetables

Ginseng

Four residue trials were conducted in the Republic of Korea in 2013. Mancozeb WP 75% formulation was applied five times (10 day intervals) to four-year old ginseng as a foliar application. Three trials of which were decline trials. The concentration in spray solution was 0.12 kg ai/hL and a spray volume of 2,000 L/ha was used. The calculated dose rate of each application was 12-13 kg ai/ha. Ginseng was collected at 45 days (0, 25, 35, 45, 55 days in the decline trials) after the last application. Foliage and stem were removed before shipment to an analytical laboratory. After removing the soil particles on ginseng roots by washing with tap water, it was blended and stored at -20 °C or -60 °C until analysis. The mass of sample was more than 2 kg.

The residues from application of mancozeb formulation were analysed for both mancozeb and ETU. In control samples, no residue was not detected (< LQO). Ginseng processing studies were also conducted. These are described in the following section.

Table 5 Mancozeb and ETU residues in ginseng from supervised trials performed in the Republic of Korea

^a *Panax ginseng* C.A. Mey (Violet-stem variant)

^b WP 75% formulation was used.

^c The residue value is an average of analytical results for three harvested samples.

^d The two trials were not independent. These were conducted in an adjacent location of 8 km distance and by the same application method and on the same days.

^e In the trial conducted in Sunheung, analysis of control sample was performed only at 0 day; while for trial conducted in Punggi only at 0 and 45 days.

^f At 45 days, duplicate samples were collected.

Spices

Spices (cardamom, coriander, cumin, fennel and black pepper) were collected from the retail outlets during 2009–2014 in India. About 20–500 g of sample of each spice was collected and out of which 10–20 g of homogenized sample was taken for the analysis.

Figure 1 Distribution of mancozeb residues in cumin seed (n=383)

Dotted line indicates that the residue value (10 mg CS₂/kg) covers at least 99th percentile of residues.

FATE OF RESIDUES IN STORAGE AND PROCESSING

In processing

The Meeting received information on the fate of mancozeb residues during the processing of ginseng.

Ginseng

Four-year old ginseng cultivated under shaded conditions was treated five times with a 75% WP formulation at a spray concentration of 0.12 kg ai/hL (12–13 kg ai/ha per application) with 10 day treatment intervals. The fresh ginseng was collected 45 days or decline days (0, 25, 35, 45, and 55 days) after the last application. The harvested ginseng was treated with tap water to remove the soil particles and then dried.

To produce dried ginseng, the washed fresh ginseng was air-dried at 60 °C. Red ginseng was prepared by steaming fresh ginseng for three hours at 98 °C and then by air-drying at 65 °C and further drying under the sunlight. The dried or red ginseng were cut and extracted three times by refluxing in water at 85 °C. The extract was concentrated to 72° Brix. Dried ginseng, red ginseng and the water extracts were packed in inert plastic bottles and stored at -20 °C until analysis.

Water contents in fresh ginseng, dried ginseng, red ginseng, water extract of dried ginseng and water extract of red ginseng were 71%, 8%, 9%, 47% and 52%, respectively.

Table 7 Mancozeb and ETU residues in processing ginseng products

Processing studies were performed once in the Yeongju location and three times in Sunheung and Punggi location each. Pre-processing samples were not analysed. Residue values for fresh ginseng were taken from field trial data.

n.a.: not analysed

Ginseng variety: Panax ginseng C.A. Mey (Violet-stem variant)

Processing factors were calculated:

For mancozeb, the concentration of mancozeb in dried ginseng was divided by the concentration of mancozeb in fresh ginseng.

For ETU, the concentration of ETU in dried ginseng was divided by the sum of ETU and mancozeb (expressed as ETU equivalents by multiplying 0.378 of conversion factor) in fresh ginseng in order to account for mancozeb as a potential source of ETU during processing.

Table 8 Summary of processing factors for mancozeb in ginseng (RAC)

Processed commodity	Calculated processing factors		Pf, best estimate	
	Mancozeb	ETU	Mancozeb	ETU
Dried ginseng	< 1.0, 1.2, 1.3, 1.3, 1.3, 1.4, 2.0, 2.0, 2.0, 2.0, 2.8	1.75

APPRAISAL

Mancozeb was evaluated in 1993 in the CCPR periodic review programme. Since then, in 2012, the Meeting evaluated residue data on mancozeb and maneb, however, made no recommendation for MRLs. Currently, a number of MRLs for dithiocarbamates are established based on the residue data derived from use of mancozeb, maneb, metiram, thiram, ziram and propineb.

Dithiocarbamates-Mancozeb was listed by the Forty-fifth Session of the CCPR (2013) for the evaluation of additional MRL in 2014 JMPR. The Meeting received supervised residue trial data from Thailand (chili pepper) and the Republic of Korea (ginseng and the processed products). In addition, India submitted monitoring data on spices (cardamom, coriander, cumin, fennel and black pepper).

The mancozeb residue is defined as total dithiocarbamates, determined as CS₂, evolved during acid digestion and expressed as mg CS₂/kg, for compliance with MRLs. Dithiocarbamate residues are not fat soluble.

In 1993, the JMPR established a group (or in any combination) ADI of 0–0.03 mg/kg bw for ethylene-bis-dithiocarbamates (EBDCs: mancozeb, maneb, metiram and zineb) and an ADI of 0–0.004 mg/kg bw for their metabolite ethylenethiourea (ETU). The parent EBDC and ETU are defined as the residues for evaluating dietary intake. The Meeting is assessing combined residues of mancozeb and ETU using the ratio of the ADIs (7.5) to express residues in terms of mancozeb-toxicity-equivalents (MTE).

Methods of analysis

The analytical method used for the determination of dithiocarbamates in chili pepper was considered by the JMPR in 1995. According to the method, dithiocarbamate residues in chili pepper were converted to CS₂ by treatment with hydrochloric acid in the presence of stannous chloride. The CS₂ in the head-space was determined by GC-ECD and the limit of quantification was 0.05 mg CS₂/kg. The validity of the analytical results was supported by a set of recovery test and procedural recoveries.

Mancozeb and ETU in ginseng and its processed products were directly measured using analytical method ABY0064.

The method ABY0064 is based on the direct determination, by HPLC-MS/MS, of a derivatized EBDC (EBDC-dimethyl produced by S-methylation). In the method, disodium EDTA and iodomethane are used for decomposing and methylating EBDC compounds, and then the extracts are cleaned up with C₁₈ SPE cartridge. In the mass analysis, individual EBDCs are distinguished using compound-specific transition ions.

The method ABY0064 was fully validated with analytical matrices of orange, olive and their processed products. The recoveries of mancozeb were within an acceptable range (70–120%) at fortification levels of 0.01 mg/kg and 0.1 mg/kg. The LOQs were 0.01 mg/kg. In ginseng residue trials, procedural recoveries were acceptable and the LOQs were 0.01 mg/kg or 0.02 mg/kg.

A method developed for determination of ETU was fully validated for the same matrices used in a validation study of ABY0064. The recoveries and RSDs were within an acceptable range at fortification levels of 0.01 mg/kg and 0.1 mg/kg and the LOQs were 0.01 mg/kg. In ginseng residue trials, procedural recoveries were acceptable and the LOQs were 0.01 mg/kg.

Spectrometry was used for the analysis of dithiocarbamates in spices. Dithiocarbamate residues in spices were converted to CS₂ and two cupric complexes of N,N-bis (2-hydroxyethyl) dithiocarbamic acid, which were measured at 453 nm. LOQs of dithiocarbamates in spices (cardamom, coriander, cumin, fennel and pepper) were 0.1 mg/kg. At fortification levels of 0.1–1.0 mg CS₂/kg, recoveries were 88–110% in cumin, coriander, fennel, cardamom and black pepper.

Stability of residues in stored analytical samples

Storage stability tests for ginseng samples were performed simultaneously with freezer storage of field trial samples or processed samples. Mancozeb and ETU residues were stable during the study period, 103 days until analysis of mancozeb and ETU for fresh ginseng and 11–100 days (mancozeb analysis) or 55–100 days (ETU analysis) for the processed products.

In residue trials of chili pepper, analysis of mancozeb, as CS₂, was conducted on the day the samples were harvested.

Results of supervised trials on crops

The MRLs for mancozeb are expressed as CS₂. For trials using the headspace method, residues are reported in terms of CS₂. For trials using the HPLC-MS/MS method, residues are reported as mancozeb and ETU. For those trials, maximum residue estimates are made by converting mancozeb to CS₂-equivalents.

To estimate dietary intakes, residues are expressed in terms of mancozeb toxicity-equivalents (MTE). The conversion factor for ETU to MTE is the ratio of the ADI for mancozeb to that of ETU, which is 7.5. Thus, when residues were measured as mancozeb and ETU, the total MTE was estimated by multiplying the ETU residue by 7.5 and adding the result to the measured mancozeb residue. The resulting ETU-equivalent was then converted to MTE using the 7.5 factor. The molecular weights of these compounds are CS₂=76.1 g/mol, ETU=102.2 g/mol, and mancozeb=541.0 g/mol, assuming that the 2 moles of ETU are formed from one mole of mancozeb, leading to the following conversion factors:

$$\text{CS}_2 \text{ mancozeb equivalent: } 541.045 / (4 \times 76.139) = 1.777 \times \text{CS}_2 \text{ mg/kg}$$

$$\text{Mancozeb MTE equivalent is: mancozeb mg/kg (measured as mancozeb)}$$

$$\text{MTE for ETU} = 7.5 \times \text{ETU mg/kg}$$

$$\text{MTE for combined residues of mancozeb measured as CS}_2 \text{ mg/kg and ETU mg/kg:}$$

$$\text{MTE}_{(\text{MCZ}+\text{ETU})} = 1.777 \times \text{CS}_2 \text{ mg/kg} + 7.5 \times \text{ETU mg/kg}$$

*Fruiting vegetables, other than Cucurbits**Peppers, Chili*

Mancozeb is registered in Thailand for use on chili peppers at a GAP of 3×0.4 kg ai/hL, with 5 day intervals and a PHI of 7 days. A total of six trials were conducted in Thailand in 2005–2008, matching the GAP.

The residues, as CS₂ were (n=6): 0.31, 0.48, 0.75, 0.80, 1.2 and 1.7 mg CS₂/kg.

The Meeting estimated a maximum residue level of 3 mg CS₂/kg, an STMR of 1.4 mg MTE/kg and an HR of 3.0 mg MTE/kg for chili pepper. Using the default factor of 7 for dried chili pepper, the Meeting estimated a maximum residue level of 20 mg CS₂/kg, a STMR-P of 9.8 mg MET/kg and an HR-P of 21 mg MET/kg for dried chili pepper.

*Root and tuber vegetables**Ginseng*

Mancozeb is registered in the Republic of Korea for use on ginseng at a GAP of 5×0.12 kg ai/hL, with 10 day intervals and a PHI of 45 days. Four trials matching the GAP conducted in the Republic of Korea in 2013 were submitted. Two trials were conducted on the same dates of application in sites closely located and with the same application method; therefore, the trials are not considered to be independent. Only three trials could be considered for estimation of a maximum residue level.

The measured concentrations of mancozeb in ginseng were (n=3): 0.05, 0.05 and 0.11 mg/kg, which is equivalent to 0.028, 0.028 and 0.062 mg/kg as CS₂.

The measured concentrations of ETU in ginseng were (n=3): < 0.01, 0.01 and 0.04 mg/kg.

The Meeting estimated a maximum residue level of 0.15 mg CS₂/kg.

For dietary intake, the STMR is 0.125 mg MTE/kg and the HR is 0.41 mg MTE/kg.

Results of monitoring studies on spices

Monitoring of spices was conducted for dithiocarbamates in India during 2009–2014. Residues in spices came from the use of mancozeb and other dithiocarbamates. Spice samples were analysed based on the determination of CS₂.

The numbers of samples analysed were: 383 for cumin seed, 1,037 for cardamom, 248 for coriander seed, 272 for black pepper and 286 for fennel seed.

In all of the cardamom (1,037 samples) and black pepper (272 samples), CS₂ residues were < 0.1 mg/kg.

In coriander seed, CS₂ residues were < 0.1 (247), 0.4 mg CS₂/kg.

In fennel seed, CS₂ residues were < 0.1 (283), 1.1, 2.0 and 2.8 mg CS₂/kg.

In cumin seed (383 samples), CS₂ residues ranged from 0.11 mg/kg to 17 mg CS₂/kg, with a median of 3.6 mg CS₂/kg.

For compliance, the Meeting estimated maximum residue levels of 0.1 mg CS₂/kg for black pepper, cardamom, coriander seed, and fennel seed, and 10 mg CS₂/kg for cumin seed. The Meeting noted that the maximum residue estimate covers at least 98% of the observed residues.

For dietary intake, the Meeting estimated STMRs of < 0.18 mg MTE/kg for black pepper, cardamom, coriander seed, and fennel seed, and 6.4 mg MTE/kg for cumin seed.

Fate of residues during processing

The Meeting received information on the fate of mancozeb residues during the processing of ginseng. Conversion of residues to their CS₂, mancozeb, and/or ETU equivalents was done, as needed, as described above for supervised residue trials.

RAC and processed	Pf, best estimate		STMRRAC		Median-P		HRRAC		Highest residue-P	
	mancozeb	ETU*	mancozeb (mg/ kg)	ETU (mg/kg)	mancozeb (mg /kg)	ETU equiv. (mg/kg)	mancozeb (mg/ kg)	ETU (mg/kg)	mancozeb (mg /kg)	ETU equiv. (mg/kg)
Ginseng			0.05	0.01			0.11	0.04		
Ginseng, dried including red ginseng	1.5	4.2			0.075	0.1197			0.17	0.3389

* Fraction yield of ETU = $[ETU]_{proc}/([ETU]_{rac} + 0.378 \times [mancozeb]_{rac})$

In dried ginseng, each processing factor for mancozeb, ETU and CS₂ residue was calculated as follows:

For mancozeb, the concentration of mancozeb in dried ginseng was divided by the concentration of mancozeb in fresh ginseng.

For ETU, the concentration of ETU in dried ginseng was divided by the sum of ETU and mancozeb (expressed as ETU equivalents) in fresh ginseng in order to account for mancozeb as a potential source of ETU during processing. The stoichiometric conversion factor for mancozeb to ETU is 0.377 (102.2 g ETU/mol ÷ 271.2 g mancozeb/mol).

For compliance, the Meeting estimated a maximum residue level of 0.3 mg CS₂/kg, based on a maximum residue level of 0.15 mg CS₂/kg for ginseng and the processing factor of dried ginseng, 1.5 (1.5×0.15=0.225 mg/kg).

For dietary intake, the Meeting estimated an STMR-P of 0.075+7.5×0.1197=0.97 mg MTE/kg and an HR-P of 0.17+7.5×0.33894=2.71 mg MTE/kg.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

The mancozeb residue is defined as total dithiocarbamates, determined as CS₂, evolved during acid digestion and expressed as mg CS₂/kg, for compliance with MRLs in plant and animal commodities.

For estimation of dietary intake in plant and animal commodities, the residue definition is mancozeb and ETU.

Dithiocarbamate residues are not fat soluble.

DIETARY RISK ASSESSMENT

Long-term intake

A group ADI (or in any combination) for ethylene-bis-dithiocarbamates (EBDCs: mancozeb, maneb, metiram and zineb) is 0–0.03 mg/kg bw. The International Estimated Daily Intakes (IEDIs) for mancozeb were estimated based on the 17 GEMS/Food Consumption Cluster Diets using only the STMR or STMR-P values estimated by the current JMPR. The results are shown in Annex 3 of the 2014 JMPR Report. The IEDIs ranged 0-6% of the maximum ADI. The Meeting concluded that the

long-term intake of residues of mancozeb from uses added by the current JMPR is unlikely to present a public health concern.

Short-term intake

The ARfD for mancozeb and its metabolite ETU is not available currently. The Meeting noted that the dithiocarbamates were last evaluated in 1993 before the ARfD established by the JMPR.

EMAMECTIN BENZOATE (247)

First draft prepared by Ms T. van der Velde-Koerts, Centre for Nutrition, Prevention and Health Services (VPZ), National Institute for Public Health and the Environment (RIVM), The Netherlands

EXPLANATION

Emamectin benzoate is a foliar insecticide derivative of abamectin, a naturally occurring soil actinomycete. Emamectin benzoate was first evaluated by the JMPR in 2011 for toxicology and residues. The 2011 Meeting established an ADI of 0–0.0005 mg/kg bw and an acute RfD of 0.03 mg/kg bw, expressed as emamectin benzoate. The 2011 Meeting defined the residue as emamectin B1a benzoate for plant and animal commodities for compliance with the MRL and for estimation of dietary intake. Since the molecular weight difference between emamectin B1a benzoate and emamectin benzoate (consisting of 90% emamectin B1a benzoate and 10% emamectin B1b benzoate) is marginal, residues are not corrected for molecular weight. The 2011 Meeting considered the residue not fat soluble.

Emamectin benzoate was scheduled at the 45th session of the CCPR (2013) for the evaluation of additional maximum residue levels by the 2014 JMPR. The manufacturer submitted additional supervised residue trials on rape forage, almonds, pecans and rape seeds, which were evaluated by the present Meeting.

RESIDUE ANALYSIS

The Meeting received information on analytical methods for the determination of emamectin benzoate and its avermectin-like metabolites as used in the supervised residue trials. The analytical residue methods have been evaluated according to the guidance provided by OECD (Series on Pesticides number 39) as indicated on page 25 of the FAO manual 2009.

Validation results are required for every commodity submitted for MRL-setting: at least one full validation for a commodity within the five defined crop groups (high acid content, high water content, high oil content, high protein content, high starch content) and a reduced validation for every other commodity within a certain crop group. Where validation results do not meet the criteria given below, this is indicated.

When the analytical method is validated according to a full validation scheme, it means that

- at least 5 recovery experiments per level were conducted on at least 2 levels (LOQ and 10× LOQ) and average recovery per level was shown to be between 70–120% and the relative standard deviation (RSD_r or CV) per level was shown to be < 20%,
- at least two control samples were analysed and were shown to be below 0.3×LOQ and
- the calibration was conducted with at least 5 single points or at least 3 duplicate points and was shown to be linear (either standards in solvent or matrix matched standards).

When the analytical method is validated according to a reduced validation scheme, it means that

- a full validation is available for a crop in the same crop group (high acid content, high water content, high oil content, high protein content, high starch content);
- at least 3 recovery experiments per level were conducted on at least 2 levels (LOQ and 10× LOQ) and the average recovery per level was shown to be between 70–120% and the relative standard deviation (RSD_r or CV) per level was < 20%;
- at least two control samples were analysed and shown to be below 0.3× LOQ
- the calibration was conducted with at least 5 single points or at least 3 duplicate points and was shown to be linear (only relevant for matrix matched standards; standards in solvent are already covered by full validation).

Analytical methods used in study reports in plant commodities

HPLC-MS/MS method RAM 465/01

HPLC-MS/MS Method RAM 465/01 is used for the determination of emamectin benzoate and its avermectin-like residues in almond and pecan nutmeat and almond hulls. Description and validation of RAM 465/01 and its modifications has previously been submitted for the JMPR 2011 evaluation. A modification of the method was issued on 20 March 2007 for almonds and pecans as described in the JMPR 2011 evaluation report [Ediger, 2007, MK244/0714]. The 30 May 2008 modification used in the 2008 supervised residue trials on almonds and pecans [Oakes, 2009, MK244/50014] is the same as the 20 March 2007 modification.

Additional validation results are available from the 2008 supervised residue trials [Oakes, 2009, MK244/50014]. Since all analyses were performed in the same laboratory, the present reviewer combined the recovery results from identical commodities to get within-laboratory reproducibility and recovery results. Reduced validation results are available at 0.001 and 0.005 mg/kg (n=3–4, each level) in almond nutmeat and pecan nutmeat and at 0.001 mg/kg (n=3, each level) in almond hulls for MAB1a (NOA 426007), MAB1b (NOA 422390), 8,9-ZMa (NOA 438376), AB1a (NOA 438309), MFB1a (NOA 415692) and FAB1a (NOA 415693). Limited validation results are available at 0.05–0.1 mg/kg in almond hulls (n=2, each level). Average recoveries for these validations ranged between 70–120% with an RSD < 20% for reduced validations. The only exception is 0.001 mg/kg FAB1a in almond nutmeat where the RSD = 25%. Residues of the analytes were below LOQ (i.e. < 0.001 mg/kg) when measured in untreated control samples of almond nutmeat, pecan nutmeat or almond hulls. Linearity of the response was assessed using 5 single standards in solvent. The response was shown to be linear (1/× weighted) across the range 0.005–0.1 µg/L or 0.05–20 ng/L for ionisable analytes and 0.02–2.0 µg/L for neutral analytes. The correlation coefficient (r) for the calibration regression lines was greater than 0.999 in all cases.

The 20 March 2007 modification of HPLC-MS/MS method RAM 465/01 is valid for quantification of emamectin benzoate (B1a and B1b) and its avermectin-like residues at levels between 0.001–0.005 mg/kg in almond nutmeat and pecan nutmeat and at 0.001–0.1 mg/kg in almond hulls. The only exception is 0.001 mg/kg FAB1a (NOA 415693) in almond nutmeat where the RSD = 25% (n=3). Since this compound is not in the residue definition for enforcement or dietary risk assessment, this has no impact on the MRL derivation.

HPLC-MS/MS method TP/03

Method TP/03 is used for the determination of emamectin benzoate and its isomer 8,9-ZMa in rape seeds and rape forage.

Method TP/03 involves extraction of residues of emamectin B1a (NOA 426007), emamectin B1b (NOA 422390) and 8,9-ZMa (NOA 438376) from rape seeds and rape forage [Balshaw and Fernandez, not dated]. Homogenised sample (5 or 10 g) is mixed with acetonitrile acidified to 1% with acetic acid. Sodium chloride and magnesium sulphate are added and mixed vigorously followed by centrifugation. Where the sample to solvent ratio is not 1:1 a concentration step is included using a nitrogen evaporator. The acetonitrile layer is cleaned up with a primary secondary amine cartridge and magnesium sulphate. The extract is then analysed using HPLC-MS/MS using external standards for emamectin benzoate and 8,9-ZMa. For emamectin B1a benzoate the MRM transition ions were m/z 886.6 to m/z 158 (quantification) and m/z 126 and 302 for confirmation. For emamectin B1b benzoate the MRM transitions were m/z 872.5 to m/z 158 (quantification) and m/z 82 and 126 for confirmation. For 8,9-ZMa the MRM transitions were m/z 890.6 to m/z 305 (quantification) and m/z 193 and 567 for confirmation.

Validation results for rape seeds and rape forage are reported in the supervised residue trials [Lean, 2014a/b, MK244/10298, MK244/10300] as well as a separate validation report [Balshaw and Fernandez, not dated]. Full validation results are available for rape seeds at 0.005 and 0.05 mg/kg

(n=6, each level) for emamectin benzoate (B1a and B1b). Reduced validation results are available at 0.05 mg/kg (n=3) for 8,9-Zma in rape seeds and at 0.05 mg/kg (n=3) for emamectin benzoate (B1a and B1b) and 8,9-Zma in rape forage. Limited validation results are available at 0.005 mg/kg (n=2) for 8,9-Zma in rape seeds and rape forage and for emamectin benzoate (B1a and B1b) in rape forage. Limited validation results are available at 0.1 mg/kg (n=1) for emamectin benzoate (B1a and B1b) and 8,9-Zma in rape forage. Average recoveries for these validations ranged between 70%-120% with an RSD < 20% for full or reduced validations. Residues of the analytes were below 0.3LOQ (i.e. < 0.002 mg/kg) when measured in untreated control samples of rape seeds and rape forage. The linearity of response was verified for 5–7 single standards in solvent. The linear range was 0.005 to 0.20 mg/kg for 1/× weighted regression and forced origin with a coefficient of determination (R^2) > 0.99 for each analyte.

HPLC-MS/MS method TP/03 is considered valid for quantification of emamectin benzoate (B1a and B1b) at levels between 0.005–0.05 mg/kg in rape seeds and rape forage. The quantification of 8,9-Zma at levels of 0.005–0.05 mg/kg in rape seeds and rape forage is considered insufficiently validated. Since 8,9-Zma is not in the residue definition for enforcement or dietary risk assessment, this has no impact on the MRL derivation.

Stability of pesticide residues in stored analytical samples

Emamectin benzoate is stable in commodities with high oil content such as nutmeat and canola grain for a minimum of 9 months and for a minimum of 2 years in high water content crops and dry crops under deep-frozen conditions. The reports of all relevant storage stability studies have previously been submitted [JMPR 2011 evaluation].

USE PATTERN

Emamectin benzoate is registered for use in several countries for control of insects on several commodities as is indicated in the JMPR 2011 evaluation. Additional label information on tree nuts and rape seed was submitted to the present Meeting and is presented in table 1.

Table 1 lists only the uses for which an original label was available and the dose rate could be verified by the Meeting. The label information on tree nuts is the same as for the JMPR 2011 evaluation and this information is repeated here for convenience. The labels on rape seed and tree nuts indicate that thorough spray coverage is essential for optimum performance. The use of greater water volumes generally results in better coverage, especially in hot and dry weather conditions or when the plant canopy is dense. The use of an adjuvant typically improves coverage and penetration and results in optimum insect control, especially in crops with hard-to-wet leaf surfaces.

Table 1 Registered pre-harvest uses of emamectin benzoate, relevant for the present evaluation

Crop	Country	Formul g ai/kg or g ai/L	Method	Rate per applic (g ai/ha)	Spray concentr (g ai/hL)	Number	Spray interval (days)	PHI, days
Tree nuts ^a including pistachios	USA	SG 50 ^c	concentrate airblast foliar spray ground equipment	11.2-16.8	3.0-4.5	1-3, max 50.4 g ai/ha per season	7	14
	USA	SG 50 ^c	dilute airblast foliar spray ground equipment	11.2-16.8	0.30-0.45	1-3, max 50.4 g ai/ha per season	7	14
Rape seed (canola) for	Australia	EC 17 ^c	foliar spray ground	2.6-5.1	2.6-5.1	1-2	^d	14

Crop	Country	Formul g ai/kg or g ai/L	Method	Rate per applic (g ai/ha)	Spray concentr (g ai/hL)	Number	Spray interval (days)	PHI, days
seed production ^b			equipment					
	Australia	EC 17 ^c	foliar aircraft spray	2.6-5.1	13-26	1-2	^d	14

SG = water soluble granule, EC = emulsifiable concentrate

^a The tree nut class in the USA includes: almond, beechnut, Brazil nut, butternut, cashew, chestnut, chinquapin, filbert (hazelnut), hickory nut, macadamia nut (bush nut), pecan, walnut (black and English/Persian).

^b The Australian label on rape seed contains a restriction for use as feed: "do not use on canola grown as forage crop and also the intended use table indicates: canola for grain production"

^c The use of a penetrating type spray adjuvant (tree nuts) or a non-ionic surfactant (rape seed, tree nuts) is recommended. Do not use sticker/binder type adjuvant for tree nuts.

^d Sample crops twice a week after application to determine if a second application is required.

RESIDUES RESULTING FROM SUPERVISED TRIALS ON CROPS

The Meeting received supervised residue trials on rape forage, almonds, pecans and rape seed.

Crop group	Commodity	Table no.
Tree nuts	Almonds	Table 2
	Pecans	Table 3
	Rape seed	Table 4
Oilseeds	Almond hulls	Table 5
	Rape forage	Table 6

Application rates are reported as emamectin benzoate (g ai/ha). Unquantifiable residues are shown as below the reported LOQ (e.g., < 0.001 mg/kg). Residues, application rates and spray concentrations have been rounded to two significant figures. Residue data are recorded unadjusted for percentage recoveries or for residue values in control samples unless otherwise stated. Where multiple samples were taken from a single plot individual values are reported, but the mean value is selected for MRL derivation, if according to cGAP. Where multiple analyses were conducted on a single sample, the average value is reported. Where results from separate plots with distinguishing characteristics such as different formulations, crop varieties or treatment schedules were reported, results are listed for each plot. However in such cases only one residue value may be selected per location. Residues from the trials conducted according to critical GAP have been used for the estimation of maximum residue levels, STMR and HR values. Those results are underlined.

Tree nuts

The Meeting received supervised residue trials on almonds and pecans.

Supervised residue field trials on almonds and pecans were carried out in the USA in 2006 and 2007 [Ediger 2007, MK244/0714, Oakes, 2009, MK244/50014]. The 2006 trials were summarized and evaluated by the 2011 JMPR. The 2007 trials are summarized here. Almond and pecan trees were treated with three foliar cover spray applications using a tractor mounted sprayer or airblast sprayer. The spray volume was either 93–95 L/ha (very concentrate spray as used for aircraft equipment), 450–780 L/ha (concentrate spray as used for airblast sprayers) or 1300–2300 L/ha (dilute spray as used for ground equipment). The spray mix included a horticultural oil, non-ionic surfactant or organo-silicone adjuvant. There were no unusual weather conditions. Whole nuts were harvested at maturity. Samples were prepared by separating shells from nutmeat to generate at least 1.4 kg of nutmeat (=RAC). Samples were stored at -20 °C for a maximum of 9 months. Samples were analysed for MAB1a (NOA 426007), MAB1b (NOA 422390), 8,9-Zma (NOA 438376), AB1a (NOA 438309), MFB1a (NOA 415692) and FAB1a (NOA 415693) by HPLC-MS/MS Method RAM 465/01

(modification 30 May 2008). Results were not corrected for control levels (< 0.001 mg/kg for each analyte) nor for average concurrent method recoveries (70%-120% for each analyte). Results are shown in table 2 and table 3. Results represent the mean of two replicate samples taken from each plot.

Residues of avermectin-like residues were not found in any of the almond or pecan nutmeat samples (< 0.001 mg/kg). Several trials have been conducted on the same location. From such trials only the highest (mean) value is selected for MRL derivation if compliant with cGAP.

Metabolites < LOQ were assumed not to be present

Rape seed

The Meeting received supervised residue trials on rape seed (canola).

Supervised residue field trials on rape seed (canola) were carried out in 2009, 2010 and 2011 in Australia [Lean, 2014a/b, MK244/10298, MK244/10300 and additional information in Syngenta, 2014]. Rape seed on 12–160 m² plots was treated with two foliar applications using a gas powered hand-held boom sprayer. The spray volume was 74–88 L/ha (concentrate spray) or 154–250 L/ha (intermediate spray) or 403–575 L/ha (dilute spray). The spray mix included a non-ionic adjuvant. There were no unusual weather conditions. The mature crop was desiccated by wind-rowing, herbicide desiccation (Reglone® with 200 g/L diquat) or unaided natural desiccation. Herbicide desiccation involves the use of a herbicide to dry off the plant, which leaves it attached in the ground, preventing the crop from blowing away. Whereas wind-rowing involves the cutting of the crop and laying it in the rows to dry, providing a greater chance for loss of crop due to wind. Seeds (at least 2 kg, from at least 12 plants) were collected from each plot 0–15 days after cutting or chemical desiccation. Crops were headed directly in the field in case of unaided natural desiccation. Samples were stored at -2 °C or lower for a maximum of 265 days (2009–2010 samples) and 99 days (2011 samples).

Samples were analysed for MAB1a (NOA 426007), MAB1b (NOA 422390) and 8,9-Zma (NOA 438376) by HPLC-MS/MS Method TP/03. The isomer 8,9-Zma was only analysed in the 2009 and 2010 residue trials. The other avermectin-like metabolites were not quantified at all. Results were not corrected for control levels (< 0.005 mg/kg for each analyte) nor for average concurrent method recoveries (70–120% for each analyte). Results are shown in Table 4.

HPLC-MS/MS method TP/03 is considered valid for quantification of emamectin benzoate (B1a and B1b) in rape seeds at levels between 0.005–0.05 mg/kg. The quantification of 8,9-Zma at levels of 0.005–0.05 mg/kg in rape seeds is considered insufficiently validated. Since 8,9-Zma is not in the residue definition for enforcement or dietary risk assessment, this has no impact on the MRL derivation.

No residues of MAB1a, MAB1b or 8,9-Zma were not found in any of rape seed samples (< 0.005 mg/kg). The other avermectin-like metabolites were not quantified at all. Several trials have

been conducted on the same location. From such trials only the highest value is selected for MRL derivation if compliant with cGAP.

Table 4 Results from supervised field trials on rape (seeds) using an EC formulation (17 g ai/L) with adjuvant

*DAT = days after treatment. This timepoint includes the time the crop lies or stands drying in the field (in case of wind-rowing or herbicide desiccation) and refers to the time at which the seeds were collected from the plant.

DAC = days after cutting or desiccation, where the crop was kept in the field, before actual samples were taken.

^a Results are for seeds + pods. Since the residues are < LOQ, results can be used for MRL derivation for seeds if according to cGAP

^b Windrowed crop was harvested at 0 days after cutting or herbicide desiccated crop was harvested at the day of desiccation, meaning the crop was not dried off at harvest. Such samples are not considered representative for MRL derivation and the corresponding residues are not selected.

Miscellaneous fodder and forage crops

The Meeting received supervised residue trials on almonds and rape.

Almond hulls

Supervised residue field trials on almonds were carried out in 2006 and 2007 in the USA [Ediger, 2007, MK244/0714, Oakes, 2009, MK50014]. The 2006 trials were summarized and evaluated by the 2011 JMPR. The 2007 trials are summarized here. Almond trees were treated with three foliar cover spray applications using a tractor mounted sprayer or airblast sprayer. The spray volume was either 93-94 L/ha (very concentrate spray as used for aircraft equipment), 700- 780 L/ha (concentrate spray as used for airblast sprayers) or 1600-1900 L/ha (dilute spray as used for ground equipment). The spray mix included a horticultural oil, non-ionic surfactant or organo-silicone adjuvant. There were no unusual weather conditions. Whole nuts were harvested at maturity. Samples were prepared by separating shells from nutmeat to generate at least 1.4 kg of nutmeat (=RAC). Samples were stored at -20 °C for a maximum of 9 months. Samples were analysed for MAB1a (NOA 426007), MAB1b (NOA 422390), 8,9-Zma (NOA 438376), AB1a (NOA 438309), MFB1a (NOA 415692) and FAB1a (NOA 415693) by HPLC-MS/MS Method RAM 465/01 (modification 30 May 2008). Results were not corrected for control levels (< 0.001 mg/kg for each analyte) nor for average concurrent method recoveries (70%-120% for each analyte). Results are shown in table 5. Results represent the mean of two replicate samples taken from each plot.

Several trials have been conducted on the same location. From such trials only the highest (mean) value is selected for MRL derivation if compliant with cGAP.

For the overall conclusion on avermectin-like metabolites also the data from the 2011 JMPR are taken into account. Residues of avermectin-like metabolites were found at levels (< 0.001–0.010 mg/kg for individual analytes) in several almond hull samples at DALT = 7–35, except in trial WC-IR-06-7116/CA (JMPR 2011). In this single trial MFB1a residues were particularly high: 0.018–0.036 mg/kg at DALT 7–21. Where metabolites were > LOQ, the sum of the four avermectin-like metabolites ranged from 0.002–0.010 mg/kg, expressed as MAB1a, except in trial WC-IR-06-7116/CA (JMPR 2011), where the sum ranged from 0.019–0.038 mg/kg at DALT 7–21. Where MAB1a was at least 0.01 mg/kg, the ratio of the sum of the avermectin-like metabolites to MAB1a ranged from 0.04–0.30 (median 0.09), except in trial WC-IR-06-7116/CA, where the ratio ranged from 0.28–0.78 at DALT=7–35.

^a Results are from two replicate field samples, the mean may be selected for MRL derivation if compliant with cGAP.

Sum1a expressed as MAB1a = sum of MAB1a plus its avermectin-like metabolites, corrected for molecular weight (MAB1a + 1.000 × 8,9-Zma + 1.016 × AB1a + 0.9693 × MFB1a + 0.9844 FAB1a). Metabolites < LOQ were assumed not to be present

Rape forage

Supervised residue field trials on rape forage were carried out in 2009 and 2010 in Australia [Lean, 2014a, MK244/10298 and additional information in Syngenta, 2014]. Rape forage on 12–160 m² plots were treated with two foliar applications using a gas powered hand-held boom sprayer. The spray volume was 74–88 L/ha (concentrate spray) or 403–575 L/ha (dilute spray). The spray mix included a non-ionic adjuvant. There were no unusual weather conditions. Immature foliage samples (at least 1 kg, from at least 12 plants) were collected 36–6 days before normal desiccation of the crop. Samples were stored at -2 °C or lower for a maximum of 274 days.

Samples were analysed for MAB1a (NOA 426007), MAB1b (NOA 422390) and 8,9-Zma (NOA 438376) by HPLC-MS/MS Method TP/03. Results were not corrected for control levels (< 0.005 mg/kg for each analyte) nor for average concurrent method recoveries (70%-120% for each analyte). Results are shown in table 6.

HPLC-MS/MS method TP/03 is considered valid for quantification of emamectin benzoate (B1a and B1b) at levels between 0.005–0.05 mg/kg in rape forage. The quantification of 8,9-Zma at levels of 0.005–0.05 mg/kg in rape seeds and rape forage is considered insufficiently validated. Since 8,9-Zma is not in the residue definition for enforcement or dietary risk assessment, this has no impact on the MRL derivation.

Residues of MAB1a in rape forage ranged between < 0.005–0.014 mg/kg; residues of MAB1b ranged between < 0.005–0.006 mg/kg. Residues of 8,9-Zma were not found in any of the samples. The other avermectin-like metabolites were not analysed.

Table 6 Results from supervised field trials on rape forage using an EC formulation (17 g ai/L) with adjuvant

* = days before cutting or days before desiccation, i.e. the period before normal harvest of the crop

APPRAISAL

Emamectin benzoate is a insecticide derivative of abamectin. Emamectin benzoate was first evaluated by the JMPR in 2011 for toxicology and residues. The 2011 Meeting established an ADI of 0–0.0005 mg/kg bw, expressed as emamectin benzoate. The ARfD was re-evaluated by the 2014 JMPR which reduced the ARfD to 0.02 mg/kg bw expressed as emamectin benzoate. The 2011 Meeting defined the residue as emamectin B1a benzoate for plant and animal commodities for compliance with the MRL and for estimation of dietary intake. Since the molecular weight difference between emamectin B1a benzoate and emamectin benzoate (consisting of 90% emamectin B1a benzoate and 10% emamectin B1b benzoate) is marginal, residues are not corrected for molecular weight. The 2011 Meeting considered the residue not fat soluble.

Emamectin benzoate was scheduled by the Forty-fifth Session of the CCPR (2013) for the evaluation of additional maximum residue levels by the 2014 JMPR. The manufacturer submitted additional supervised residue trials on almonds, pecans and rape, which were evaluated by the present Meeting.

Methods of Analysis

The Meeting received description and validation data for an analytical method for emamectin B1a and B1b benzoate and its 8,9-ZMa isomer in rape commodities for use in supervised residue trials. The analytical method is based on extraction with acidified acetonitrile and analysis by HPLC-MS/MS. The Meeting considered the method valid in the range 0.005–0.05 mg/kg emamectin B1a in rape seeds.

The analytical method for the determination of residues in almonds, pecans and almond hulls was considered valid by the 2011 Meeting.

Stability of pesticide residues in stored analytical samples

Storage stability studies were provided to the 2011 Meeting demonstrating the stability of emamectin B1a benzoate for at least 27 months at -20 °C or lower in stored plant commodities with high water content, 18 months in plant commodities with high starch content and at least 9 months in plant commodities with high oil content.

All crop commodities from supervised residue trials were analysed within the verified storage stability period. Oilseeds and rape forage were stored at -2 °C. Since parent is shown to be stable for a long period of time, trials where temperatures during storage were raised to -2 °C, were not rejected.

Results of supervised residue trials on crops

The Meeting received supervised trials data for emamectin benzoate on rape forage, tree nuts, rape seed and almond hulls. In addition, the 2011 JMPR trials on lettuces were re-evaluated by the present Meeting because of an ARfD exceedance for leaf lettuce.

Lettuce

The International Estimated Short Term Intake (IESTI) for emamectin benzoate was recalculated as the ARfD was changed from 0.03 to 0.02 mg/kg bw and a revised IESTI calculation model was available at the 2014 Meeting. The IESTI for the diets submitted to the JMPR represented 0–190% of the ARfD (0.02 mg/kg bw, expressed as emamectin benzoate) for children. The ARfD is exceeded for leaf lettuce (total, i.e., raw and processed commodities) in the diet for children.

At the 2011 JMPR, maximum residue levels for head lettuce, leaf lettuce and Cos lettuce were recommended based on head lettuce data, of 1 mg/kg. The present Meeting re-evaluated the separate datasets for head lettuce, Cos lettuce and leaf lettuce that were available to the 2011 JMPR. The leaf lettuce dataset was considered insufficient to recommend a maximum residue level (n=1–3, depending on the GAP used). The Cos lettuce dataset could however be used to propose a maximum residue level for leaf lettuce and Cos lettuce. The Meeting decided to retain the previous recommendation for head lettuce (current Codex MRL of 1 mg/kg) based on head lettuce data and to propose a new maximum residue level for Cos lettuce and leaf lettuce, based on the Cos lettuce data.

The 2011 Meeting agreed to combine the dataset for indoor and field grown Cos lettuce matching the Italian GAP (3 foliar spray applications, interval 7 days, 14.2 g ai/ha with a 3 day PHI) to represent residues in field and indoor grown Cos lettuce. This resulted in the following dataset: 0.030, 0.033, 0.042, 0.052, 0.10, 0.11, 0.30 and 0.33 mg/kg (n=8).

The present Meeting agreed that the dataset for Cos lettuce matching Italian GAP could be used to support a maximum residue level recommendation for Cos lettuce and leaf lettuce. The Meeting decided to withdraw its previous recommendations for Cos lettuce and leaf lettuce of 1 mg/kg and estimated a new maximum residue level 0.7 mg/kg for Cos lettuce and leaf lettuce. The Meeting estimated an STMR of 0.076 mg/kg and a HR of 0.33 mg/kg.

Tree nuts

The 2011 JMPR Meeting was unable to estimate a maximum residue level for almonds or pecans as the dataset was considered insufficient. Additional trials were submitted to the present Meeting and these were combined with the trials evaluated by the 2011 JMPR.

Field trials involving almonds were performed in the USA.

Critical GAP for tree nuts in the USA is for three foliar spray applications at 16.8 g ai/ha (maximum of 50.4 g ai/ha per season, interval 7 days) and a PHI of 14 days, with adjuvant. In almond trials from the USA (3 × 17 g ai/ha; interval 7 days and a 14 day PHI, applied with adjuvant) matching US GAP emamectin B1a benzoate residues in almonds (nutmeat) were: < 0.001 (4) mg/kg (including 1 value from the 2011 JMPR).

Field trials involving pecans were performed in the USA.

Critical GAP for tree nuts in the USA is for three foliar spray applications at 16.8 g ai/ha (maximum of 50.4 g ai/ha per season, interval 7 days) and a 14 day PHI, with adjuvant. In pecan trials from the USA (3 × 17 g ai/ha; interval 7 days and PHI 14 days, with adjuvant) matching US GAP emamectin B1a benzoate residues in pecans (nutmeat) were < 0.001 (5) mg/kg (including 1 value from the 2011 JMPR).

The Meeting agreed that the dataset for almonds and pecans matching USA GAP could be used to support a maximum residue level recommendation for tree nuts, and estimated a maximum residue level of 0.001* mg/kg in/on tree nuts and estimated an STMR of 0.001 mg/kg and an HR of 0.001 mg/kg.

Rape seed

Field trials involving rape were performed in Australia. Rape seeds were harvested using three different techniques: natural desiccation, herbicide desiccation, and wind-rowing. In natural desiccation seeds were collected after the plants had dried off naturally. Herbicide desiccation involves the use of a herbicide to dry off the green plant followed by seed collection up to 15 days later. Wind-rowing involves the cutting of the green crop and laying it in the rows to dry, followed by seed collection up to 15 days later. Since no residues were found in rape seeds in any of these trials, the impact of the harvest technique could not be assessed. Therefore, trials matching cGAP were selected irrespective of the harvest technique. Trials where the seeds were collected at the day of cutting (wind-rowing technique) or at the day of desiccation (herbicide desiccation technique) were excluded, since in this case the seeds were harvested from the green plant and such samples are not representative for maximum residue level derivation.

Critical GAP for rape in Australia is for two foliar spray applications at 5.1 g ai/ha with an unspecified interval and PHI 14 days. In rape trials from Australia (2×5.3 –6.1 g ai/ha; interval 6–9 days and PHI 13–17 days, with adjuvant) matching this GAP emamectin B1a benzoate residues in rape seeds were < 0.005 (6) mg/kg. Trials at higher dose rate and shorter PHI (2×11 –13 g ai/ha, interval 5–8 days and PHI 5–8 days) confirmed the non-residue situation: < 0.005 (4) mg/kg.

The Meeting agreed that the dataset for rape matching Australian GAP could be used to support a maximum residue level recommendation for rape seeds, and estimated a maximum residue level of 0.005* mg/kg in/on rape seed and estimated an STMR of 0 mg/kg. An HR is not considered necessary, since bulking/blending of the seeds is likely for a pre-harvest application.

Almond hulls

The 2011 JMPR Meeting was unable to estimate a maximum residue level for almond hulls as the dataset was considered insufficient. Additional trials were submitted to the present Meeting and these were combined with the trials evaluated in the 2011 JMPR report.

Field trials involving almonds were performed in the USA. Three spray concentrations were tested in one trial: very concentrated (for aircraft equipment), concentrated (for airblast equipment) and dilute (for ground equipment). In this one trial, the highest residue was found for the concentrated spray concentration as used for airblast equipment: 0.088 mg/kg versus 0.057–0.059 mg/kg. Since one trial is not sufficient to conclude on the effect of spray concentration and a second trial, where a concentrate spray concentration was used, produced much lower residues (0.018 mg/kg), the Meeting decided to take the highest residue from each location irrespective of the spray concentration.

Critical GAP for tree nuts in the USA is for three foliar spray applications at 16.8 g ai/ha (maximum of 50.4 g ai/ha per season, interval 7 days) and PHI of 14 days, with adjuvant. In almond trials from the USA (3×17 g ai/ha; interval 7 days and PHI 14 days, with adjuvant) matching this GAP emamectin B1a benzoate residues in almond hulls were 0.018, 0.020, 0.043, 0.088 mg/kg (n=4), as received (including 1 value from the 2011 JMPR). Since the dry weight for almond hulls is 90%, no dry weight correction is needed.

The Meeting agreed that the dataset for almond hulls matching USA GAP could be used to support a maximum residue level recommendation for almond hulls, and estimated a maximum residue level of 0.2 mg/kg in/on almond hulls and estimated a median residue of 0.0315 mg/kg. A highest residue is not considered necessary, since bulking/blending of the hulls is likely for use as feed commodity.

Rape forage

Field trials involving rape forage were performed in Australia. The only GAP available on rape is from Australia and this GAP contains a restriction not to use emamectin benzoate on rape grown as forage crop (i.e., rape forage). The Meeting decided not to use the trials.

Residues in animal commodities

The Meeting estimated the dietary burden of emamectin benzoate residues on the basis of the livestock diets listed in the FAO manual appendix IX (OECD feedstuff table). Calculation from highest residue, STMR (some bulk commodities) and STMR-P values provides the levels in feed suitable for estimating maximum residue levels, while calculation from STMR and STMR-P values from feed is suitable for estimating STMR values for animal commodities.

The 2014 JMPR Meeting recalculated the livestock dietary burden based on the uses presented by the 2011 JMPR and including the residue values for almond hulls from the 2014 JMPR Meeting. The maximum dietary burden for cattle for maximum residue level setting is not changed, while the mean dietary burden for cattle changed only marginally from 0.018 ppm in the 2011 JMPR Meeting to 0.021 ppm in the 2014 JMPR Meeting. Poultry is not exposed to emamectin benzoate through feed treated with emamectin benzoate. The Meeting therefore confirmed its previous recommendations for animal commodities.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits.

Definition of the residue for compliance with the MRL and for dietary risk assessment for plant and animal commodities: *emamectin B1a benzoate*

The Meeting considers the residue not fat soluble.

Summary of recommendations

CCN	Commodity name	MRL proposed mg/kg	MRL Previous mg/kg	STMR mg/kg	HR mg/kg	Comment
VL 0483	Leaf lettuce	0.7	1	0.076	0.33	-
VL 0510	Cos lettuce	0.7	1	0.076	0.33	-
TN 0085	tree nuts	0.001*		0.001	0.001	-
SO 0495-	rape seed	0.005*		0	-	-

CCN	Commodity name	MRL mg/kg	Median residue mg/kg	Highest residue mg/kg	Comment
-	almond hulls	0.2	0.0315	-	feed stuff

DIETARY RISK ASSESSMENT**Long-term intake**

The International Estimated Daily Intakes (IEDI) for emamectin benzoate was calculated from recommendations for STMRs for raw and processed commodities in combination with consumption data for corresponding food commodities. The results are shown in Annex 3.

The IEDI of in the 17 GEMS/Food cluster diets, based on the estimated STMRs in the 2011 and 2014 JMPR represented 1–9% of the maximum ADI of 0.0005 mg/kg bw, expressed as

emamectin benzoate. No conversion factor is needed to convert emamectin B1a benzoate residues to emamectin benzoate residues.

The Meeting concluded that the long-term intake of residues of emamectin benzoate from uses considered by the 2011 and 2014 Meeting is unlikely to present a public health concern.

Short-term intake

The International Estimated Short Term Intake (IESTI) for emamectin benzoate was recalculated due to the ARfD being changed from 0.03 to 0.02 mg/kg bw and the availability of a revised IESTI calculation model at the present Meeting. The IESTI was calculated from recommendations for STMRs and HRs for raw and processed commodities evaluated in the 2011 and 2014 JMPR Meeting in combination with consumption data for corresponding food commodities. The results are shown in Annex 4 to the 2014 Report.

The IESTI for the general population represented 0–30% of the ARfD (0.02 mg/kg bw, expressed as emamectin benzoate) and the IESTI for children represented 0–30% of the ARfD. No conversion factor is needed to convert emamectin B1a benzoate residues to emamectin benzoate residues.

The Meeting concluded that the short-term intake of residues of emamectin benzoate from uses considered by the 2011 and 2014 Meeting are unlikely to present a public health concern.

FENAMIDONE (264)

First draft was prepared by Dr Ursula Banasiak, Delegate of the Federal Institute for Risk Assessment, Berlin, Germany

EXPLANATION

Fenamidone is a broad-spectrum fungicide belonging to the imidazolinone group. The compound was evaluated the first time by the 2013 JMPR for toxicology where an ADI of 0–0.03 mg/kg bw and an ARfD of 1 mg/kg bw was allocated. The evaluation for residues was scheduled for the 2014 JMPR.

The current Meeting received information on physical and chemical properties, metabolism studies on plants and animals, analytical methods, supervised trials data, processing studies as well as use patterns.

IDENTITY

Fenamidone (RPA 407213) is the S-enantiomer of the stereoisomeric molecule RPA 405803 with the chiral centre in the 5-position. The S-isomer has been shown to be the biologically active enantiomer.

Common name: Fenamidone

Chemical name:

IUPAC: (S)-5-Methyl-2-methylthio-5-phenyl-3-(phenylamino)-3,5-dihydro-4H-imidazol-4-one

CA: (5S)-3,5-dihydro-5-methyl-2-(methylthio)-5-phenyl-3-(phenylamino)-4H-imidazol-4-one

CAS number: 161326-34-7

Molecular formula: C₁₇H₁₇N₃OS

Structural formula:

Molecular mass: 311.4

Minimum purity: Active substance (ai) manufactured 975 g/kg

Formulations

Fenamidone is available in numerous commercial formulations in different types (SC, WG, WP-soluble bag) in many countries.

PHYSICAL AND CHEMICAL PROPERTIES

Fenamidone is a thermally stable solid. The compound is poorly soluble in water and soluble in toluene, dichloromethane and acetone. It is stable at pH 5 and pH 7 and hydrolyses under acidic or alkaline conditions, is not explosive and not self-igniting. For details see Table 1.

METABOLISM AND ENVIRONMENTAL FATE

Fenamidone active substance as defined by the ISO common name and the CA name is the S-enantiomer of the stereoisomeric molecule RPA405803 with the chiral centre in the 5-position of the dihydro-imidazolone ring. This S-enantiomer has been shown to be the biologically (fungicidally) active enantiomer. The minimum purity of fenamidone in the technical substance is 975 g/kg.

The chiral carbon atom in the 5-position of the dihydro-imidazolone ring is substituted by 4 non-hydrogen substituents, i.e., by an amino, carbonyl, methyl and phenyl group. Prerequisite for isomerisation/racemisation of this type of centre of chirality is the presence of a hydrogen atom as a substituent that can be split off easily. In fenamidone, no hydrogen is linked to the chiral centre.

Therefore, racemisation is chemically not possible and the configuration and the optical purity, respectively, established by synthesis (5S, ee > 99%) does not change afterwards.

All fenamidone studies on metabolism, residues and toxicology were conducted with this pure S-enantiomer as test substance. Accompanying analysis was usually conducted using achiral methods without the possibility to examine a potential isomerisation/racemisation during the interaction with animal, plant and environmental matrices. In order to investigate this possibility a study (M-173254-01-1) was performed using chiral HPLC analysis of different samples out of “nature-of-residue” studies on soil metabolism, water-sediment, hydrolysis, aqueous and soil photolysis as well as metabolism on lettuce, grape, potato and rat (ADME) and on the livestock animals hen and goat. In no case, there was any evidence of enantiomerization or racemization of the parent substance and its metabolites during metabolic conversions or physico-chemical degradation.

The metabolism and distribution of fenamidone in plants and animals was investigated using the ^{14}C -labelled test materials as shown below.

[C-phenyl-UL- ^{14}C]-fenamidone

[N-phenyl-UL- ^{14}C]-fenamidone

* Denotes position of ^{14}C -label

Chemical names, structures and code names of metabolites and degradation products of fenamidone are summarized in Table 2. Compounds are referred to primarily by the code number of the S-enantiomer, with the code of the corresponding racemic compound additionally mentioned.

Racemic compounds are generally used as reference standards in metabolism/degradation and residue studies. Nevertheless, the codes for the S-enantiomer were frequently used below for describing the metabolites, because their enantiomeric stability in the S-configuration has been demonstrated.

Animal metabolism

The metabolism of fenamidone has been studied in laboratory rats, lactating goats and laying hens.

Rats

Rat metabolism studies were evaluated by the WHO Core Assessment Group of the 2013 JMPR and are summarized as follows: In experiments conducted in rats using [^{14}C]fenamidone labelled at either the C-phenyl or N-phenyl part of the molecule, the time to reach the maximum plasma concentration of radioactivity was 2 hours after a single oral dose of 3 mg/kg bw and 26 hours after a single oral dose of 300 mg/kg bw. Gastrointestinal absorption was greater than 80%. Radioactivity distributed to most tissues, with no evidence of accumulation. Relatively high concentrations of radioactivity (approximately 400 times higher than that in plasma) were detected in the thyroid following dosing with C-phenyl- but not N- phenyl-labelled fenamidone, suggesting the distribution of a radiolabelled metabolite to the thyroid. Fenamidone undergoes extensive metabolism in the rat by phase I (oxidation, reduction and hydrolysis) and phase II reactions (conjugation). The plasma elimination half-life was at least 60 hours. More than 20 metabolites were detected in rat excreta, with the majority of radioactivity excreted in the faeces (up to approximately 90% of the administered dose) and the remainder in urine. Mass balance data indicated that the majority of radioactivity (> 80%) was eliminated within 48 hours of dosing.

Lactating goats

Burri (1999) investigated the fate of fenamidone following repeated oral administration to the lactating goat in two separate studies (643724, M-183880-01-1 and 684088, M-183833-01-1, see Table 3).

Two dose levels were used for each label position, with one lactating Saanen goat being used per dose and label. The dose levels were 1.0 ppm and 10.4 ppm for [C-phenyl-UL- ^{14}C]-fenamidone and 1.5 ppm and 11.5 ppm for [N-phenyl-UL- ^{14}C]-fenamidone in the diet. Dosing was performed twice daily by capsule during seven consecutive days. Goats were sacrificed at 22 hours after the last

(14th) administration. Milk, urine and faeces were sampled during the course of the study and liver, kidney, muscles and fat were obtained after the end of the experiment. The total radioactive residues (TRR) were determined by LSC in liquid matrices after solubilisation, in solid matrices by combustion. The samples were prepared as follows:

Milk

Studies 643724 and 684088: Radioactivity in the milk was determined by LSC after solubilisation. The milk was defatted by centrifugation. The defatted milk was de-proteinised by adding acetone (1 + 4, v/v). After shaking for 30 min. at room temperature, an incubation for 16 hours at about 4 °C and centrifugation, the supernatant was removed and the pellet was further extracted twice with acetone, twice with acetone/water (1 + 1, v/v) and once with methanol/water (C-phenyl-label: 1 + 1, v/v; N-phenyl-label: 2 + 8, v/v). The remaining non-extracted radioactivity was determined by combustion. The five fractions (whey) were pooled for partitioning. The whey was concentrated to about 800 mL at 35 °C. Thereafter, the whey was partitioned twice with dichloromethane, once with ethyl acetate and twice with acidic ethyl acetate (pH 1–2). The radioactivity in the milk fat was determined by combustion.

Liver and kidney

Study 643724: The tissue was homogenized and extracted once with acetonitrile, twice with acetonitrile/water (1 + 1, v/v), twice with methanol/water (1 + 1, v/v) and once with methanol/water (2 + 8, v/v). Additionally, acidic (2 × methanol/0.2 M HCl, 8 + 2, v/v) and basic extractions (methanol/0.5 M NH₄OH, 8 + 2, v/v) were performed. Radioactivity in each extract was measured after centrifugation. Thereafter, a Soxhlet extraction in methanol/water (8 + 2, v/v) for 16 hours was performed. Liver and kidney were further extracted with Tris buffer (0.1 M), incubated in pronase/Tris buffer and extracted with Tris buffer. The remaining non-extracted radioactivity was determined by combustion. For liver, hydrolysis was performed in 2 M HCl at 70 °C for approximately 16 hours.

Study 684088: The tissue was incubated in pronase/phosphate buffer for 6 h at 40 °C and then methanol was added to facilitate precipitation of the tissue. Thereafter, the tissue was extracted three times with methanol/water (1 + 1, v/v) and once with methanol/water (2 + 8, v/v). Radioactivity in each extract was measured after centrifugation. Thereafter, a Soxhlet extraction in methanol/water (1 + 1, v/v) at 70 °C for 16 hours was performed. The remaining non-extracted radioactivity was determined by combustion.

Muscle

Study 643724: The tissue was extracted (1–3 mL solvent per g tissue) once with acetonitrile, twice with acetonitrile/water (1 + 1, v/v), once with methanol/water (1 + 1, v/v), followed by a Soxhlet extraction in methanol/water (8 + 2, v/v) for 16 hours. Due to the low radioactivity amounts, the muscle extracts were not further worked up.

Study 684088: The tissue was homogenised for radioactivity determination. Due to low radioactivity amounts no extraction of muscle tissue was performed.

Fat, omental and perirenal

Study 643724: Samples were extracted twice with dichloromethane and once with dichloromethane/ethanol (1 + 1, v/v).

Study 684088: Samples were extracted twice with dichloromethane, once with dichloromethane/ethanol (1 + 1, v/v) and once again with dichloromethane. A further extraction with hexane was performed. The remaining tissue was extracted three times with methanol/water (1 + 1, v/v) and once with methanol/water (2 + 8, v/v). Thereafter, the residue was incubated with pronase/phosphate buffer for 6 h at 40 °C, three times extracted with methanol/water (1 + 1, v/v) and once with methanol/water (2 + 8, v/v). Thereafter, a Soxhlet extraction in methanol/water (1 + 1, v/v) at about 70 °C for 16 hours was performed.

Faeces

Studies 643724 and 684088: Samples collected from 24 to 48 hours and from 144 to 168 hours after the first administration were extracted once with acetonitrile, twice with acetonitrile/water (1 + 1, v/v) and three times with methanol/water (1 + 1, v/v), followed by a Soxhlet extraction in methanol/water (8 + 2, v/v). Extractions were performed as described for organs/tissues.

After extraction, the remaining solid was dried, and aliquots were combusted to obtain material balances of radioactivity for each examined sample. The extracts were partitioned further with different solvents and analysed by HPLC, TLC and LC-MS to determine the metabolic profiles. The TRR in mg/kg as parent equivalents in goat milk are shown in Table 4.

^a Values corrected for background

The balance of the applied radioactivity and the excretion pattern of the lactating goats treated with radiolabelled fenamidone are presented in Table 5. At sacrifice, at both dose levels and with both labels, small amounts of radioactivity (totally 0.6 to 1.0% of the administered radioactivity) were detected in edible organs/tissues and blood. The ratio of residues in high dose to low dose animals was approximately 10, reflecting the ratio of the doses (see Table 6).

^a Values corrected for background

The distribution of TRR in goat matrices following treatment at the high dose with [¹⁴C]fenamidone is summarised in Tables 7 (milk and fat) and 8 (liver and kidney). The majority of the TRR could be extracted using organic solvents, Soxhlet extraction, pronase incubation (liver and kidney) and hydrolysis (liver). The characterization and identification of metabolites was carried out with matrices of the high dosed goats only. Due to low TRR in muscle, no extraction of the tissue was performed in case of the N-phenyl-label study. In case of the C-phenyl-label study, the muscle was extracted but the extracts were not further worked up due to the low radioactivity amounts. The total extracted radioactivity amounted to 63.6% (0.01 mg eq/kg) of the TRR. The radioactivity remaining in the muscle was 36.4% of the TRR (0.006 mg eq/kg).

Laying hens

Burri (1999) investigated the fate of fenamidone following repeated oral administration to the laying hen in two separate studies (643735, M-183883-01-1 and 684090, M-183837-01-1, see Table 3).

Two dose levels were used for each label position, with one group of five white leghorn hybrid hens being used per dose level and label. Two groups of hens were orally dosed daily by

capsule with [C-phenyl-UL-¹⁴C]-fenamidone at doses of 1.3 ppm and 13.8 ppm in the diet for fourteen consecutive days. Two other groups of hens were similarly dosed with [N-phenyl-UL-¹⁴C]-fenamidone at doses of 1.0 ppm and 9.8 ppm in the diet for fourteen consecutive days. The concentration profiles of radioactivity in eggs as well as the excretion patterns via excreta were followed. The hens were sacrificed at approximately 24 hours after the last (14th) dose and blood, plasma, liver, muscle, fat and skin were collected. The TRR were determined by LSC in liquid matrices after solubilisation, in solid matrices by combustion. The samples were prepared as follows:

Eggs

Study 643735: The egg samples (white and yolk) were de-proteinised by adding acetone (1 + 2 or 1 + 4, v/v). Following centrifugation, the supernatant was removed and the pellet extracted once with acetone. Further extraction steps with acetonitrile/water (1 + 1, v/v) and methanol/water (2 + 8, v/v) as well as a Soxhlet extraction in methanol/water (8 + 2, v/v) were performed. The egg yolk of the high dose group was further extracted with Tris buffer (0.1 M), incubated in pronase/Tris buffer and extracted with Tris buffer. The remaining non-extractable radioactivity was determined by combustion. Due to the low radioactivity amounts, the low dose egg yolk and egg white samples were not further worked up.

Study 684090: Egg white and egg yolk of eggs between 144 and 168 hours as well as 312 and 336 hours after the first administration was pooled per time point and group and radioactivity was re-determined. These pools were used for further work-up. Due to the low radioactivity amounts, the high dose egg white samples, the low dose egg yolk and egg white samples were not analysed. The egg yolk samples were de-proteinised by adding acetone (1 + 4, v/v). After shaking for 30 min at room temperature, the samples were left for 16 hours at about 4 °C. Following centrifugation (10 min at 1600 g), the supernatant was removed and the pellet extracted once with acetone. Further extraction steps with acetone/water (1 + 1, v/v) and methanol/water (1 + 1, v/v) as well as a Soxhlet extraction in methanol/water (1 + 1, v/v) were performed.

Muscle

Study 643735: The tissue was homogenised for radioactivity determination. Thereafter, the samples were pooled and extracted (high dose group only). The extractions were performed with acetonitrile, methanol and methanol/water in different ratios. Muscle tissue was extracted once with acetonitrile, twice with acetonitrile/water (1 + 1, v/v), twice with methanol/water (1 + 1, v/v) and once with methanol/water (2 + 8, v/v). Radioactivity in each extract was measured after centrifugation. Additionally, a Soxhlet extraction in methanol/water (8 + 2, v/v) for 16 hours was performed.

Study 684090: The tissue was homogenised for radioactivity determination. Due to low radioactivity amounts no extraction of muscle tissue was performed.

Liver

Study 643735: The tissue was homogenised for radioactivity determination, pooled per group and extracted. The extractions were performed with acetonitrile, methanol and methanol/water in different ratios. Liver tissue was extracted once with acetonitrile, twice with acetonitrile/water (1 + 1, v/v), twice with methanol/water (1 + 1, v/v) and once with methanol/water (2 + 8, v/v). Radioactivity in each extract was measured after centrifugation. Additionally, a Soxhlet extraction in methanol/water (8 + 2, v/v) for 16 hours was performed. The liver tissue of the high dose group was additionally extracted/incubated with Tris buffer and pronase.

Study 684090: The organs were homogenised for radioactivity determination. Thereafter, the liver tissue was pooled per group and extracted by incubation with pronase for 6 hours at 40 °C. Thereafter, the tissue was further extracted three times with methanol/water (1+1, v/v) and twice with methanol/water (2 + 8, v/v). Radioactivity in each extract was measured after centrifugation. Additionally, a Soxhlet extraction in methanol/water (1 + 1, v/v) at about 80 °C for 16 hours was performed. Finally, the residual sample was hydrolysed in 1 N HCl at 70 °C for approximately 16 hours.

Fat and skin

Study 643735: The tissues were extracted as follows: twice with dichloromethane, once with dichloromethane/acetone (1 + 1, v/v), once with acetone, twice with acetonitrile/water (1 + 1, v/v). Additionally, the skin sample was extracted with methanol/water (2 + 8, v/v) followed by a Soxhlet extraction in methanol/water (8 + 2, v/v).

Study 684090: The tissue was extracted as follows: twice with dichloromethane, twice with dichloromethane/ethanol (1 + 1, v/v), three time with methanol/water (1 + 1, v/v) and once with methanol/water (2 + 8, v/v). Thereafter, the tissue was extracted by incubation with pronase for approximately 16 hours at 40 °C. Thereafter, the tissue was further extracted twice with methanol/water (1 + 1, v/v).

Excreta

Individual excreta samples from the respective time intervals were homogenised in water (1 + 1, w/v) and the radioactivity determined in subsamples by combustion.

Studies 643735 and 684090: The excreta samples collected from 96 to 120 hours and from 312 to 336 hours after the first administration were pooled by time point and by group and were extracted once with acetonitrile, twice with acetonitrile/water (1 + 1, v/v), with methanol/water and water, followed by a Soxhlet extraction in methanol/water (8 + 2, v/v).

After extraction, the remaining solid was dried, and aliquots were combusted to obtain material balances of radioactivity for each examined sample. The extracts were partitioned further with different solvents and analysed by HPLC and as far as appropriate by TLC and LC-MS to determine the metabolic profiles. The TRRs in mg/kg (as parent equivalents) in eggs after administration of radiolabelled fenamidone are shown in Table 9. At the plateau after 9 days, the residues in egg yolk were about 7 times (C-label) higher than in the egg white.

Table 9 TRR in eggs following oral administration of [¹⁴C]fenamidone for 14 days.

As shown in Table 10, the overall recoveries of radioactivity were > 91% of the total applied radioactivity (TAR) for the low and high dose groups, respectively. The majority of the radioactivity was in excreta (approximately 90% TAR). All eggs together contained 0.1% of the dose administered, most of which was retained in the yolk. At sacrifice, at both dose levels and in both labels, negligible amounts of radioactivity (0.1% of TAR) were detected in edible organs/tissues and blood. The ratio of residues in high dose to low dose animals ranged from 5 to 16 (see Table 11). The major amounts of radioactivity in the excreta could be extracted. Table 13 shows the results for the low dose (C-phenyl label only) and the high dose samples (both labels).

	% TRR	% TAR	% TRR	% TAR	% TRR	% TAR
96–120	83	6.1	83	5.5	85	6.1
312–336	80	6.1	85	5.8	80	5.7

In the excreta extracts of the C-phenyl-label groups, at least sixteen radioactive fractions were found, in amounts ranging from < 0.1% to 1.9% of the TAR (low dose) and < 0.1% to 1.8% (high dose). Fenamidone was detected in small amounts (0.1–0.2% TAR low and high dose). RPA 409445, RPA 412708, RPA 412636 and hydroxy-RPA 412708 were found in minor amounts (< 0.1 to 0.6% TAR). Hydroxy-fenamidone was found in amounts of 1.3 to 1.9% of the TAR. Unknown fractions occurred at levels up to 1.6% TAR. The excreta extracts from the N-phenyl-label application (high dose only) showed at least nine radioactive fractions ranging from < 0.1% to 1.6% of the TAR. The parent compound occurred in a minor amount of 0.1% of the TAR. Hydroxy-fenamidone was found in a maximal amount of 1.1%. Unknown metabolite fractions occurred in maximal amounts of 1.6% of the radioactivity administered.

The characterization of the TRR and identification of metabolites (components) in eggs and edible tissues was carried out for the high dose samples only. The findings are summarized in Table 13 for egg white and egg yolk and in Table 14 for liver, fat and skin.

Fenamidone is extensively metabolised in animals. The metabolic profiles differ quantitatively between the species investigated, but qualitatively there are no major differences. The routes and metabolites in animals are consistent across the studies. Figure 1 presents the proposed metabolic pathway for fenamidone in livestock.

Figure 1 Proposed metabolic pathway of fenamidone in livestock.

Metabolite codes in parentheses are the numbers for the racemic compounds, as used in the original study report. The metabolites have been shown to be present as the S-enantiomers.

Plant metabolism

The metabolism of fenamidone has been studied in grapes, tomatoes, lettuce, carrots and potatoes. The test material used in the studies is characterized in Table 15.

Grapes

The metabolism of fenamidone in grapes was investigated by Voelkel in 1999 (655266, M-183815-01-1). C-phenyl-¹⁴C-fenamidone alone was used in this study. Grape vine plants (Pinot Noir variety) were treated with four foliar applications of C-phenyl-¹⁴C-fenamidone during the course of berry growth and maturation to a total application of 1.65 kg ai/ha. The details of grape vine treatment are given in Table 16.

Table 16 Timing and details of grape vine treatments with [¹⁴C]fenamidone

Treatment	Rate, g ai/ha	Timing	Growth stage
1	505	136 days before harvest	Before flowering Flower buds starting to separate
2	485	100 days before harvest, 36 days following first treatment	80% flower hoods fallen, Young fruits starting to swell
3	504	78 days before harvest, 58 days following first treatment	Well-formed bunches start to hang
4	156	24 days before harvest, 112 days following first treatment	Beginning of maturation

Before treatment the soil surface around the base of each vine as well as the adjoining vine plants were protected with plastic sheeting so as to prevent loss of the radioactive material into the surrounding environment and, therefore, potential uptake by the roots of the vine plants. At harvest, 24 days following the last treatment, all remaining grape bunches on the vines were removed. Prior to processing, all bunches were washed using water, followed by aqueous methanol and finally methanol. The grapes were then removed from the stems and then, following chilling to reduce enzyme activity, separated into skin, pips and pulp. All samples were assayed for TRR by LSC, either directly or following processing and sample combustion.

The individual components of the grape bunches were subjected to a succession of solvent partition and extraction procedures culminating in enzyme treatment followed by harsh hydrolytic conditions, the last being used to investigate the small amounts of unextracted radioactive residue. The extracts obtained were subjected to TLC as well as HPLC in order to investigate the extracted components of the residue. Selected extracts were then analysed using LC/MS to obtain structural information with regard to those components resolved by the chromatography used. The distribution of radioactivity in the washes and various grape bunch parts and for the grapes for the pre-harvest and for the mature harvest samples is shown in Table 17.

Table 17 Distribution of radioactive residues in the pre-harvest and mature grapes

Sampling date	Pre-harvest grape bunches (prior of last application)				Mature harvest grape bunches (24 days after fourth treatment)

^a mg parent eq/kg

Similar results for the distribution of radioactivity were obtained for the pre-harvested grapes and the mature harvest grapes. The major part of the radioactivity associated with the grape bunches could be extracted and represented 89.1% of the TRR (including the washes) for mature harvest grape bunches. The non-extracted radioactivity was confined mainly to the stem, skin and pips and some effort was made to release it for further analysis. The procedures used included enzyme treatment, followed by acid and alkali hydrolysis. Table 18 shows the metabolites identified and components resolved in mature harvest grapes from vines treated four times to a total of a nominal 1.65 kg fenamidone/ha. The extracted radioactivity from each grape bunch part as well as the washes were

separately analysed by HPLC. Parent compound was the only component detected in the washings demonstrating the stability of fenamidone on the surface of the grape bunches when exposed to field conditions. Results for the stem, skin, pips and pulp extracts showed the presence of two major components, which were indicated to be parent compound and the metabolite RPA 410193. In addition to fenamidone and RPA 410193 up to eleven additional radioactive components were detected in the plant fractions. Individually these radioactive components did not exceed 4.2% of the TRR in the mature grapes. Despite this, attempts were made to obtain additional information regarding the structure of two of the components in the most abundance (M1 at 4.2% TRR and M2 at 3.4% of the TRR). From the evidence obtained, it is suggested that M1 may be hydroxylated RPA 410193, and M2 may be hydroxylated parent compound. In both cases it was reasonable to assume that the hydroxylation has taken place in the amino-phenyl ring and that the basic ring structure of the parent compound remained intact.

The metabolism of fenamidone in field grown grapes is mainly characterised by the formation of RPA 410193, i.e. loss of the thiomethyl group and formation of an imidazolidinedione. Some evidence was obtained to suggest that hydroxylation of parent compound as well of the major metabolite, RPA 410193 also occurred. The number of other metabolites detected, albeit at very low levels, demonstrated the further metabolism of fenamidone. With regard to the TRR in the grapes in excess of 80% was accounted for in terms of identified and tentatively identified metabolites. Figure 2 shows the proposed metabolic pathway for fenamidone in grapes.

Fenamidone

Figure 2 Proposed metabolic pathway for fenamidone (RPA 407213) in grapes

Metabolite codes in this pathway are the numbers for the racemic reference compounds, as used in the original study report. In an additional study, it has been shown that all metabolites and degradation products were formed as the S-enantiomers.

Tomato

The metabolism of fenamidone in tomatoes was investigated by Oliver in 1999 (10616, M-173256-01-1) on the variety “Gardeners Delight” following treatment with [^{14}C]fenamidone at a cumulative rate equivalent to 1.5 kg ai/ha. This was applied in three foliar spray treatments, each of 0.5 kg ai/ha, during the course of fruit growth. Untreated control plants were grown among the treated plants and also at some distance from the treated plants. Both labels, C-phenyl and N-phenyl, were used separately to study the metabolism of the molecule. For each treatment fenamidone was formulated as a 10% EC. The crop was grown to maturity under glass and was sampled at two interim time points and at maturity. There was an interval of 7 days between the last application and harvest. Following harvest, the fruits were picked, weighed fresh, rinsed with acetonitrile and then frozen prior to further analysis. The frozen fruits were then homogenised and extracted with acetonitrile. The rinses and extracts were concentrated prior to analysis by HPLC in order to establish the quantitative and qualitative nature of the residue. Selected representative extracts were cleaned-up using C_{18} solid phase extraction cartridges and analysed using LC-MS/MS to obtain confirmation of the identities indicated by HPLC.

The distribution of radioactivity and the calculated TRR for the treated plants are shown in Table 19. For both labels, extraction efficiencies of 87.1% and 91.8% were achieved. The components of the TRR at final harvest are summarised in Tables 20.

^a Numbers in brackets indicate the number of components present.

The metabolic profile obtained with each label was similar. Parent fenamidone was the major component present, with significant amounts of RPA 410193 along with a number of minor components. A metabolic pathway for fenamidone metabolism in tomato is proposed in Figure 3.

Figure 3 Proposed metabolic pathway for fenamidone (RPA 407213) in tomato

Metabolite codes in this pathway are the numbers for the racemic reference compounds, as used in the original study report. In an additional study, it has been shown that all metabolites and degradation products were formed as the S-enantiomers.

Lettuce

The metabolism of fenamidone on iceberg lettuce was investigated by Oliver and Clarke in 1999 (10617, M-173236-01-1) using [^{14}C]fenamidone labelled on two positions. Fenamidone was applied to lettuces in a 10% EC formulation. Four foliar spray applications were made at the nominal field rate of 0.4 kg ai/ha, the total treatment rates achieved over four applications were 1.4 kg ai/ha for the C-phenyl and the N-phenyl treated lettuces. The plants were grown to maturity outdoors, under ambient environmental conditions. After final harvest, 7 days after the fourth application, the outer wrapper leaves were separated from the lettuce heads. The wrapper leaves were rinsed with acetonitrile. Both plant parts were frozen, then homogenised and extracted by maceration with acetonitrile, methanol/water and acetonitrile/water. Aliquots of the dry extracted residue were combusted to determine the amount of unextracted radioactivity.

Table 21 shows the TRR in the different plant parts at harvest, seven days after 4th application. The acetonitrile rinses and combined plant extracts were subjected to quantitative and qualitative analysis by reverse-phase HPLC and normal phase TLC. Metabolite identification was confirmed by LC-MS. The principal components of the TRR are given in Table 22.

^a RPA 412708 and fenamidone glucoside conjugate eluted from HPLC column with same retention time

The metabolic profile obtained with each label was similar. The major component in each crop part was parent fenamidone. The remaining extracted radioactivity was comprised of RPA 410193 and multiple unidentified polar components. In addition, trace levels of RPA 412636 and a glucoside conjugate of fenamidone were present in extracts from the C-phenyl-label treatment. A metabolic pathway for fenamidone metabolism in lettuce is proposed in Figure 4.

Figure 4 Proposed metabolic pathway for fenamidone (RPA 407213) in lettuce

Metabolite codes in this pathway are the numbers for the racemic reference compounds, as used in the original study report. In an additional study, it has been shown that all metabolites and degradation products were formed as the S-enantiomers.

Potato

An outdoor study was conducted by Clark in 1999 on potatoes (10615, M-173249-02-1) using N-phenyl and C-phenyl-[^{14}C]fenamidone in order to investigate plant metabolism. Three foliar spray applications were made each at the nominal field rate of 0.5 kg ai/ha. The total treatment rates achieved over three applications were 1.30 kg ai/ha and 1.36 kg ai/ha for the C-phenyl and N-phenyl label respectively. The potatoes were grown to maturity outdoors, under ambient environmental conditions. After final harvest, 14 days after the third application, the haulm was separated from the tubers. The tubers were rinsed with water and peeled. All plant parts were frozen, then homogenised and extracted by maceration with acetonitrile, acetonitrile/water and methanol. Aliquots of the dry extracted residue were combusted to determine the amount of unextracted radioactivity. The TRR are given in Table 23. Following concentration, the combined plant extracts were subjected to quantitative and qualitative analysis by HPLC and TLC, employing certified reference standards as retention time and relative front markers. The compound identification was confirmed by LC-MS/MS for parent, RPA 412636 and RPA 412708. The principal components of the TRR are given in Table 24. All concentration data are given in mg parent eq/kg.

Table 23 Potato TRR at final harvest, 14 days after 3rd application.

^a C-phenyl specific metabolites

An additional indoor experiment was carried out in order to determine the nature of the major unidentified polar component of the potato tuber TRR which was unretained on the initial reversed-phase HPLC. Two post emergence applications, one of C-phenyl-[^{14}C : ^{13}C]fenamidone (4:1) at a treatment rate of 1.6 kg ai/ha, the other of N-phenyl-[^{14}C : ^{13}C]fenamidone (4:1) at a treatment rate of 1.4 kg ai/ha were made to separate groups of potato plants grown in pots under greenhouse conditions. The treatment solutions were applied to the haulm (cut stem, mature and immature leaves) and at the soil surface surrounding the base of the stem to try to maximise the incurred TRR, and reproduce the field situation as far as practicable. These plants were grown to maturity and then harvested. The resultant potato tubers were rinsed with water and homogenised. Representative subsamples were extracted by maceration with acetone/water. The TRR for greenhouse grown potato tubers are summarised in Table 25.

As previously, the TRR for greenhouse grown tubers was also low. HPLC analysis of extracts from greenhouse grown potato tubers was carried out. These were shown to have similar profiles to those previously obtained from field grown potato tubers, for both labels. The C-phenyl-[^{14}C , ^{13}C]fenamidone treated tuber extract was subjected to solid phase extraction (SPE) to separate the polar residue from the parent compound. The appropriate fractions were concentrated and analysed using a second HPLC method to retain and resolve individual polar components. This method resolved the previously unretained material, corresponding to that which accounted for 39.5% TRR (0.034 mg/kg) in extracts derived from C-phenyl-fenamidone treated field grown potato tubers, into nine discrete entities (Table 26) confirming its multicomponent nature.

Table 25 TRR in whole potato tubers (grown indoors)

^a Treated with C-phenyl-[^{14}C : ^{13}C]fenamidone (4 : 1)

P1–P9: Individual polar fractions

Additional analysis indicated that P3 and P4 are likely to be RPA 412636 conjugates, which hydrolyse to release free RPA 412636. Thus, a further 0.01 mg/kg (11.5% TRR) of the C-phenyl-fenamidone treated field grown potato tubers extractable radioactive residue was characterised as being conjugated RPA 412636. The total amount of RPA 412636 found in treated potato tuber extracts as free or conjugated material was 0.015 mg/kg (17.8% TRR).

The N-phenyl-[^{14}C , ^{13}C]fenamidone treated tuber extract concentrate was also analysed on the second HPLC system. The resulting chromatogram showed the presence of four peaks of polar origin. Therefore, the polar material, which accounted for 30.8% TRR (0.012 mg/kg) in extracts derived from N-phenyl-fenamidone treated field grown potato tubers, is postulated to be composed of at least four discrete entities, as presented in Table 27.

Table 27 Composition of polar material in N-phenyl treated potato tubers

Sample	Concentration, mg parent eq/kg				
	PA	PB	PC	PD	Total
Greenhouse grown potato tubers ^a	< 0.001	< 0.001	< 0.001	< 0.001	0.001

^a Treated with N-phenyl-[^{14}C : ^{13}C]fenamidone (4 : 1)

PA–PD: Individual polar fractions

The presence of fewer polar entities in sample extracts derived from N-phenyl-fenamidone compared to C-phenyl-fenamidone treated potato tubers is due to the position of the ^{14}C -radiolabel. Cleavage of the N-N bond during potato metabolism of N-phenyl-fenamidone results in loss of non-radiolabelled RPA 412636 and RPA 412708. This process is likely to be accompanied by formation of radiolabelled aniline analogues. These are known to bind to plant matrices and are likely to contribute to the 53.9% (0.02 mg/kg) unextracted radioactive residue for N-phenyl-fenamidone treated tubers, compared to the 26.8% (0.023 mg/kg) unextracted radioactive residue for C-phenyl-fenamidone treated tubers.

In summary, the TRR found in potato tubers treated with fenamidone at 3×0.5 kg ai/ha and grown to maturity were very low (0.09 mg/kg and 0.04 mg/kg for the C-phenyl- and N-phenyl-label, respectively). Parent fenamidone accounted for 2.3 to 6 % (0.002 mg/kg) of TRR. The metabolites RPA 412708 and RPA 412636, each accounting for 6% of TRR and very low in absolute concentration (0.005–0.006 mg/kg) were identified. Because these metabolites were also identified as soil metabolites, it is assumed that they were formed in the soil and taken up directly from the soil. Furthermore, about 40% (C-phenyl-label) or 31% (N-phenyl-label) of TRR could be characterized as polar material. Figure 5 shows the proposed metabolic pathway for fenamidone in potatoes.

Figure 5 Proposed metabolic pathway for fenamidone (RPA 407213) in potatoes

Metabolite codes in this pathway are the numbers for the racemic reference compounds, as used in the original study report. In an additional study, it has been shown that all metabolites and degradation products were formed as the S-enantiomers.

Carrots

The metabolism of fenamidone was investigated in carrots grown outdoors under ambient conditions (Sur, 2006; MEF-06/243, M-275069-02-1). The test material was [N-phenyl-UL- ^{14}C]-fenamidone. The test material was applied three times as an SC 500 formulation at a rate of 0.3 kg ai/ha, giving a seasonal application rate of 0.9 kg ai/ha. The first application was made pre-emergence (one week after sowing), followed by two foliar applications to the emerged crop, 8 and 14 weeks after sowing.

Carrot leaves and roots were harvested at maturity, 14 days after the last application. The TRR found in the fractions are summarised in Table 28.

Table 28 TRR in carrots following application of [N-phenyl-UL-¹⁴C]-fenamidone

Plant part	TRR, mg fenamidone eq/kg	% Extracted	% Unextracted
Leaves	30.5	99.7	0.33
Roots	0.04	93	7.3

The majority of the radioactivity (between 81.3% and 98.7% of the TRR) was effectively extracted at ambient temperature with acetonitrile/water using a high-speed blender. After evaporation of the combined extracts of leaves, the radioactivity was partitioned between a dichloromethane and an aqueous phase. Only 1.2% of the TRR remained in the aqueous phase, whereas 97.5% of TRR was found in the organic phase. For roots, the combined acetonitrile/water extracts were simply concentrated without partitioning.

The leaf solids still contained 0.41 mg/kg (1.3% of TRR). A two-step microwave-assisted extraction, with neutral and acidic solvent then yielded the final post-extraction solids (PES), which contained only 0.104 mg/kg (0.33% of TRR). The radioactive residue in the root solids was already very low (0.008 mg/kg, 18.7% of TRR). After the same microwave extraction procedure, only 0.003 mg/kg (7.25% of TRR) remained in the final post-extraction solids (PES).

The extracts were analysed by HPLC or TLC for quantification of the parent compound and metabolites. These were identified by co-chromatography with radiolabelled or non-radiolabelled reference compounds and/or by mass spectroscopy. The distribution of radioactivity in identified or characterised components is summarised in Table 29.

NA not applicable or not analysed

ND not detected

The residue in both leaves and roots consisted predominantly of unchanged fenamidone. The metabolic pattern showed that the three rings of fenamidone remain intact with no intermediate metabolites resulting from cleavage on the N-phenyl ring, although there was clear evidence for degradation of the N-phenyl ring and re-incorporation of the ¹⁴CO₂ in the plant leaves in the form of radiolabelled glucose. Aniline, the three isomer aminophenols (2-, 3-, 4-aminophenol) and 2- and 4-nitroaniline or conjugates thereof were specifically included as targets for analysis, but were not detected in either leaves or roots. A minor metabolic reaction was the nitration of the N-phenyl ring in the 2- and 4-positions to produce RPA 413255 and RPA 411639, respectively. A further route of degradation was hydrolysis of the N=C bond of the imidazolinone ring leading to the metabolites RPA 410193, RPA 221701, and RPA 221607 by replacement of the thiomethyl substituent by a carbonyl group. Figure 6 shows the proposed metabolic pathway for fenamidone in carrots.

Overall, the five plant metabolism studies submitted provide a clear understanding of the fate of the fenamidone in plants, both the C-phenyl and N-phenyl portions. The metabolic profiles differ

quantitatively between the plant species, but qualitatively there are no major differences; the routes and products of metabolism in plants are consistent across the studies. The overall metabolic pathway is consistent between the different crop categories fruits and fruiting vegetables, leafy vegetables, root and tuber vegetables. Parent fenamidone forms the largest part of the residue and the only significant metabolite is RPA 410193, diketo-fenamidone, formed by oxidative hydrolysis of the thiomethyl side chain.

Figure 6 Proposed metabolic pathway for fenamidone in carrots

Metabolite codes in this pathway are the numbers for the racemic reference compounds, as used in the original study report. In an additional study, it has been shown that all metabolites and degradation products were formed as the S-enantiomers.

Environmental fate in soil and water-sediment systems

The FAO Manual (FAO, 2009) explained the data requirements for studies of environmental fate. The focus should be on those aspects that are most relevant to MRL setting. For fenamidone, supervised residue trials data were received for foliar spray on permanent crops and on annual crops. A further application is on cotton seed as in furrow treatment. Therefore, according to the FAO manual, studies on the aerobic degradation in soil, photolysis, hydrolysis, rotational crops (confined, field) and field dissipation were evaluated. For information on hydrolysis and photolysis see also chapter “Physical and chemical properties”, Table 1. The fate and behaviour of fenamidone in soils was investigated using fenamidone radio-labelled in two different positions, [C-phenyl-UL-¹⁴C]- and [N-phenyl-UL-¹⁴C]-fenamidone.

Aerobic degradation in soil

The route of aerobic degradation of fenamidone has been investigated in three soils: a clay loam (Loam by USDA classification; Simmonds and Burr, 1999; Report 201609, M-173243-01-1), a sandy loam and a loam (Burr and Bullus, 2000; Report 202200, M-240551-01-1). Fenamidone radio-labelled in two different positions, [C-phenyl-UL-¹⁴C]-fenamidone and [N-phenyl-UL-¹⁴C]-fenamidone, was applied separately to the clay loam and sandy loam soils, only [C-phenyl-UL-¹⁴C]-fenamidone was applied to the loam. The clay loam was treated at a rate equivalent to 1.6 kg ai/ha, the sandy loam and loam at rates equivalent to 1.2 kg ai/ha. The samples were also connected to a series of traps to retain any volatiles. Throughout the 365-day duration of the studies, the soil samples were maintained in the dark at 20 ± 2 °C and at known moisture contents.

Good overall radiochemical balances were obtained in each case; 94% to 97% of TAR at day 0, 92% to 99% of TAR at mean, over all incubation intervals. Fenamidone was rapidly metabolised in the three soils to two major metabolites, RPA 412708 and RPA 412636, both observed only from the C-phenyl treatment. RPA 411639 and RPA 413255 were observed as minor metabolites in the clay loam and loam, and at higher levels in the sandy loam, where two other major metabolites were found, RPA 221607 and RPA 221701. There were no unique metabolites observed from the N-phenyl label. Levels of volatile radioactivity remained quite low, < 10% of the TAR after 365 days. Unextracted radioactivity increased with time, reaching 31% and 46% for the C-phenyl-label and N-phenyl-label respectively in the clay loam, 14% and 26% respectively in the sandy loam and 21% for the N-phenyl-label in the loam. Various unknown metabolites were formed, which could be separated into numerous individual components, none of which reached a significant level (< 8% of TAR) and consequently the unknown components were not considered to contain any major metabolites. The composition of radioactivity is summarized in Tables 30 to 34.

Under aerobic conditions, fenamidone was rapidly metabolised by three significant degradation routes. In the first route of degradation two major metabolites, RPA 412708 and RPA 412636 are formed. RPA 412708 is formed through the loss of the aniline ring. This is followed by further degradation with hydrolysis and the loss of the S-methyl group to form RPA 412636. In addition RPA 407213 was transformed by nitro addition in the 2 or 4 position to form RPA 411639 and RPA 413255. Mineralisation of both C-phenyl and N-phenyl rings resulted in the evolution of carbon dioxide. No unique metabolites were observed from N-phenyl labelled fenamidone. The proposed principal degradation pathways are presented in Figure 7.

Figure 7 Proposed degradation pathways for fenamidone in aerobic soil

Metabolite codes in brackets are the numbers for the racemic compounds, as used in the original study report. The metabolites have been shown to be present as the S-enantiomers.

Soil photolysis

The photolytic degradation of fenamidone has been studied on a sandy loam soil. Two studies have been conducted, one with C-phenyl fenamidone (Burr and McDonald, 1999; Report 201428, M-173233-01-1) and the other with N-phenyl fenamidone (Burr, 1999; Report 202094, M-173271-01-1).

Portions of the soil, at a moisture content equivalent to 75% of the 1/3 bar moisture holding capacity, were surface treated with radio-labelled fenamidone to achieve an application rate

approximately equal to a cumulative field application rate of 1.5 kg ai/ha. The samples were placed inside glass incubation units fitted with quartz glass lids and aerobically incubated at $20 \pm 1^\circ\text{C}$. Irradiated samples were exposed to an artificial xenon light source (290 to 800 nm) for 13.3 or 12.7 hours each day (for the C-phenyl-label and N-phenyl-label, respectively), the equivalent of 1 day of natural summer sunlight. Non-irradiated control samples were incubated in continuous darkness. Trap solutions (ethylene glycol and potassium hydroxide) were connected to the incubation units to retain any volatile degradates.

At intervals up to 30 days after treatment, duplicate samples were removed for analysis. Good radiochemical balances were achieved for both the irradiated and non-irradiated soil (94.9 to 96.0% of TAR). In the C-phenyl-labelled experiment, over the 30-day study duration, carbon dioxide accounted for 2.3% and 8.1% of TAR in the irradiated and non-irradiated soils, respectively. Unextracted radioactivity accounted for 10% and 15% of TAR, respectively. In the N-phenyl-labelled experiment, the corresponding values were, respectively, 3.6%, 4.2%, 9.6% and 13%. Fenamidone was rapidly degraded in both irradiated and non-irradiated soils, by the end of the study reaching mean values of approximately 26% and 10.6% of TAR respectively in the C-phenyl labelled study and 31% and 17% of TAR in the N-phenyl labelled study. The degradates present in the irradiated and non-irradiated soils showed no significant differences. The composition of radioactivity is summarized in Tables 35 and 36.

Fenamidone was readily degraded under both irradiated and non-irradiated soil conditions and it is concluded that photolytic processes do not contribute significantly to the degradation of fenamidone applied to the soil surface. Two major metabolites, RPA 412708 and RPA 412636, were observed, together with a large number of minor metabolites, each less than 5% of TAR, with similar quantities in both irradiated and non-irradiated conditions. Mineralisation of the C-phenyl ring resulted in the formation of carbon dioxide. The proposed photolytic degradation pathway for fenamidone in soil is presented in Figure 8.

With regard of the route of degradation in soil it can be concluded, that the degradation of fenamidone primarily proceeds by the action of aerobic soil microorganisms. Irradiation with sunlight does not influence the degradation pathway.

Figure 8 Proposed degradation pathway for fenamidone in soil under dark and irradiated conditions

Metabolite codes in parentheses are the numbers for the racemic compounds, as used in the original study report. The metabolites have been shown to be present as the S-enantiomers.

Rate of aerobic degradation in soil

A laboratory study has been conducted (Simmonds and Burr, 1999; Report 201610, M-173246-01-1) in which the rate of degradation of [C-phenyl-UL-¹⁴C]-fenamidone under aerobic conditions has been

investigated in three soils incubated for 6 months at 20 °C and one soil for 12 months at 10 °C in the dark. A high pH calcareous silty clay loam, a sandy loam and a clay loam were all incubated at 20 ± 2 °C, and a different clay loam was incubated at 10 ± 2 °C, to cover a range of pH, organic matter and clay content. Throughout the study, the moisture content of the soils was maintained at approximately 45% of the maximum water holding capacity. The soils were treated at a nominal application rate of 1.6 kg ai/ha. Volatile traps were attached to the samples flask to retain any volatile metabolites. At intervals during the study samples were removed for analysis. The overall mean recoveries were good, ranging from 93% to 96% of TAR. Fenamidone was rapidly metabolised. The abundance and distribution of metabolites was consistent with the aerobic soil degradation study report above. The DT₅₀ and DT₉₀ values obtained for fenamidone and for the metabolites RPA 412708, RPA 411639 and RPA 413255 are presented in Table 37 for the soils incubated at 20 °C and 10 °C (in the dark). All values calculated using a kinetic modelling program (KIM).

Table 37 DT₅₀ and DT₉₀ values for soils incubated at 20 °C and 10 °C

The rate of degradation of fenamidone and metabolites in a clay loam, a sandy loam and a loam soil at 20 °C were also determined in the two aerobic soil degradation studies (Simmonds and Burr, 1999; Report 201609, M-173243-01-1; Burr and Bullus, 2000; Report 202200, M-240551-01-1). All values calculated using a kinetic modelling program (KIM) are shown in Table 38.

Clay loam	C-phenyl	124	643	0.99550
	N-phenyl	129	Not calculated	0.99350

In summary, under aerobic conditions, fenamidone was rapidly degraded at 20 °C in all tested soils leading to the formation of two major metabolites RPA 408065 and RPA 412636. The DT_{50s} ranged from 0.9 to 9.6 days. The rate of degradation was slower at 10 °C (DT₅₀ 22.7 days).

Field dissipation

The behaviour of fenamidone was investigated at four field sites in Europe, in Italy, France, Germany and the UK (Wicks, 1999; Report 202140, Bayer reference M-183886-01-1). Fenamidone formulated as a suspension concentrate was sprayed onto a smooth seed bed at a nominal rate of 1.6 kg ai/ha, before growing grass cover. Irrigation water was applied to the treated plots as required so that precipitation plus irrigation was usually in excess of historical average precipitation. Soil samples from different depths to a maximum of 0.6 m below the surface were then collected at regular intervals up to 12 months and analysed for fenamidone, RPA 411639, RPA 413255, RPA 412708 and RPA 412636 using LC-MS/MS. The LOQ of each compound in soil was 0.005 mg/kg. Residues of the five analytes at each of the four test sites are presented in Table 39. The calculated DT₅₀ and DT₉₀ values for the four sites are presented in Table 40.

The data from the field study were analysed under a separate study (Reinken, 2002; Report OE02/062, M-210997-02-01). Environmental conditions like fluctuating soil moisture and soil temperature have a significant impact on the degradation of plant protection products under outdoor conditions. In order to achieve a comparability of half-lives or rate constants observed at various field locations the measured field data were analysed employing a normalisation procedure. In the original study reports the estimation of first-order dissipation half-lives was based only on standard kinetic modelling which does not take into account the specific soil-climate conditions at the different field sites.

Standardised transformation rates of fenamidone and the four principal metabolites (RPA 412708, RPA 412636, RPA 411639 & RPA 413255) were investigated in this study by a detailed kinetic analysis based on the reported field residue data using a special computer program. A mathematical model was employed able to describe the observed time-dependent field concentrations based on a first-order kinetic scheme, a reference soil temperature of 20 °C and a reference soil moisture of 100% FC (field capacity). The evaluation method accounted for effects of daily changing temperature and moisture according to established model assumptions.

The agreement of measured and calculated concentrations was good, with coefficients of determination (r²) between 0.86 and 0.96. Normalised half-life values and DT₅₀ values and field capacity for fenamidone and metabolites are given for each field site in Table 41 (all average values are calculated as geometric means). The degradation of fenamidone at reference conditions (20 °C and 100% field capacity) was consistent between the individual sites, giving half-lives between 4 and 7 days. Normalised half-life values for the four metabolites were also very similar across the sites. The representative average half-lives were 5 days for fenamidone, 12 days for RPA 412708, 47 days for RPA 412636, 21 days for RPA 411639 and 43 days for RPA 413255. The calculated half-lives (t_{1/2}) are identical to first-order DT₅₀ values.

In summary, field dissipation studies were undertaken at four sites in Europe using clay loam, silt loam and sandy loam soils. In all cases dissipation of fenamidone was rapid with a mean half live of 5 days. Half-lives for the metabolites were 12 days for RPA 412708, 47 days for RPA 412636, 21 days for RPA 411639 and 43 days for RPA 413255.

Hydrolytic degradation

The hydrolytic degradation of fenamidone was examined by Corgier and Turier (1996; Report 442527, M-164512-01-1). [C-phenyl-UL-¹⁴C]-fenamidone was used as test material in aqueous buffered solutions at pH values of 4, 5, 7 and 9 under sterile conditions at 25 °C and at an initial concentration of 3.9 mg/L. Duplicate samples were taken for analysis at intervals up to 31 days. In addition, two samples at each pH were attached to suitable trapping solutions and removed after 35 days. Recovery of radioactivity ranged from 96.2 to 102.3% with a mean value of 100.3 ± 0.9%.

No volatile compounds were found in the traps at any pH. Sterility of the samples was maintained throughout the incubation. During the course of the test, the concentration of fenamidone decreased and other compounds were detected. Table 42 presents the amounts of fenamidone and its main hydrolysis products occurring during the study.

Hydrolytic degradation of fenamidone was shown to follow pseudo-first-order reaction kinetics resulting in three major hydrolysis products that exceeded 10% of TAR; RPA 410193 at pH 4, RPA 413350 and RPA 412708 at pH 9. Fenamidone is considered stable at pH 5 and 7 (less than 10% degradation after one month), but half-lives could be estimated at these pH values. The hydrolytic degradation characteristics are presented in Table 43.

Table 43 Rates of hydrolytic degradation of fenamidone at different pH values

pH	r ²	K, day ⁻¹	DT ₅₀ , days
4	0.993	-0.0166	42
5	0.981	-0.0031	222
7	0.942	-0.0017	411
9	0.991	-0.0251	28

In summary, fenamidone can be considered to be stable at pH 5 and 7. The compound is hydrolysed at pH 4 and 9 with DT₅₀ values of 42 and 28 days respectively. A proposed degradation pathway is given in Figure 9.

Figure 9 Proposed hydrolytic degradation pathway for fenamidone (RPA 407213)

Metabolite codes in parentheses are the numbers for the racemic compounds, as used in the original study report. The metabolites have been shown to be present as the S-enantiomers.

Residues in rotational crops

Confined radio-labelled succeeding crop studies

Three confined rotational crop studies have been conducted, one in 2001 and two in 2013. The first study was conducted by McMillan-Staff *et al.* in 2001 (report C010569 with amendments C021273 and C021274, M-199243-03-1). The quantity and nature of the residues in following crops were investigated after application of [C-phenyl-UL-¹⁴C]-fenamidone to bare sandy loam soil at an application rate equivalent to 2.02 kg ai/ha (exception: 1.6 kg ai/ha for the 30 and 120 day lettuce). Representative rotational crops, a leafy crop (lettuce), a root crop (turnip) and a grain crop (barley), were sown after ageing periods of 30, 120 (lettuce, turnip), 150 (barley) and 365 days. The rotational crops were grown outdoors in circular vessels 80 cm in diameter and 60 cm deep. The treatment was applied to the surface of each treated vessel and crops planted after the specified intervals. Plant samples were harvested at maturity; interim immature samples were also taken and analysed. At harvest, the lettuce and barley were cut at ground level and only the parts above the soil analysed, the turnips were harvested intact and then divided into leaf and root. The plant parts were homogenised and analysed. Extracts containing sufficient radioactivity were characterised by HPLC, TLC and LC-MS as appropriate.

The highest residues in all the plant commodities were found at the 30-day planting interval. Residues after 120/150 and 365 days were significantly lower. The proportions of the radioactivity extracted, identified and characterised in each of the plant commodities are summarised in Table 44 and the nature of the extractable radioactivity is presented in Table 45.

^a Unretained compounds^b Slightly retained compounds

The profile of identified and characterised components was similar in each of the crops and at each planting interval. RPA 412636 and a conjugate of RPA 412708 were the major components in all crop parts, unconjugated RPA 412708 was also detected in some plant parts. The RPA 412708 conjugate was putatively identified as the glucoside conjugate in many samples. Additional work proposed the presence of amino acids in two regions (“unretained compounds” and “slightly retained compounds” in Table 45), these were classified as tentatively identified in the plants and demonstrate that fenamidone residues were reincorporated into natural occurring compounds in the plant. Two distinct unknowns (U5 and U6) were characterised and a number of polar and non-polar components were also detected. No parent fenamidone was detected in any plant part.

Two further confined rotational crop studies have been conducted with radiolabelled fenamidone (C-phenyl label: Bongartz and Miebach, 2013, report M1301876-6, M-447085-01-1, M-447085-02-1; N-phenyl label: Bongartz and Miebach, 2013, report M1301877-7, M-451106-01-1). The quantity and nature of the residues in following crops were investigated after single applications of C-phenyl-UL- $^{14}\text{C}/^{13}\text{C}_6$]-fenamidone (referred as C-phenyl label) and [aniline-UL- $^{14}\text{C}/^{13}\text{C}_6$]-fenamidone (referred as N-phenyl label) to bare sandy loam soils at application rates of 0.97 kg ai/ha for the C-phenyl label and 0.96 kg ai/ha for the N-phenyl label. Representative rotational crops, a leafy crop (Swiss chard), a root crop (turnip) and a cereal crop (wheat), were sown after ageing periods of 30, 191 and 324 days.

The rotational crops were grown outdoors in 1 m² planting containers. The treatment was applied to the surface of each treated vessel and crops planted after the specified intervals. The application to the soil and the ageing of the soil (0 to 30 days after soil treatment) were conducted in the outdoor “vegetation area”, the plant cultivation took place under artificial temperature and light conditions in a greenhouse. At harvest, the Swiss chard and wheat were cut at ground level and only the parts above the soil analysed, the turnips were harvested intact and then divided into leaf and root. The plant parts were homogenised and analysed as follows:

Conventional extraction and sample preparation of all plant parts (RAC):

Aliquots of the homogenised samples were extracted 3 × with acetonitrile/water (8/2, v/v) and 1 × with pure acetonitrile. The extraction steps were conducted using a homogeniser. The residues were air-dried and weighed yielding the solids. The TRR of each RAC was calculated from the specific radioactivity of the test compound, the amount of the sample used for extraction and the sum of radioactivity, measured in the extracts and the remaining solids. The combined and concentrated conventional extracts were subjected to HPLC analysis. Significant losses of radioactivity during the concentration process or radioactivity in the distillates were not observed. Recoveries of the concentration processes ranged from 95.6% to 103%.

Exhaustive extraction of solids:

Depending on the amount of residues in the solids of the conventional extraction, an exhaustive extraction was performed with 1 × acetonitrile/water (1/1, v/v) and 1 × with acetonitrile/water (1/1, v/v) plus formic acid. The exhaustive extracts were concentrated and analysed by HPLC. Significant losses of radioactivity during the concentration process or radioactivity in the distillates were not observed. Recoveries of the concentration processes ranged from 95.5% to 104%.

Enzyme digestion of solids 2 of wheat grain (1st rotation) after exhaustive extraction with microwave assistance:

Further characterisation of the solids 2 of wheat grain was performed by an enzyme digestion with diastase followed by a partition of the digestion solution against ethyl acetate. After partition, the aqueous phase was concentrated and further analysed by HPLC.

Hydrolysis of fenamidone-hydantoin-conjugates to fenamidone-hydantoin (P10):

The hydrolysis of fenamidone-hydantoin-conjugates to fenamidone-hydantoin was investigated under extreme conditions with hydrochloric acid and sodium hydroxide at 100 °C for at least 1 h and resulted into multiple degradation products or non-reproducible results. Therefore the hydrolysis was

performed according to the residue method 00863. Representative conventional extracts of the first and second rotation were hydrolysed under mild acidic conditions with formic acid for approx. 2 hours at 70 °C.

Extracts containing sufficient radioactivity were characterised by HPLC, TLC and LC-MS as appropriate. The TRR found in each crop part are presented in Table 46. The highest residues in all the plant commodities were found at the 30-day planting interval for both labels, with the exception of wheat straw treated with the phenyl label, where higher residues were found at the second rotation (191 days). In general, residues after 191 and 324 days were significantly lower. The proportions of the radioactivity extracted, identified and characterised in each of the plant commodities are summarised in Tables 47 (C-phenyl label) and 48 (N-phenyl label). The nature of the extracted radioactivity is shown in Tables 49 and 50. In general, the TRR in the plants were significantly higher in the C-phenyl label study compared with the N-phenyl label study, primarily because of the higher uptake of C-phenyl label-specific metabolites from the soil following soil cleavage of the parent compound. For both labels, the majority of the radioactivity was extracted in the initial extraction, with the exception of wheat grain. Extraction of the remaining residues was performed with exhaustive extraction techniques, using elevated temperature conditions (microwave) and where required enzyme digestion. Parent compound and non-label-specific metabolites were isolated from crop extracts and their identities confirmed by spectroscopic methods.

The extracted residues were systematically analysed for the presence of potentially released aniline. In the extract of Swiss chard (TRR: 0.13 mg eq/kg) rotated after application of aniline-labelled fenamidone to soil, no aniline could be detected.

^a Incorporated CO₂ (characterized by enzymatic digestion)

Parent compound was detected together with fenamidone-4-nitro in one region of the conventional extract of Swiss chard of the first rotation at maturity, only. The region amounted to 0.002 mg/kg (0.2% of TRR). The major metabolites were fenamidone-hydantoin (RPA 412636) and its conjugates fenamidone-hydantoin-glucoside, fenamidone-hydantoin-serine and fenamidone-hydantoin-malonyl-glycoside. These metabolites represented in sum approx. 50 to 70% of the TRR in the plants of all rotations, except wheat grain and turnip roots. 2-phenyl-propionic acid was detected in higher amounts in these plants and ranged from approx. 15 to 73% of the TRR. Another important metabolite in wheat was fenamidone-imino-hydantoin and amounted up to approx. 19% of the TRR in wheat straw.

^a Incorporated CO₂ (characterized by enzymatic digestion)

Low amounts of parent compound and fenamidone-4-nitro were detected together in one region of the conventional extracts, mainly in crops of the first rotation. The region amounted from < 0.001 mg/kg (3.7% of TRR) for turnip roots (1st rotation) to 0.02 mg/kg (6.8% of TRR) for wheat hay (1st rotation). Parent compound, fenamidone-desthiomethyl-2-nitro, fenamidone-desthiomethyl-4-nitro and fenamidone-2-nitro were prominent in the conventional extracts of the non-edible parts of wheat and amounted to ≤ 0.06 mg/kg. Fenamidone-nitro-GSH was a prominent metabolite in Swiss chard and amounted to ≤ 0.03 mg/kg.

In contrast to the earlier study, where the major components of the residue in succeeding crops were RPA 410193, RPA 412636, RPA 412708 and RPA 412708 conjugate, neither RPA 410193 nor RPA 412708 but fenamidone-hydantoin (RPA 412636) were found in the two newer studies. No nitro products were seen in the earlier study, whereas this route of metabolism is significant in the two newer studies. The following metabolic reactions were observed:

- Electrophilic nitration in the aniline ring of parent compound forming fenamidone-2-nitro and fenamidone-4-nitro (most likely in the soil)
- Conjugation with hexose and malonic acid after electrophilic nitration in the aniline ring and hydroxylation of the molecule forming fenamidone-hydroxy-nitro-malonyl-glycoside
- Nucleophilic substitution of methyl mercaptane in the imidazolinone ring of fenamidone-2-nitro by addition of water forming fenamidone-desthiomethyl-2-nitro
- Conjugation with glutathione after electrophilic nitration in the aniline ring of parent and nucleophilic substitution of methyl mercaptane forming fenamidone-nitro-GSH
- Cleavage of the aniline moiety of fenamidone-desthiomethyl-2-nitro forming fenamidone-hydantoin (most likely in the soil)
- Conjugation of fenamidone-hydantoin with glucose, hexose plus malonic acid and serine forming fenamidone-hydantoin-glucoside, fenamidone-hydantoin-malonyl-glycoside and fenamidone-hydantoin-serine

- Addition of ammonia by simultaneous elimination of water in the hydantoin ring forming fenamidone-imino-hydantoin
- Degradation of fenamidone-hydantoin to 2-phenyl-propionic acid
- Cleavage of the aniline moiety of parent compound followed by conjugation with hexose or serine forming fenamidone-thiohydantoin-glycoside and fenamidone-thiohydantoin-serine
- Cleavage of the aniline moiety of parent compound followed by hydroxylation of the methyl group of the imidazolinone ring forming fenamidone-hydroxymethyl-thiohydantoin
- Mineralisation of parent compound leading to carbon dioxide. Carbon dioxide was incorporated into natural compounds (e.g. starch).

Proposed degradation pathways for both the phenyl- and alanine-labelled forms of fenamidone in succeeding crops are presented in Figures 10 and 11.

Figure 10 Proposed metabolic pathway of C-phenyl-¹⁴C-fenamidone in succeeding crops

Figure 11 Proposed metabolic pathway of N-phenyl- ^{14}C -fenamidone in succeeding crops

Field succeeding crop studies

Seven field succeeding studies were carried out, one in Europe and six in the USA. Rotational crops were cereals (wheat, maize), fruiting vegetables (sweet corn) root and tuber vegetables (turnip, radish) leafy vegetables (lettuce, spinach), pulses (soya bean, dry) and strawberries.

Study by Cavallé, 2006; Report RA-2750/03, M-274302-01-1

Two field rotational crop trials with fenamidone have been conducted in Northern Europe, one in the UK and one in Germany. Six spray applications were made to target crops of potatoes, using fenamidone as SC formulation at a rate of 0.15 kg ai/ha. Rotational crops of wheat, turnip and lettuce were grown. Three plant back intervals of 30, 180 and 365 days were investigated. Samples of wheat forage, wheat grain, wheat straw, turnip leaf, turnip root and lettuce head were analysed at harvest for residues of fenamidone and its metabolites (RPA 410193, RPA 412636, RPA 412708 and RPA 412708 conjugate). The days after the last treatment of the previous crop ranged in the UK trial from 265 to 617 days for wheat forage, 361 to 719 days for wheat grain and straw, from 300 to 449 days for turnip leaf and root and from 118 to 449 days for lettuce head. In the German trial, the days after the last treatment of the previous crop ranged from 245 to 419 days for wheat forage, 354 to 740 days for wheat grain and straw, from 110 to 445 days for turnip leaf and root and from 83 to 419 days for lettuce head. In all samples, the residues were for all analytes lower than the LOQ of 0.01 mg/kg, with the exception of two wheat straw samples and one lettuce sample with residues of RPA 412708 conjugate at 0.01 mg/kg.

Samples were stored deep-frozen for periods up to 316 days for fenamidone and its metabolites (RPA 410193, RPA 412636 and RPA 412708), except for lettuce samples in the first rotation where the maximum storage interval was 480 days and for turnip in the first rotation where

the maximum storage interval was 463 days. It has been shown that fenamidone and its metabolites are stable for at least 12 months in stored frozen samples of potato (tuber), wheat (grain, hay, straw, forage) and leaf lettuce. The stability of fenamidone and its main plant metabolite RPA 410193 was demonstrated on strawberries over 18 months (M-247921-01-1) which is a representative commodity with high water content. Therefore the storage period of leaf samples (lettuce and turnip) is well covered by appropriate storage data.

Study by Norris, 2001; Report B003034, M-238683-01-1

A crop rotation study with fenamidone has been conducted in the USA. Two field rotational crop trials were conducted in California and Washington. Six broadcast applications were made to bare soil, using fenamidone as SC formulation at a rate of 0.2 kg ai/ha. Rotational crops of wheat, radish and spinach were grown. Two plant-back periods were investigated: 28/30 days and 201/234 days. Radish roots and tops, spinach leaves, and wheat forage (immature), hay, straw and grain, were harvested at maturity and analysed for residues of fenamidone, RPA 412636, RPA 412708, and RPA 410193. No measurable residues were found in any of the rotational crop fractions from the Washington site. However, measurable residues of RPA 412636 were found in many of the fractions from the California site (see Table 51). The maximum storage interval from harvest to extraction was 269 days. Adequate storage stability data are available to support the storage conditions and intervals.

Table 51 Residues of fenamidone and metabolites in rotated crops in California (two treated plots)

Study by Mackie, 2001; Report B003122, M-238779-01-1

A field rotational crop study has been conducted on wheat in the USA. Twenty-two field trials were conducted during the 1999/2000 growing season. A single application of fenamidone was made to bare soil as SC formulation at a rate of 1.2 kg ai/ha. Application was 30 ± 1 day before planting at test sites growing winter wheat varieties or spring wheat varieties that are seeded in the fall. Wheat forage,

hay, grain, and straw samples were collected at normal commercial harvest and analysed for fenamidone, RPA 412708, RPA 410193 and RPA 412636. The results are shown in Table 52. The maximum storage interval from harvest to extraction was 358 days. Adequate storage stability data are available to support the storage conditions and intervals.

Table 52 Residues of fenamidone and metabolites in rotated crops (wheat)

Trial	Plant back interval	Plant part	Residue, mg/kg			
			Fenamidone	RPA 412708	RPA 410193	RPA 412636

Study by Beedle and Harbin, 2004; Report 201165, M-242538-01-1

A field rotational crop study has been conducted on strawberries in the USA. Eight field trials were conducted in 2003. Four broadcast foliar applications of fenamidone were made to the primary crop (a leafy vegetable, cucurbit or fruiting vegetable) as SC formulation at a rate of 0.3 kg ai/ha, and with 4–5 days between applications. The primary crop was tilled into the ground at least 2 days after the final application, and strawberries were planted as a rotational crop 28 to 30 days after the last application of the previous crop. Strawberries were collected at normal harvest. The residues of fenamidone and its metabolites RPA 412708, RPA 410193 and RPA 412636 were quantitated in strawberries by LC-MS/MS with an LOQ of 0.02 mg/kg. In all eight trials, no residues of fenamidone, RPA 412708, RPA 410193 and RPA 412636 greater than the LOQ of 0.02 mg/kg were observed in strawberries as rotational crop. The maximum storage interval from harvest to extraction was 294 days. Adequate storage stability data are available to support the storage conditions and intervals.

Further to the studies described above, field rotational crop studies have been conducted in the USA with sweet corn, maize and soya beans. The samples were analysed for fenamidone as well as for the sum of RPA 412636 and RPA 412708 (measured as RPA 412636) by LC-MS/MS. The results (mean of two field samples) are summarized in Table 53.

Study by Hartz and Helfrich, 2008; Report RARPY018, M-305323-01-1

A field rotational crop study has been conducted on sweet corn in the USA. Twelve field trials were conducted during the 2007 growing season. Three applications of fenamidone were made to bare soil as a SC formulation at a target rate of 0.3 kg ai/ha, and with 5–9 days between applications. The soil was tilled after the third application to simulate a failed crop and sweet corn was then planted with a

target planting interval of 25 to 30 days. Sweet corn forage and kernel plus cob with husks removed were collected at normal commercial harvest (BBCH 73–79). Stover (fodder) was collected at BBCH 89. All the samples were analysed for fenamidone as well as for RPA 412636 and RPA 412708 (measured as RPA 412636). The results are summarized in Table 53. The maximum storage interval from harvest to extraction was 344 days. Adequate storage stability data are available to support the storage conditions and intervals.

Study by Hartz and Helfrich, 2008; Report RARPY021, M-305368-01-1

A field rotational crop study has been conducted on maize in the USA. Nine field trials were conducted during the 2007 growing season. Three applications of fenamidone were made to bare soil as SC formulation at a target rate of 0.3 kg ai/ha, and with 5–8 days between applications. The soil was tilled after the third application to simulate a failed crop and maize was then planted with a target planting interval of 25 to 30 days. Maize forage was collected at BBCH 85–87. Grain and stover (fodder) were collected at BBCH 89 (normal commercial harvest). All the samples were analysed for fenamidone as well as for RPA 412636 and RPA 412708 (measured as RPA 412636). The results are summarized in Table 53. The maximum storage interval from harvest to extraction was 336 days. Adequate storage stability data are available to support the storage conditions and intervals.

Study by Hartz, 2008; Report RARPY017, M-305308-01-1

A field rotational crop study has been conducted on soya beans in the USA. Eleven field trials were conducted during the 2007 growing season. Three applications of fenamidone were made to bare soil as SC formulation at a target rate of 0.3 kg ai/ha, and with 5–10 days between applications. The soil was tilled after the third application to simulate a failed crop. Soya bean was then sown with an interval of 25 to 30 days. Soya forage and hay were collected at BBCH 65–74. Soya bean seed (grain) was collected at BBCH 89 (normal commercial harvest). All the samples were analysed for fenamidone as well as for RPA 412636 and RPA 412708 (measured as RPA 412636). The results are summarized in Table 53. The maximum storage interval from harvest to extraction was 337 days. Adequate storage stability data are available to support the storage conditions and intervals.

Table 53 Residues of fenamidone, RPA 412636 and RPA 412708 in rotated crops

^a Sum of RPA 412636 and RPA 412708, measured as RPA 412636

In summary, after application of 0.9–1.2 kg ai/ha to the bare soil, in the following crops no residues of fenamidone were found at or above the LOQ of 0.02 mg/kg in human food but metabolites as RPA412708 and RPA412636 occurred in commodities that may be used as animal feeds. The sum of RPA412708 and RPA412636 reached up to 0.14 in soya bean hay, 0.29 mg/kg in sweet corn stover and 0.21 mg/kg in field corn forage; RPA412636 occurred up to 0.07 mg/kg in wheat forage, 0.27 mg/kg in wheat straw and 0.45 mg/kg in wheat hay.

RESIDUE ANALYSIS

Analytical methods

The Meeting received descriptions and validation data for analytical methods for residues of fenamidone and its relevant metabolites RPA 410193, RPA 412708 and RPA 17879 in plant and animal commodities. Residue analytical methods rely on GC with NP-detection, GC-MS or LC-MS/MS. Typical LOQs achieved for plant and animal commodities fall in the range of 0.01–0.02 mg/kg. Methods have been subjected to independent laboratory validation (ILV). The methods described briefly below have been used for the analysis of the samples generated during the supervised field trials, processing fraction studies and storage stability investigations (report number in brackets).

Plant commodities

Method number AR 150-97, M-165219-01-1

Validation: Report No. 98-139 (R004058), M-165838-01-1

Radiovalidation: Report No. 99-82 (R004785), M-166513-01-1

ILV: Report No. 99-23 (R005021), M-170314-01-1

Analytes: Fenamidone, RPA 410193

LOQ: 0.02 mg/kg (GC-NPD, GC-MS), 0.01 mg/kg (LC-MS/MS)

Description: Fenamidone and RPA 410193 residues are extracted from homogenized sample by acetone / water. The raw extract is purified using a polystyrene-divinylbenzene cartridge SPE followed by an aminopropyl (NH₂) SPE cartridge. Quantification was by GC-NPD, GC-MS or LC-MS/MS.

Residue trials: Grapes (97–579, 97–580, 97–581, 97–582, 97–636, 97–687, 97–742, 98–561, 98–562, 98–563, 98–631, 98–690, 98–721, R.19/00, R.20/00, R.33/01, R.34/01, R.48/01), Bulb onions (R.75/02, R.82/02, R.83/02), Melons (00–535, 00–536, 02 R 655, 02 R 656), Cucumbers (02 R 651, 02 R 653), Watermelons (UNESP RA-944/05, UNESP RA-945/05, UNESP RA-946/05), Lettuce (98–514, 99–506), Potatoes (97–555, 97–556, 97–557, 97–558, 97–691, 97–745, 98–525, 98–526, 98–527, 98–635, 98–669, 98–688, 98–700, 99–648, 99–664, R.23/01, R.32/01, R.50/01).

Method number 00868, M-229394-01-1

Validation: Report No. P 1980 G, M-370932-01-1

Analytes: Fenamidone, RPA 410193

LOQ: 0.01 mg/kg (LC-MS/MS)

Description: Fenamidone and RPA 410193 residues are extracted by homogenisation with acetone / water. After centrifugation an aliquot was concentrated to the aqueous remainder and dissolved in acidified acetonitrile/water. Quantification was by LC-MS/MS.

Residue trials: Grapes (09-2179, 09-2180), Strawberries (09-2169), Leek (RA-2682/03), Bulb onion (RA-2683/03), Witloof chicory (RA-2566/04, 08-2205), Head cabbage (RA-2900/03, RA-2901/03), Cauliflower (RA-2902/03, RA-2903/03), Melons (RA-2536/05), Cucumbers (RA 2648/03, RA 2540/04), Tomatoes (09-2235, 09-3235, RA-2541/05), Potatoes (09-2170), Lettuce (RA-2542/04, RA-2518/05, RA-2519/05, RA-2553/06, 09-2158, 09-2159, 09-2216)

Method number RPAC 45683, M-238850-01-1, method appended, p. 99

Validation: Report No. 019-056 (B003198), M-238850-01-1
 Analytes: Fenamidone, RPA 410193, RPA 412636, RPA 412708
 LOQ: 0.02 mg/kg (LC-MS/MS)
 Description Method analogue to AR 150-97

Method number unknown, M-238851-01-1, method appended, p. 48

Validation: Report No. B003199, M-238851-01-1
 Radiovalidation: Report No. 019-057 (B003200), M-238852-01-1
 Analytes: Fenamidone, RPA 410193, RPA 412636, RPA 412708
 LOQ: 0.02 mg/kg (LC-MS/MS)
 Description Method analogue to AR 150-97
 Residue trials: Ginseng (09800), Lima beans (09530), Snap beans (08895)

Method number RPAC 45911, M-238680-01-1 (method appended, p. 199)

Analytes: Fenamidone, RPA 412636, RPA 410193 (412708), RPA 410193
 LOQ: 0.02 mg/kg (LC-MS/MS)
 Description: Fenamidone, RPA 412636, RPA 412708 and RPA 410193 are extracted from homogenized sample matrix by accelerated solvent extraction (ASE) with acetone / water at enhanced temperature conditions. After dilution with water and filtration, quantification was by LC-MS/MS.
 Residue trials: Onions (98W14461), Green onions (98W14461), Cabbage and broccoli (201225), Melons (99W14488), Cucumbers (99W14486), Summer squash (99W14487), Peppers (201227), Tomatoes (99W17533), Lettuce (00W13043, 00W14459), Mustard greens (201226), Spinach (201214), Carrots (08524), Potatoes (99W17534, 01AC05), Celery (201214), Sunflower seed (07999) and storage stability study EC-99-448

Method number RPAC 45952, M-240317-01-1

Analytes: Fenamidone, RPA 410193 (RPA 412708), RPA 412636
 LOQ: 0.02 mg/kg (LC-MS/MS)
 Description: Fenamidone and metabolites are extracted from homogenized sample matrix by accelerated solvent extraction (ASE) with acetone / water at enhanced temperature conditions. After dilution with acetone extracts were cleaned up on a laboratory packed column containing carbon, silica and alumina. Final extracts are quantified by LC-MS/MS.
 Residue trials: Cotton seed and by-products (201163)

Method number 01163, M-354028-01-1

Validation: Bayer Ref: M-449868-01-1

Analytes: Fenamidone, RPA 410193

LOQ: 0.01 mg/kg (LC-MS/MS)

Description: Modified QuEChERS method for crop matrices. Water is added to the sample material depending on its moisture content. Residues of fenamidone and RPA 410193 are extracted from sample material by vigorous shaking with acetonitrile. For liquid-liquid partition and phase separation, salt (magnesium sulphate, sodium chloride, sodium citrate and sodium hydrogen citrate) is added to the homogenate and the sample is shaken again. After centrifugation an aliquot of the upper organic phase is diluted with acetonitrile/water. This final extract is quantified by LC-MS/MS.

Residue trials: Grapes (10–2010, 10–2011), Strawberries (10–2014, 11–2004, 12–2039), Tomatoes (10–2013), Lettuce (10–2012), Potatoes (10–2065), Witloof chicory (10–2040)

Method number 00862, Bayer Reference: M-255146-01-1

Analytes: Fenamidone, RPA 410193, RPA 412636 and RPA 412708

LOQ: 0.01 mg/kg (LC-MS/MS)

Description: Fenamidone, RPA 410193, RPA 412636 and RPA 412708 are extracted from crop materials using acetone/water in a high-speed blender. After centrifuging, the supernatant is removed and the solids re-extracted with acetone/water. An aliquot of the combined supernatants is concentrated to the aqueous phase and adjusted to volume with acidified water, then filtered for analysis by LC/MS/MS.

Study: Rotational crops; turnip, lettuce, wheat (RA-2750/03)

Method number 00863, Bayer Reference: M-274241-01-1

Analytes: RPA 412708 conjugate

LOQ: 0.01 mg/kg (LC-MS/MS)

Description: RPA 412708 conjugate is extracted from samples with acetone: water (5:1 v/v) twice, the samples blended in a blender and centrifuged. The supernatant is removed, further acetone added and concentrated to an aqueous remainder using a sample concentrator. Formic acid is added and the sample heated in an oven for 2 hours at 70 °C to hydrolyse. Subsamples of the hydrolysed extracts are mixed with acetonitrile or water, filtered (0.2 µm filter) and analysed by LC-MS/MS.

Study: Rotational crops; turnip, lettuce, wheat (RA-2750/03)

Animal commodities

Method number AR 200-99, M-166398-01-1

Validation: Report No. 99-95, M-183960-01-1

Analytes: Fenamidone, RPA 412708, RPA 412636

LOQ: 0.01 mg/kg (GC-NPD)

Description: Residues of fenamidone, RPA412708 and RPA412636 are extracted from milk samples by homogenisation with acetonitrile. The extracts are purified using an octadecyl cartridge. Final determination of residues is by GC on a semi-capillary column, using a thermionic detector and quantification against external standards.

Residue trials: Milk (00W25043)

Method number AR 178-98, M-166460-01-1

ILV: Report No. 99-52, M-183964-01-1

Analytes: Fenamidone, RPA 412708, RPA 412636

LOQ: 0.05 mg/kg (GC-NPD)

Description: Residues of fenamidone, RPA412708 and RPA412636 are extracted from animal products by homogenisation with acetonitrile. The extracts are purified using a polystyrene divinylbenzene cartridge followed by an aminopropyl cartridge. For kidney, whole egg and muscle, final determination of residues is by gas chromatography on a semi-capillary column, using a thermionic detector and quantification against external standards. For liver, final determination of residues is by GC-MS and quantification against external standards.

Residue trials: Animal products (00W25043)

Multi-residue methods

Plant material: Method number DFG S19, M-368426-01-1

Validation: Report No. R&D/CRLD/AN/9915480, M-166310-01-1

Analytes: Fenamidone, RPA410193

LOQ: 0.01 mg/kg (GC-MS)

Description: Residues of fenamidone and RPA410193 are extracted from the plant samples by homogenisation with water / acetone, then partition into ethyl acetate / cyclohexane. The organic extracts are cleaned up by fractionation using gel-permeation chromatography, followed by purification using a silica column. Final determination of residues is by GC-MS, monitoring three ions per analyte for determination and confirmation.

Animal products: Method number 01323, M-410297-01-1

ILV: Report No. 2011/0107/01, M-440254-01-1

Analyte: Fenamidone, RPA 412708 and RPA 412636

LOQ: 0.01 mg/kg (LC-MS/MS)

Description: QuEChERS multi residue method for animal matrices: For milk, residues of fenamidone, RPA 412708 and RPA 412636 are extracted by vigorous shaking with acetonitrile. Salts (magnesium sulphate, sodium chloride, sodium citrate and sodium hydrogen citrate) are added and the sample is shaken again. A portion of the acetonitrile layer is transferred to a dispersive SPE clean-up tube, shaken and centrifuged before aliquots of the supernatant are acidified for determination of fenamidone, RPA 412708 and RPA 412636 by LC-MS/MS). RPA 412636 is determined separately from fenamidone and RPA 412708.

For eggs, muscle, liver and kidney, residues of fenamidone, RPA 412708 and RPA 412636 are extracted by vigorous shaking with acetonitrile (and homogenisation for muscle, liver and kidney). Salts (magnesium sulphate, sodium chloride, sodium citrate and sodium hydrogen citrate) are added and the sample is shaken again. Fat is frozen out of the extract before a portion of the acetonitrile layer is transferred to a dispersive SPE clean-up tube, shaken and centrifuged before aliquots of the supernatant are acidified for determination of fenamidone, RPA 412708 and RPA 412636 by LC-MS/MS as for milk.

For fat, samples are melted (60 °C) and partitioned with water and acetonitrile. After re-melting, salts (magnesium sulphate, sodium chloride, sodium citrate and sodium hydrogen citrate) are added and the sample is shaken again. Fat is frozen out of the extract before a portion of the acetonitrile layer is transferred to a dispersive SPE clean-up tube, shaken and centrifuged before aliquots of the supernatant are acidified for determination of fenamidone, RPA 412708 and RPA 412636 by LC-MS/MS as for milk.

Validation data for the methods described above are available from specific method validation studies or from residue studies where specific method validation recovery experiments were performed separate from routine sample analysis. These method recovery data, for plant and animal commodities are summarised in Table 54.

Table 54 Method recovery data of fenamidone and metabolites in plants and animal products

Stability of residues in stored analytical samples

Information was received on the freezer storage stability of fenamidone residues and its metabolites in plant commodities. The storage stability data for fenamidone and RPA 410193 in grapes, potatoes, lettuce, strawberries and turnips are described as follows. The results are shown in Table 55.

Grapes, potatoes, lettuce

Reference: Kieken and Queyrel, 1999 (report R&D/CRLD/AN/mr/9915970, M-166527-01-1), Kieken and Queyrel, 2000 (report R&D/CRLD/AN/mba/0015230, M-183934-01-1)

Method: AR 150-97, GC-NPD, LOQ 0.02 mg/kg for both fenamidone and RPA 410193

Description: Untreated control samples were fortified with fenamidone and its metabolite RPA 410193 at a concentration of 0.2 mg/kg and then frozen below –20 °C. Samples were analysed immediately after fortification (0 day) and after storage intervals up to 1 year (12 or 13 months). At each interval, two stored samples were analysed, with one or more procedural recovery samples (control samples spiked just before analysis at 0.2 mg/kg).

Strawberries

Reference: Uceda, 2005 (report 03-21, M-247921-01-1)

Method: AR 306-03, GC-MS, LOQ 0.01 mg/kg

Description: Samples of strawberries were fortified with fenamidone and RPA 405682 at a level of 0.1 mg/kg. The samples were stored in glass bottles at about –18 °C or below and were analysed at nominal storage intervals of 0, 4, 14 and 18 months.

Turnips

Reference: Cavaillé, 2007 (report MR-07/232, M-286141-01-1)

Method: 00868, LC-MS/MS, LOQ 0.01 mg/kg

Description: Turnip root samples were fortified with fenamidone or RPA 404862 at a level of 0.2 mg/kg. The samples were stored in plastic containers at about –18 °C or below and were analysed at nominal storage intervals of 0, 2, 6 and 12 months. Procedural recovery experiments were conducted at all storage intervals by spiking control samples of turnip with a mixture of fenamidone and RPA 410193 at a level of 0.2 mg/kg. Additional recoveries for both analytes at 0.01 mg/kg were also performed at the 0 and 12 month intervals.

The stability of fenamidone and its metabolites RPA 410193, RPA 412636 and RPA 412708 were examined in nineteen crop commodities. Raw and processed commodities were included: bulb onion, cotton gin trash, cotton hulls, cotton meal, cotton oil, cotton seed, cucumber, leaf lettuce, potato chips (crisps), potato flakes, potato tubers, potato wet peel, tomato fruit, tomato paste, tomato puree, wheat forage, wheat grain, wheat hay, and wheat straw. The study is described as follows below. The results are shown in Table 56 for fenamidone and RPA 412636, and in Table 57 for RPA 412708 and RPA 410193.

Various commodities

Reference: Hudson and Carringer, 2001 (report EC-99-448, M-238849-01-1)

Method: RPAC 45911, LC-MS/MS, LOQ 0.02 mg/kg for each analyte

Description: Untreated control samples were fortified with fenamidone, RPA 412636, RPA 412708 and RPA 410193 at a concentration of 0.3 mg/kg and then frozen below -20°C . Each analyte was fortified into separate control samples. All matrices were analysed for 12 months stability with the exception of cotton. Cotton matrices were analysed from 1 to 6 months. At each interval, two stored samples were analysed, with a procedural recovery sample (control sample spiked just before analysis at 0.2 mg/kg).

^a Unexplained high value not included in calculation of mean (possible fortification error)

The stability of incurred fenamidone residues was examined in tomatoes over a 21-month period after harvest under freezer conditions. Residues of RPA 410193 were below 0.01 mg/kg in all the samples, so it was not possible to assess its stability. The study is described below (see Table 58).

Reference: Schulte, 2011 (report MR-11/028, M-404654-02-1)

Method: 00868, LC-MS/MS, LOQ 0.01 mg/kg for each analyte

Description: Incurred fenamidone residues in tomato fruits ranged from 0.05 to 0.38 mg/kg at the first analysis made 17 months after sampling. The samples were analysed again at nominal storage intervals of 14–21 months after sampling (2–4 months after initial analysis). Procedural recovery experiments were conducted at all storage intervals by spiking control samples of tomato at levels of 0.01 to 1.0 mg/kg. Residues in the control samples were all < 0.01 mg/kg.

In summary, residues of fenamidone, RPA412636, RPA412708 and RPA410193 stored under freezer conditions at –20 °C are stable for at least 12 months in a wide range of raw and processed crop matrices, including examples of high-water and high-starch crops and for at least 6 months in cotton products (high oil content). Residues of fenamidone and RPA410193 are stable in high-acid commodities (strawberry) for at least 18 months.

USE PATTERN

The fungicide fenamidone is registered in many countries for control of diseases on a large variety of crops. Fenamidone is applied either as solo product or in combinations with other active substances as propamocarb, mancozeb, iprovalicarb and fosetyl-Al. The information available to the Meeting on registered uses on berries, vegetables and on oil seed is summarized in Table 59 and refers for application rates etc. to fenamidone only. The manufacturer submitted labels for all fenamidone uses.

Carrots	VR Root and tuber vegetables	78
Potato		79
Ginseng		80
Witloof chicory (sprouts)	VS Stalk and stem vegetables	81
Celery		82
Cotton seed	SO Oilseed	83
Sunflower seed		84
Snap bean forage	AL Legume animal feeds	85
Cotton fodder, dry	AM Miscellaneous fodder and forage crops	86

In the residue supervised trials tables, where two samples were taken from a single plot, the average value is reported (individual sample results in parentheses). Where results from separate plots with distinguishing characteristics such as different formulations, varieties or treatment schedules were reported, results are listed for each plot. In these cases, the higher residue has been used for calculation purposes. Dates of duration of residue sample storage before analysis were provided. If the duration of samples storage was longer than the covered frozen stability, it is indicated in the text.

Residue values from the trials conducted according to the maximum GAP have been used for the estimation of maximum residue levels. Those results included in the calculations by the OECD MRL-calculator are underlined.

Residues are reported separately for fenamidone ("Fen") and diketo-fenamidone (RPA 410193). The code name RPA 410193 is used throughout this section, irrespective of what nomenclature (synonyms: AE C650488, RPA 405862, DK-Fen) was used in the residue studies.

For HR and STMR estimation, sums of fenamidone (MW 311.4) and RPA 410193 (MW 281.3), expressed as fenamidone (conversion factor 1.11), are needed. When residues are undetectable in a commodity, the sum of the LOQs of both components is not appropriate for all plant commodities because the days after the last treatment (DALT) differ from 2 days (e. g. lettuce) to 35 days (strawberry). To select the best option, the relative ratio of parent and metabolite was estimated:

Plant commodity	DAT, Days	Samples with measured residues for both analytes (n)	Residue parent ÷ RPA 410193	
			Range	Average
Strawberries	35	3	1–2	1.7
Grapes	28	33	2–8	4.4
Lettuce	21	5	5–16	9
Lettuce	14	3	19–42	27
Peppers	14	1	36	36
Cauliflower	14	1	8	8
Spring onion	7	1	19	19
Potato foliage	7	3	27.5–37	33
Melons, peel	3	5	2.5–23	11
Tomatoes	3	2	18	18
Lettuce	2	9	148–530	306
Mustard greens	2	8	135–710	403
Spinach	2	5	361–1030	659
Celery	2	4	111–220	145

The residues of RPA 410193 are found in the same order of magnitude as the parent in berries harvested 4 to 5 weeks after treatment. In plant commodities harvested at shorter periods (2–21 days), the level of the metabolite is much lower than the parent in most cases. The method for calculation of the total residues of the sum of fenamidone and RPA 410193 is illustrated as follows:

- Plant commodities except for grapes and strawberries

Fenamidone, mg/kg	RPA 410193, mg/kg	Total, mg/kg
< 0.02	< 0.02	< 0.02
0.05	< 0.02	0.05
0.42	0.08	0.51 ^a
^a 0.42 + (0.08 × 1.11) = 0.5088		

- Grapes and strawberries

Fenamidone, mg/kg	RPA 410193, mg/kg	Total, mg/kg
< 0.02	< 0.02	< 0.04
0.05	< 0.02	0.07
0.42	0.08	0.51

Most of the submitted residue supervised trials have been overdosed in terms of the number of applications. The Meeting received additional information and comparative trials on grapes (40 trials) and tomatoes (16 trials). Grapes were treated either 3 × 0.13 kg ai/ha or 7 × 0.12 kg ai/ha and samples were taken at a 28-day PHI. Tomatoes were treated either 3 × 0.15 kg ai/ha or 5 × 0.15 kg ai/ha and harvested at a PHI of 3 days. The results indicate no significant difference between the data sets (Simonin, 2013; M-451095-01-1).

Berries and other small fruits

Grapes

Thirty-five trials on grapes were conducted in Europe (France, Italy, Spain, Portugal, Greece, Germany and Belgium) between 1997 and 2010 by foliar spray. Trials conducted during 1997 and 1998 received seven applications (interval 14 days), whereas trials conducted during 2009 and 2010 received three applications.

Three supervised residue trials were conducted in Brazil in the growing season 1998/99. The maximum period of sample storage at –20 °C was for the Brazilian trials 795 days prior to analysis

Fenamidone

(storage stability covered for one year only). Storage stability data on strawberries show that the residues are stable for at least 18 months in an acid content commodity. The results are summarized in Table 60.

Table 60 Residues in grapes from supervised trials with fenamidone

Strawberries

Fifteen trials on strawberries were conducted in Europe (Germany, Belgium, Netherlands and France) between 2004 and 2012. The trials were conducted in indoor strawberry crops, housed under plastic or glass. Two applications by drip irrigation to individual strawberry plants or one drip application

followed by one foliar application were made. In the trials matching Belgium GAP, both drip applications in irrigation water, made 14–26 days apart, were at a rate of 0.45 kg ai/ha. In the trials according to the UK GAP, the two applications were made at an interval of 21–22 days, the first application at 0.18 kg ai/ha (drip) and the second at 0.27 kg ai/ha (foliar spray). The results are summarized in Table 61.

Onion, bulb

Supervised field residue trials were conducted in Brazil in 2001, in the USA in 1999 and in Europe (Germany, France, Netherlands and the UK) in 2003. In Europe, fenamidone was applied by foliar

spray four times to onion plants at the rate of 0.15 kg ai/ha, whereas the US trials were conducted with 6×0.2 kg ai/ha (interval 7 days). The results are summarized in Table 63.

Spring onion

Four trials on spring onion were conducted in the USA in 1999 (98W14461, M-238680-01-1). Fenamidone was applied by foliar spray to onion plants at the rate of 6×0.2 kg ai/ha (interval 7 days). For results see Table 64.

*Brassica vegetables**Cabbage*

Field trials on head cabbage were conducted in Europe (Germany, France and Portugal) and in the USA during 2003. In the European trials, fenamidone was sprayed three times at the rate of 0.15 kg ai/ha. In the USA, four applications were made at intervals of 4–5 days, at the rate of 0.28–0.31 kg ai/ha. The results are summarized in Table 65.

Fruiting vegetables, Cucurbits

Cucumber

Nine trials on cucumber performed indoor were conducted in Europe during 2002, 2003 and 2004: two trials in France, three in Spain, two in Italy, one in Greece and one in the Netherlands with 3 × 0.15 kg ai/ha by foliar spray. Nine supervised trials on cucumbers were performed outdoors during 1999 in the USA. Six applications in the range of 0.19–0.215 kg ai/ha at intervals of 3–6 days were made. The results are summarized in Table 67.

Summer squash

Nine field trials on summer squash were carried out during 1999 in the USA (99W14487, M-240407-01-1). At each trial, six spray applications in the range of 0.19–0.21 kg ai/ha were made at intervals of 4–6 days. The results are summarized in Table 68.

Melons

Twenty trials on melon were conducted in Europe during 2000, 2002 and 2005, six trials in France, six in Spain, six in Italy, one in Greece and one in Portugal. The spray application rates were 3×0.14 –0.15 kg ai/ha. Twelve trials were conducted outdoors and eight trials conducted indoors. In the indoor trials (02 R 656, M220462-01-1), the samples were stored frozen for about 18 months.

Fenamidone

Eight supervised trials on cantaloupe melon were carried out outdoors during 1999 in the USA. Fenamidone was applied six times by foliar spray at rates of 0.19–0.21 kg ai/ha at intervals of 5 days. The results are summarized in Table 69.

Watermelons

Three supervised trials on watermelon were carried out in Brazil during 2004. The foliar spray application rates were 5×0.15 kg ai/ha or 5×0.3 kg ai/ha (interval 7 days). The results are summarized in Table 70.

*Fruiting Vegetables other than Cucurbits**Peppers*

Six supervised field trials on sweet pepper and three trials on chilli pepper were carried out during 2003 in the USA (201227, M-260625-01-1). At each trial, four foliar spray applications were made at intervals of 4–6 days, at rates in the range of 0.27–0.35 kg ai/ha. The results are summarized in Table 71.

Tomato

Eight supervised trials on indoor tomatoes and four trials on outdoor tomatoes were conducted in Europe (France, Italy, Spain, Germany and Netherlands) during 2005, 2009 and 2010. Fenamidone was applied by foliar spray three times at a rate of 0.15 kg ai/ha and an interval in the range of 6–7 days. The maximum storage period from harvest to analysis was 512 days.

Seventeen supervised field trials on tomato, including two trials on cherry tomatoes, were carried out during 1999/2000 in the USA (outdoors). Each trial consisted of two plots. The first plot was treated four times at rates in the range of 0.2–0.31 kg ai/ha and intervals of 4–6 days. The second plot of each trial was treated six times at lower rates in the range of 0.19–0.21 kg ai/ha. The results are summarized in Table 72.

Leafy vegetables

Lettuce

Supervised trials on indoor lettuce (19) and eighteen trials on field lettuce (18) were conducted in Europe (France, Germany, Belgium, Spain and Netherlands) between 1998 and 2010. Fenamidone was applied three times by foliar spray at a rate in the range of 0.11–0.16 kg ai/ha and an interval in the range of 7–47 days. In the 2004 trials (RA-2542/04 (M-265329-01-1), the maximum storage period from harvest to analysis was 17.5 month.

Eighteen field trials on lettuce were conducted during the year 2000 in the USA (outdoors), nine on open-leaf and nine on head varieties. Fenamidone was applied four times at 7-day intervals to lettuce plants at the rate of about 0.3 kg ai/ha (range: 0.29–0.34 kg ai/ha). The results are shown in Table 73.

Table 73 Residues in lettuce from supervised trials with fenamidone

Mustard greens

Eight supervised trials on mustard greens were carried out during 2003 in the USA (outdoors) (201226, M-260567-01-1). At each trial, four foliar sprays were applied at intervals of 4–5 days, at rates in the range of 0.29–0.32 kg ai/ha. The results are summarized in Table 74.

*Legume vegetables**Lima beans*

Eight field trials on lima beans were conducted in the USA (09530, M-489331-01-1). The results are shown in Table 76. At each trial four foliar applications of 0.3 kg ai/ha each plus adjuvant (sticker/spreader) were made. At the NC30 trial, a 5th application was made due to the slow maturation of the lima beans. The applications were timed so that commercially mature succulent lima bean seeds

without pods could be sampled 3–4 days after the final application (at all three Maryland trials the plants with pods on them were harvested 2 days after the final application due to a forecasted heavy rain event). The beans were harvested by hand (either by pulling the entire plant or by handpicking pods in the field). The succulent lima bean seeds were then removed from the pods either by hand or by using a pea sheller.

Common beans

Eight field trials on common beans (snap beans) were conducted in the USA and Canada (08895, M-489329-01-1). The results are shown in Table 77. At all trials, four foliar applications of the test substance were made 6–8 days apart at a rate of approximately 0.3 kg ai/ha (for a total application of 1.2 kg ai/ha). An adjuvant was included in each application. At trial CA86 a fifth foliar application of 0.3 kg ai/ha was made, due to slow maturation of the pods at that site. The applications were timed so that mature snap bean pods with seed could be collected 3–4 days after the final application. Samples were harvested by hand or using clippers/pruners.

Root and tuber vegetables

Carrots

Thirteen supervised trials on carrots were carried out in the USA and Canada (08524, M-278032-01-1). At each trial, four foliar spray applications were made at rates in the range of 0.26–0.33 kg ai/ha. Applications were performed at intervals of 6–8 days between the first and second and the third and fourth treatments. There was an extended interval (28 to 104 days) between the second and the third applications. The residue results are summarized in Table 78.

Ginseng

Five supervised trials on ginseng were carried out in 2007 in the USA and Canada. At each trial, nine applications at rates in the range of 0.29–0.32 kg ai/ha were performed at intervals of 7–15 days

between each foliar application. Samples were prepared by washing the roots with water and drying at 18–46 °C in a commercial drying facility. Samples of washed and dried roots were stored frozen at below –20 °C for up to 658 days until extraction and analysis. A sufficient stability of fenamidone was demonstrated for up to 650 days using spiked samples. The residue results are shown in Table 79.

Potato

Twenty-seven supervised trials on potato were conducted in Europe (Belgium, France, Germany, Greece, Italy, The Netherlands, Spain and the UK) between 1997 and 2010. Five, six or twelve foliar spray applications of fenamidone were performed at rates in the range of 0.1–0.16 kg ai/ha and intervals in the range of 7–14 days.

Eighteen supervised trials on potato were carried out during 1999 in the USA and three trials on potato were carried out in 2001 in Canada. In the trials fenamidone was applied either with six treatments at a rate of 0.19–0.23 kg ai/ha or with four applications at a rate of 0.29–0.315 kg ai/ha by foliar spray. Applications were performed at intervals of 3–7 days. All samples except those from the Florida trial (17534-16) were stored frozen for 176 days or less. The samples from trial 17534-16 were stored for 394 days (storage stability covered up to 12 month).

Seven residue trials were conducted in potato during 1998, 1999, 2000 and 2006 in Brazil by foliar spray. In trials performed in 1998, 1999 and 2000, fenamidone was applied three times to potato plants at rates of 0.15 kg ai/ha and 0.3 kg ai/ha on different plots. In trials performed in 2006, fenamidone was applied six times to potato plants at a rate of 0.15 kg ai/ha. The results are summarized in Table 80.

*Stalk and stem vegetables**Witloof chicory (sprouts)*

Nine indoor residue trials were conducted in Belgium, France, Germany and Netherlands in 2004, 2008 and 2010. In 2004 four residue trials were conducted in Belgium, France and the Netherlands consisting of one application through the irrigation water system at a maximum rate of 0.6 g ai/hL of fenamidone and a water volume of 40 L/m², at the commencement of forcing.

In 2008 and 2010 five residue trials were conducted in France, Germany and the Netherlands. These trials were treated twice, one dip application for two minutes in a solution containing 6.0 g ai/hL, immediately after field sampling of the roots. After storage of the roots in a cold room for 3–8 months, a second application was made at the commencement of forcing in the irrigation water system at a maximum rate of 0.6 g ai/hL. Sprout and root samples were taken on day 21 (or 20) after the second application. The results are summarized in Table 81.

Celery

Six supervised trials on celery were carried out during 2003 in the USA (201214, M-242541-01-1). At each trial, fenamidone was applied by foliar spray at rates of about 0.3 kg ai/ha four times at intervals of 4–6 days. The results are summarized in Table 82.

*Oilseed**Cotton seed*

Twelve trials were conducted on cotton in the USA during 2003(201163, M-242540-01-1). In each trial, cotton plants were treated at-planting with a single in-furrow over-the-seed application at a target rate of 0.3 kg ai/ha. Samples of mature cotton were harvested 127–190 days post treatment from each test location by hand or using either stripper or picker harvest equipment. Samples were then ginned to yield undelinted cotton seed. The results are summarized in Table 83.

Sunflower seed

Nine trials with fenamidone on sunflower were conducted in 2009 in the USA (07999, M-251287-02-1). In each trial, one plot was planted with sunflower seeds treated with fenamidone resulting in a rate of 0.19 kg ai/100 kg seed. Two trials included an additional plot planted with seed treated at an exaggerated rate of 0.95 kg ai/100 kg seed. Samples of mature sunflower seed were harvested from each test location 104–146 days after sowing of the treated seed. The maximum storage period from sampling to analysis was 433 days. A sufficient stability of fenamidone and its metabolites was demonstrated for up to 438 days using spiked samples. The results are shown in Table 84.

^a From sowing to sampling

Legume animal feeds

Bean forage (green)

Eight field trials on snap beans were conducted in the USA and Canada (08895, M-489329-01-1). The residues in bean forage are shown in Table 85. At all trials, four foliar applications of the test substance were made 6–8 days apart at a rate of approximately 0.3 kg ai/ha (for a total application of 1.2 kg ai/ha). At trial CA86 a fifth foliar application of 0.3 kg ai/ha was made, due to slow maturation of the pods at that site. Samples were harvested by hand or using clippers/pruners and either placed directly into sample bags or shaken lightly to remove loose soil before being placed in to sample bag. At trial CA86 the samples of plants with pods were sub-sampled by cutting four groups of three plants each into top, middle, and bottom sections and retaining a top, middle, and bottom portion from each group. This subsample was placed into the sample bag and the remaining portions were discarded.

Miscellaneous fodder and forage crops

Cotton fodder, dry

Trials were conducted on cotton in the USA during 2003 (201163, M-242540-01-1). Cotton plants were treated at-planting with a single in-furrow over-the-seed application at a target rate of 0.3 kg ai/ha. Cotton gin by-products (gin trash) were collected from the cotton harvested 127–190 days post treatment mechanically using either a picker or a stripper. Because cotton gin by-products are used as animal feed, the fodder was analysed for residues. The results are summarized in Table 86.

FATE OF RESIDUES IN STORAGE AND PROCESSING

Residues are reported separately for fenamidone (“Fen”), diketo-fenamidone (RPA 410193) and desanilino-fenamidone (RPA 412708). The codes RPA 410193 (synonyms: AE C650488, RPA 405862, DK-Fen) and RPA 412708 (synonyms: AE 050057, RPA 408056, DA-Fen) are used throughout this section, irrespective of what nomenclature was used in the reports.

In processing-nature of residues

To estimate the degradation behaviour of [C-phenyl-UL-¹⁴C]-fenamidone during industrial processing or household preparation, the processes of pasteurization (90 °C, 20 min at pH 4), baking, boiling, brewing (100 °C, 60 min at pH 5) and sterilization (120 °C, 20 min at pH 6) were simulated (17581, M-173268-01-1).

The test system consisted of flasks containing approximately 100 mL of buffer maintained at constant temperature and pH for the duration of the simulation. All samples were analysed on the day

of treatment by concurrent radio-detection and LC/MS. The recovery of TAR is summarized in Table 87 and the composition of TRR in Table 88.

Table 87 Recovery of TAR after hydrolysis

In processing-effect on the residue level

The Meeting received information on the fate of fenamidone residues during the processing of raw agricultural commodities (RAC) like grapes to juice, must, wine and pomace and tomatoes into juice, paste, ketchup and canned tomatoes. Because the residues of diketo-fenamidone (RPA 410193) are of the same order of magnitude as the parent concentrations in processed products of grapes and tomatoes, the sum of parent and RPA 410193 is calculated as follows:

Fenamidone, mg/kg	RPA 410193, mg/kg	Total, mg/kg
< 0.02	< 0.02	< 0.04
< 0.02	0.076	0.10
0.05	< 0.02	0.07
0.53	0.13	0.67 ^a

$$^a 0.53 + (0.13 \times 1.11) = 0.6743$$

Two processing studies were carried out on potatoes but were only of limited use because the residues in RAC were < LOQ. Further studies conducted on cabbage, broccoli, peppers, mustard greens and spinach investigated the fate of fenamidone and RPA 410193 after cooking.

Processing of grapes

Ten processing trials were conducted in which grapes were processed into red wine; grape juice was also produced in eight of these trials. Sixteen processing trials were conducted in which grapes were processed into white wine; grape juice was also produced in two of these trials. The results and the calculated processing factors (residue in processed commodity ÷ residue in RAC) for MRL setting and dietary intake purposes are presented in Tables 89 and 90. The information submitted on processing procedures is summarized as follows.

Red and white wine

Grape samples (bunches) were processed simulating commercial practices. The grape bunches were crushed and stemmed and the must collected in stainless steel tanks. Pectolytic enzyme was added to the juice of white grapes. Alcoholic fermentation was started by addition of dry active yeast. The fermentation was controlled on a daily basis by measurement of the temperature, density and pH-value. Alcoholic fermentation was considered complete when the must/juice density fell below 1.000. The must (red grapes) was processed to young wine and pomace by use of a water press. Red wine (only) was then subjected to malolactic fermentation. Alcoholic and malolactic fermentation were stopped by addition of potassium metabisulphite and the young wine was subjected to natural clarification, aided by addition of gelatine and potassium metabisulphite and storage for 26–27 days in a cold chamber at about 5–10 °C. Finally the clarified wine was filtered (2.5 and 1.5 µm) and stabilized by addition of potassium metabisulphite. The production of white wine followed similar processes but without malolactic fermentation.

Grape juice

For processing of red grape juice, grape bunches were crushed and stemmed and the crushed samples placed in a saucepan and treated with pectolytic enzyme for two hours at 50–65 °C. Juice was then obtained by pressing the must in a water press. Samples of white grapes were directly processed into juice using a water press. Pectolytic enzyme was added to the juice of white grapes. Samples were stabilized by addition of potassium metabisulphite.

Processing of tomatoes

Three processing studies on tomatoes were submitted. The residues of fenamidone and RPA 410193 as well as processing factors are shown in Table 91. Because the residues increase after processing in tomato puree, ketchup and paste, processing factors were calculated for MRL (parent) and for dietary intake (sum) purposes. Further information on the residue trials and the processing procedures are described below.

Study 1

A first study was conducted in 2000 in Southern France, (99-519, M-206274-01-1). The study contained a single field trial conducted in Southern France to determine the magnitude of residues of fenamidone and its metabolite diketo-fenamidone (RPA 410193) in/on tomato and processed products. Fenamidone was applied to the tomato plants in five foliar applications at the rate of 0.15 kg ai/ha. The fruit samples harvested 3 days after the last application were processed into juice, puree, paste, canned tomatoes and ketchup.

Study 2

A second study was conducted following application of fenamidone in three protected trials conducted in Europe (the Netherlands, Italy and Germany) during 2009 (09-3235, M-406443-02-1).

Fenamidone was applied to tomato plants at a rate of 0.127 kg ai/ha in three spray applications at 7-day intervals between growth stages BBCH 77 to 85 at the three trial sites. Samples of tomato fruit to be processed were harvested 3 days after the last treatment (BBCH 83–89). The processing of the fruit samples into the processed fractions juice, puree and canned tomatoes was performed using methods simulating industrial/household practices.

Tomatoes were washed in water, to produce “washings” and “whole fruit, washed” and left to drain. Cut samples were then heated in water to 80–100 °C in order to prevent enzymatic reactions. After this blanching process, the pulp was passed through a strainer to separate juice from “strain rest” (wet pomace). Sodium chloride was added to the raw juice and taken for the preparation of “raw puree”. Aliquots of the raw puree were placed into cans and pasteurized to give puree. A portion of the “raw juice” was used for processing the canned tomatoes, which were placed in cans and pasteurized. Samples of finished products and intermediate processing fractions were collected for analysis.

Study 3

A third study was conducted in California, USA (98W13074, M-238681-01-1). Field grown tomatoes were treated by foliar spray at 7-day intervals by 6 × 1.0 kg ai/ha. Samples were collected 14 days after the last application. The tomatoes were washed twice, first with tap water, then with chlorinated water. The washed tomatoes were ground and crushed, heated to 96–99 °C and fed into a finisher for separation into wet pomace and juice. The juice was concentrated by vacuum evaporation to produce puree, a sample of which was vacuum condensed to paste. The paste fraction was heated (88–89 °C), packed into cans, sealed and held at filling temperature for 10–28 minutes prior to cooling. Triplicate subsamples of the processed fractions (raw, unwashed tomatoes, tomato puree and tomato paste) were taken and all samples frozen.

Table 91 Residues of fenamidone in processed tomato commodities

Processing of potatoes

The first potato processing study was conducted in Germany (98-699, M-166638-01-1) in which two trials were performed on potato in 1998. Fenamidone was applied to potato plants by twelve foliar applications at the dose rate of 0.14–0.15 kg ai/ha with a spray interval of 7 days and a PHI of 6 days. The harvested potatoes were peeled and the peels collected. The separate samples of peel and peeled

tubers were then homogenised by grinding. No residues above the LOQ of 0.005 mg/kg could be determined in tubers (RAC), peeled tubers and in peel and no processing factors could be calculated.

The second potato processing study was conducted in Washington (USA) in 1998 (98W13063, M-240410-01-1). Potato plants from a single trial received six foliar applications of fenamidone at a rate of ca. 1 kg ai/ha. Tubers were collected 14 days after the last application and processed using procedures that simulated commercial practices. Duplicate treated samples of whole potato tubers, potato flakes, potato chips (crisps) and potato wet peel were collected for analysis. The results are shown in Table 92.

Table 92 Residues of fenamidone in processed potato commodities

RAC / Processed commodity	Residues, mg/kg			Processing factor	
	Fen	RPA 410193	Sum	Parent	Sum

Washing and cooking of vegetables

Trials were submitted of washing and/or cooking of cabbages, broccoli, peppers, mustard greens and spinach conducted in the USA. The results and the calculated processing factors (for dietary intake purposes only) are presented in Table 93. The information submitted on processing procedures is summarized as follows.

Cooking of cabbage

Bulk samples of cabbage, consisting of composites of at least 12 plants, were taken 2 days following the last application. The outer wrapper leaves were removed from the cabbage heads, which were then washed and cooked as in normal household practice. The outer 3 to 4 leaves were removed and discarded (because there was apparent pest infestation) until a tight head (similar to those sold in the grocery store) was obtained. The heads were rinsed under a stream of cool to lukewarm tap water for 30 sec and allowed to dry for 2 min. The cabbage was cut into smaller pieces and the core and stem ends were removed. Leaves were trimmed if they were discoloured. The cabbage was cooked for 2 min uncovered in water, followed by 8 min of further cooking in the boiling water after covering the pot. The cabbage was strained, allowed to cool, and transferred into a plastic bag for frozen storage up to analysis.

Washing and cooking of broccoli

Bulk samples of broccoli, consisting of composites from at least 12 plants, were collected 2 days following the last application.

To generate washed broccoli, the leaves were removed and discarded but stalks were not trimmed. The heads were rinsed under a stream of cool to lukewarm tap water for 30 sec and allowed to dry for 2 min.

To generate cooked broccoli, the broccoli was trimmed to florets (approximately 15 mm), discarding the stalks. The florets were rinsed under a stream of cool to lukewarm tap water for 30 sec and allowed to dry for 2 min. The florets were then cooked for 8 min uncovered. The florets were strained, allowed to cool, and transferred into a plastic bag for frozen storage up to analysis.

Cooking of peppers

Bulk samples of peppers, consisting of at least 36 fruit from at least 12 plants, were collected 2 days following the last application.

To generate washed peppers, the stem, husk, core and seeds were removed and discarded. The fruit were quartered and rinsed under a stream of cool to lukewarm tap water for 30 sec and allowed to dry for 2 min. The pieces were transferred into a plastic bag for frozen storage.

To generate cooked peppers, the stem, husk, core and seeds were removed and discarded. The fruit were quartered and rinsed under a stream of cool to lukewarm tap water for 30 sec and allowed to dry for 2 min, and cut into strips of approximately 5 mm width. The strips of pepper were cooked in boiling water for 6 to 7 min. The strips were strained, allowed to cool, and transferred into a plastic bag for frozen storage up to analysis.

Cooking of mustard greens

Bulk samples of mustard greens (at least 4 kg, from at least 12 plants) were collected at BBCH 19, 2 days following the last application.

To generate washed mustard greens, the leaves were rinsed in cool to lukewarm tap water in a sink for 30 sec, agitating by hand to ensure that all leaf surfaces were rinsed. The water was drained from the sink, and the rinsing procedure repeated twice more. The leaves were allowed to drain for 2 minutes. The leaves were transferred into a plastic bag for frozen storage.

To generate cooked mustard greens, the leaves were rinsed in cool to lukewarm tap water in a sink for 30 sec, agitating by hand to ensure that all leaf surfaces were rinsed. The water was drained from the sink, and the rinsing procedure repeated twice more. The drained leaves were placed into a pan containing sufficient boiling water to entirely cover the sample, and cooked, covered, with occasional stirring. After 9 minutes cooking, the contents of the pan were strained, allowed to cool, and transferred into a plastic bag for frozen storage.

Cooking of spinach

Bulk samples of spinach were collected 2 days following the last application.

To generate washed spinach, the leaves were washed in a sink and dried in a salad spinner. The leaves were transferred into a plastic bag for frozen storage.

To generate cooked spinach, the leaves were washed in a sink and dried in a salad spinner. The samples were then cooked for 5 minutes and strained, before being allowed to cool and transferred into a plastic bag for frozen storage.

Table 93 Residues of fenamidone in vegetables after cooking

RAC/processed commodity	Residues, mg/kg			Processing Factor (Sum)	Reference

RESIDUES IN ANIMAL COMMODITIES

Farm animal feeding studies

Dairy Cattle

One cattle feeding study was conducted (00W25043, M-238835-01-1). Nine lactating Holstein dairy cows were divided into three groups. Animals were treated once daily with gelatine capsules by oral bolus containing fenamidone for 35 consecutive days. One cow was maintained as control. The first group received an amount of fenamidone equivalent to 0.8 ppm, the second was fed 2.4 ppm, and the last group received 8 ppm in the diet. All cows were sacrificed after 35 days of dosing.

Milk samples from study days 18 through 35, the period when residue levels would be at their maximum, were analysed in 29 days or less. Milk samples from the last collection period were analysed 8 days after collection. All tissue samples were analysed within 29 days of collection. Therefore, storage stability data are not necessary.

Milk samples were collected twice daily and composites prepared from the p.m. milks of one day and the a.m. milks of the following day. All samples were frozen at -20°C before analysis. Milk samples from study days 18 to 35, the period when residue levels would be at their maximum, were analysed within 29 days of sampling, milk samples from the last collection period were analysed within 8 days of collection. Following oral administration to lactating cows for 35 consecutive days, at all sampling intervals, no residues of fenamidone or the two major metabolites desanilino-diketo-fenamidone (RPA 412636) and desanilino-fenamidone (RPA 412708) were found in any of the whole milk samples (see Table 96). The LOQ for fenamidone and each of its metabolites in milk is 0.01 mg/kg. The limit of detection (LOD) is 1/3 the LOQ or 0.003 mg/kg.

Table 96 Residues in whole milk following 35 days oral administration of fenamidone to dairy cows

Day	Residues, mg/kg (mean of 3 cows)					
	Control			High dose (8 ppm in the diet)		
	Fenamidone	RPA 412636	RPA 412708	Fenamidone	RPA 412636	RPA 412708
-1	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003
1	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003
4	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003
8	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003
11	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003
15	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003
18	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003
25	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003
28	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003
34	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003	< 0.003

A portion of the day-34 milk from all groups was centrifuged to separate the milk fat for analysis. Analysis of milk samples from the 8 ppm dose group resulted in fenamidone residues below the LOQ (0.01 mg/kg) in every case. Therefore, milk fat samples from the lower dose groups were not prepared.

Samples of liver, kidney, muscle and fat were collected immediately after sacrifice and frozen at -20°C until analysis. All tissue samples were analysed for fenamidone and the two major metabolites within 29 days of collection. At all sampling intervals, no residues of fenamidone or the two major metabolites were found in any of the tissue or milk fat samples, with the exception of a residue of desanilino-fenamidone (RPA 412708) detected in one milk fat sample in the highest dose group (0.011 mg/kg). Analysis of tissue and milk fat samples from the 8 ppm dose group resulted in fenamidone residues generally below the LOQ (0.05 mg/kg), therefore, tissue samples from the lower dose groups were not analysed. A summary of the results is presented in Table 97.

Table 97 Mean residues in tissues and milk fat following 35 days oral administration to dairy cows

Compound	Residues in mg/kg of 3 cows dosed with 8 ppm in the diet for 35 days

APPRAISAL

Fenamidone is a broad-spectrum fungicide belonging to the imidazolinone group. The compound was evaluated the first time by the 2013 JMPR for toxicology where an ADI of 0–0.03 mg/kg bw and an ARfD of 1 mg/kg bw was allocated. The evaluation for residues was scheduled for the 2014 JMPR.

The current Meeting received information on physical and chemical properties, metabolism studies on animals and plants, environmental fate including rotational crops data, analytical methods, use pattern, supervised trials data, processing and feeding studies.

The active substance fenamidone is the S-enantiomer of a stereoisomeric molecule with the chiral centre in the 5-position of the dihydro-imidazolone ring. This S-enantiomer has been shown to be the biologically (fungicidally) active enantiomer.

The chiral carbon atom on the 5-position of the dihydro-imidazolone ring is substituted by 4 non-hydrogen substituents, namely substituted by an amino, carbonyl, methyl and phenyl group. Prerequisite for isomerisation/racemisation of this type of centre of chirality is the presence of a hydrogen atom as a substituent that can be split off easily. In fenamidone, no hydrogen is linked to the chirality centre. Therefore, racemisation is chemically not possible and the configuration and the optical purity, respectively, established by synthesis does not change afterwards. There was also no evidence of enantiomerization or racemization of the parent substance and its metabolites during metabolic conversions in plants and animals or physical-chemical degradation in soil and water.

In this document, the code names of the S-enantiomers were used of the metabolites identified:

Name, Structure, IUPAC name, CAS name, [CAS number]	Mol. formula, molar mass Other names / codes	Occurrence, Compartment

Animal metabolism

Metabolism studies on rats reviewed by the 2013 JMPR show that fenamidone undergoes extensive metabolism in the rat by phase I (oxidation, reduction and hydrolysis) and phase II reactions (conjugation). The plasma elimination half-life was at least 60 hours. More than 20 metabolites were detected in rat excreta, with the majority of radioactivity excreted in the faeces (up to approximately 90% of the administered dose) and the remainder in urine. Mass balance data indicated that the majority of radioactivity (> 80%) was eliminated within 48 hours of dosing. The metabolites RPA 412636 and RPA 412708 were present in rat urine and rat bile, respectively.

Metabolism studies have been conducted in lactating goats. Two dose levels were used for each label position: 1 ppm and 10.4 ppm in the diet for [C-phenyl-U-¹⁴C]-fenamidone and 1.5 ppm and 11.5 ppm in the diet for [N-phenyl-U-¹⁴C]-fenamidone. Dosing was performed twice daily by capsule during seven consecutive days. The total administered radioactivity (TAR) was quickly and almost completely eliminated in the excreta. In case of the C-phenyl label, the total excreted residues were 99–102% of TAR (75–80% via faeces, 17–26% via urine, 0.1% via milk). In case of the N-

phenyl label, the total excreted residues were ca. 90% of TAR (45–52% via faeces, 36–40% via urine, 0.1–0.2% via milk). Neither fenamidone nor any of its metabolites accumulated in milk fat or milk proteins. At sacrifice, small amounts of radioactivity (totally 0.6 to 1.0% of TAR) were detected in edible organs/tissues and blood.

Residues in milk and edible tissues of goats were low. RPA 412708 and RPA 412636 were found, as well as hydroxylated fenamidone and hydroxylated RPA 412708. RPA 412636 was the most abundant residue in the goat, reaching after high dose administration 0.055 mg/kg (5.9% TRR) in liver, 0.018 mg/kg (15% TRR) in kidney and 0.002 mg/kg in milk (11% TRR). Fenamidone was identified in fat with 0.013 mg/kg (53% TRR), but was a minor component in milk (0.001 mg/kg, 0.7% TRR), liver (0.003 mg/kg, 0.3% TRR) and kidney (0.001 mg/kg, 0.6% TRR).

Metabolism studies have been conducted in laying hens. Two dose levels were used for each label position: 1.3 ppm and 13.8 ppm in the diet for [C-phenyl-U-¹⁴C]-fenamidone and 1.0 ppm and 9.8 ppm in the diet for [N-phenyl-U-¹⁴C]-fenamidone. Dosing was performed by administration of one capsule per day during fourteen consecutive days. The TAR was quickly and almost completely eliminated in excreta. The recovery of radioactivity was > 91% of the TAR. The majority of the radioactivity was in excreta (approximately 90% TAR). All of the eggs together contained 0.1% of the dose administered, most of which was retained in the yolk. At sacrifice, at both dose levels and in both labels, very minor amounts of radioactivity (0.1% of TAR) were detected in edible organs/tissues and blood.

Residues in eggs and edible tissues of hens were low. RPA 412636 was a major component in the hen, found at 0.011 mg/kg (74% TRR) in egg white, 0.014 mg/kg in egg yolk (11% TRR), 0.023 mg/kg (15% TRR) in liver and 0.002 mg/kg (16% TRR) in skin after high dose administration. RPA 412708 was the highest residue in the hen, reaching 0.028 mg/kg (25% TRR) in egg yolk but only 0.002 mg/kg (1.3% TRR) in liver. Fenamidone was identified, but was a minor component (egg yolk 0.014 mg/kg, 11% TRR; liver 0.003 mg/kg, 1.7% TRR; fat < 0.001 mg/kg, 4.6% TRR and skin 0.002 mg/kg, 14% TRR).

The Meeting concluded that, in all species investigated, the TAR was quickly and almost completely eliminated in excreta. The metabolic profiles differ quantitatively between the species, but qualitatively there are no major differences; the routes and products of metabolism in animals were consistent across the studies. Fenamidone, RPA 412708 (desanilino-fenamidone) and RPA 412636 (desanilino-diketo-fenamidone) were the components identified.

Plant metabolism

The metabolism of fenamidone has been studied in grapes, tomatoes, lettuce, carrots and potatoes.

Grapes

Following four foliar treatments of [C-phenyl-U-¹⁴C]-fenamidone to a total nominal rate of the equivalent of 1.65 kg ai/ha (0.5, 0.49, 0.5 and 0.16 kg ai/ha) to field grown grape vines during the grape berry development period, the terminal residue in the mature harvest grape bunches (1.2 mg eq/kg) was shown to comprise mainly parent compound (56% TRR) and RPA 410193 (17% TRR). The interval between the last application and harvest was 24 days. The major part of the radioactivity associated with the grape bunches could be extracted by methanol/water and represented 89% of the TRR. The non-extracted radioactivity was confined mainly to the stem, skin and pips. Further extraction procedures were made including enzyme treatment followed by acid and alkali hydrolysis (100% TRR).

The metabolism of fenamidone in grapes was characterised by the formation of RPA 410193, i.e. loss of the thiomethyl group and formation of an imidazolidinedione. Some evidence was obtained to suggest that hydroxylation of parent compound (3.4% TRR) as well of RPA 410193 (4.2% TRR) also occurred. A number of other metabolites were detected, albeit polar and at very low levels.

Tomatoes

The metabolism was investigated following three foliar applications of [^{14}C]-fenamidone, each of 0.5 kg ai/ha giving a total nominal application rate of 1.5 kg ai/ha on glasshouse grown tomatoes. Both labels, C-phenyl and N-phenyl, were used separately. At final harvest, 7 days after the last treatment, the TRR in tomato fruits was less than 0.2 mg eq/kg for both labels. About 90% of the TRR was extracted and more than 75% identified.

The major component of the extracted radioactivity in both treatment regimes was unchanged parent accounting for 66–76% TRR. The next largest component was RPA 410193 accounting for 9.3–9.4% TRR. No metabolites were formed at significant levels as a result of cleavage of the two phenyl-rings.

Lettuce

The metabolism was investigated following four foliar applications of [^{14}C]-fenamidone, each of a nominal rate of 0.4 kg ai/ha on outdoor grown iceberg lettuce. Both labels, C-phenyl and N-phenyl, were used separately. At final harvest, 7 days after the last treatment, a total of 93% and 92% of the TRR for the C-phenyl-label and N-phenyl-label treated final harvest lettuces respectively, was identified. The TRR found in the lettuce wrapper leaves (12 mg eq/kg) were significantly higher than that present in the lettuce heads (0.2–0.3 mg eq/kg).

Analysis of the extracted radioactive residues showed the major components of both labels to be parent fenamidone (about 92% TRR in whole lettuce). The remaining extracted radioactivity was comprised of RPA 410193 (0.59–0.66% TRR) and multiple unidentified polar components, which comprised less than 3% TRR in total in whole lettuce. In addition, low levels of RPA 412636 (2.7% TRR) were present in the C-phenyl-label treated lettuce head leaves extracts only.

Potatoes

The metabolism was investigated following three foliar applications of [^{14}C]-fenamidone, each of nominal 0.5 kg ai/ha on outdoor grown potatoes. Both labels, C-phenyl and N-phenyl, were used separately. At final harvest, 14 days after the last treatment, the TRR in the tubers (0.038–0.087 mg eq/kg) was significantly lower than the levels detected in the leafy part of the plant (5.9–6.6 mg eq/kg) with 1.3% of the whole plant TRR being present in the root/tuber. A total of 73% TRR of the intact potato tubers and 77% TRR of the potato haulm could be extracted for C-phenyl-fenamidone treated plants at final harvest. The corresponding values for N-phenyl-fenamidone treated potatoes were 46% and 78% for intact potato tubers and potato haulm respectively.

In potato tubers, parent fenamidone accounted for 2.3 to 6% of TRR (0.002 mg/kg) and two further metabolites were formed: RPA 412708 (desanilino-fenamidone) and RPA 412636 (desanilino-diketo-fenamidone), each accounting for ca. 6% of TRR with low absolute concentrations (0.005–0.006 mg eq/kg). A large portion of the residue was polar in nature and reported to be composed by acid labile conjugates.

Carrots

The metabolism was investigated following three applications of [N-phenyl- ^{14}C]-fenamidone, each of nominal 0.3 kg ai/ha on outdoor grown carrots. The first application was made pre-emergence followed by two foliar applications. At final harvest, 14 days after the last treatment, the TRR in leaves and roots amounted to 30.5 and 0.04 mg eq/kg, respectively. Therefore, basispetal transport of residues from the treated leaves to the roots was very limited. In leaves, 81% of the radioactivity could be extracted with acetonitrile/water using a high-speed blender and the rest by water/dichloromethane partition. In roots, 93% of the radioactivity was extracted with acetonitrile/water.

Fenamidone accounted in leaves for 89% of the TRR and in roots for 29% of the TRR. Six minor metabolites were identified. No metabolite in the roots exceeded a level of 0.01 mg/kg. Two parallel metabolic reactions were found and a combination thereof. The first reaction was an oxidative hydrolysis of the thiomethyl group at the dihydro imidazole ring to a keto substituent resulting in RPA 410193 (diketo-fenamidone). Another reaction was the nitration of the N-phenyl ring. All metabolites

contained the intact basic structure with the two phenyl rings and the imidazole ring. No cleavage product, such as aniline, aminophenols or nitroanilines was detected. In addition, radiolabelled glucose was found in the leaves resulting from complete mineralization of the fenamidone in the soil and photosynthetic uptake of the formed $^{14}\text{CO}_2$ in the plant. Small amounts of a dimer of fenamidone (0.17% of TRR, 0.05 mg/kg) were also detected in leaves.

In summary, the metabolism of fenamidone in plants after foliar application was investigated in three crop categories: fruits and fruiting vegetables, leafy vegetables, root and tuber vegetables. The metabolic pattern was shown to be similar in all these crop groups with the unchanged parent compound being the main compound of the final residue at harvest. The Meeting concluded that after foliar treatment the only significant metabolite in plants was RPA 410193 (diketo-fenamidone), formed by oxidative hydrolysis of the thiomethyl side chain of fenamidone.

Environmental fate

For fenamidone, data were received for foliar spray on permanent crops and on annual crops. A further application is on cotton seed as in furrow treatment. Therefore, according to the FAO manual, studies on the aerobic degradation in soil, photolysis, hydrolysis, rotational crops (confined, field) and field dissipation were evaluated. The fate and behaviour of fenamidone in soils was investigated using fenamidone radio-labelled in two different positions, [C-phenyl- $\text{U-}^{14}\text{C}$]- and [N-phenyl- $\text{U-}^{14}\text{C}$]-fenamidone.

Degradation in soil, photolysis and hydrolysis

Degradation of fenamidone in soil primarily proceeds by the action of aerobic soil microorganisms. In the first major pathway there is loss of the N-phenyl aniline ring to form RPA 412708, followed by loss of the S-methyl moiety and hydrolysis to form RPA 412636. Two further pathways are the concurrent formation of 2- and 4-nitro compounds by addition to parent to form RPA 413255 and RPA 411639. A further route of degradation results in the formation of numerous minor non-polar components. The rate of degradation tested in silty clay loam, sandy loam and in clay loam, is similar in both C-phenyl and N-phenyl rings with DT50s ranging from 0.9 to 9.6 days in all tested soils at 20 °C. The Meeting concluded that fenamidone was rapidly degraded in soil under aerobic conditions leading to the formation of two major metabolites RPA 412708 and RPA 412636.

Field dissipation studies undertaken at four European sites showed that the average half-lives were 5 days for fenamidone, 12 days for RPA 412708, 21 days for RPA 411639, 43 days for RPA 413255 and 47 days for RPA 412636. It can be concluded that the dissipation of fenamidone was rapid in the field.

The photolytic degradation of fenamidone was investigated on a sandy loam soil for 30 days. Artificial sunlight was provided using an artificial xenon light source for 13 hours each day. The Meeting recognized that photolytic processes do not contribute significantly to the degradation of fenamidone applied to the soil surface.

The hydrolytic degradation of fenamidone was examined in aqueous buffered solutions at pH values of 4, 5, 7 and 9 under sterile conditions at 25 °C. The Meeting recognized that fenamidone was stable at pH 5 and pH 7, but was hydrolysed at pH 4 and pH 9.

Rotational crops

One confined radiolabelled succeeding crop study was conducted in 2001 with [C-phenyl- $\text{U-}^{14}\text{C}$]-fenamidone. Following application to the soil at an application rate of 1.6–2.0 kg ai/ha, lettuce, turnip and barley were cultivated after three plant back intervals (30, 120/150 and 365 days). The residues in rotated plants comprised the following major metabolites: RPA 412636 and RPA 412708 and a conjugate thereof. The parent substance could not be detected. Residues of RPA 412636 were in lettuce ca. 20% of TRR at each plant back intervals, in turnip tops 3.5–11% of TRR, in turnip roots 5–8% of TRR and in barley grain 2–6% of TRR. The highest residues of RPA 412636 were found in barley straw with 2.04 mg/kg (29% TRR). RPA 412708 was found in lettuce at a maximum of 5.7% of TRR (0.04 mg/kg).

Two additional confined radiolabelled succeeding crop studies were carried out in 2013. Following application of 0.96 kg ai/ha [N-phenyl-U-¹⁴C]-fenamidone and 0.97 kg ai/ha [C-phenyl-U-¹⁴C]-fenamidone to the soil, wheat, turnip and Swiss chard were sown and cultivated at three plant back intervals (30, 191 and 324 days after soil treatment). Both labelled forms of fenamidone were rapidly degraded in soil with extensive uptake of the metabolites into the plants. The parent compound was only detected in Swiss chard at 30 days plant back interval, however at a low level amounting to a maximum of 0.002 mg/kg (0.2% of TRR). It was not detected in other crops. The pathway is proposed as follows: Electrophilic nitration of the aniline ring formed fenamidone-2-nitro and fenamidone-4-nitro, most probably in the soil, with RPA 413255 (fenamidone-2-nitro) being further converted to RPA 221701 (fenamidone-desthiomethyl-2-nitro) following nucleophilic substitution and the addition of water. Conjugation with hexose and malonic acid and hydroxylation lead to the formation of fenamidone-hydroxy-nitro-malonyl-glycoside. Further conjugation with glutathione and nucleophilic substitution of methyl mercaptan also lead to the formation of fenamidone-nitro-GSH. In addition to these metabolites, the C-phenyl-labelled compound underwent further degradation of the aniline moiety of fenamidone-desthiomethyl-2-nitro to RPA 412636, again, most likely in the soil. Conjugation of RPA 412636 with glucose, hexose plus malonic acid and serine formed fenamidone-hydantoin-glucoside and fenamidone-hydantoin-serine.

The Meeting concluded that parent fenamidone is quickly degraded in soil or in the follow-on crops, not resulting in residues detected at harvest. Residues of RPA 412636, RPA 412708 and conjugates thereof were the major metabolites in commodities used as animal feed and can also occur in the edible parts of rotational crops.

Seven field succeeding crop studies were conducted, one in Europe and six in the USA. Spray applications near GAP were made to bare soil to simulate a treatment of target crops like potatoes, leafy vegetables or fruiting vegetables. Rotational crops were cereals (wheat, maize), fruiting vegetables (sweet corn) root and tuber vegetables (turnip, radish), leafy vegetables (lettuce, spinach), pulses (soya bean, dry) and strawberries.

After application of 0.9–1.2 kg ai/ha per annum to the bare soil, in the follow-on crops no parent fenamidone or its plant metabolite RPA 410193 was found at or above the LOQ of 0.02 mg/kg.

In plant parts used as human food, RPA 412636 occurred up to maximum single values of 0.04 mg/kg in radish roots, 0.04 mg/kg in radish tops and 0.12 mg/kg in spinach. Residues of RPA 412636 in wheat grain were in 22 field trials < 0.02 mg/kg and in only one trial 0.061 mg/kg.

RPA 412708 and RPA 412636 occurred in commodities that may be used as animal feeds. The sum of RPA 412708 and RPA 412636 reached up to 0.14 mg/kg in soya bean hay, 0.29 mg/kg in sweet corn stover and 0.21 mg/kg in field corn forage; RPA 412636 occurred up to 0.07 mg/kg in wheat forage, 0.27 mg/kg in wheat straw and 0.45 mg/kg in wheat hay.

In conclusion, no residues of fenamidone and RPA 410193 above the LOQ of 0.02 mg/kg would be expected in follow-on crops but residues of the metabolites RPA 412708 and RPA 412636 taken up from the soil occurred in commodities that may be used as human food and animal feed.

Methods of analysis

The Meeting received descriptions and validation data for analytical methods for residues of fenamidone and its relevant metabolites RPA 410193, RPA 412708 and RPA 412636 in plant commodities and for fenamidone, RPA 412708 and RPA 412636 in animal commodities. Residue analytical methods rely on GC with NP-detection, GC-MS or LC-MS/MS. Typical LOQs achieved for plant commodities fall in the range of 0.01–0.02 mg/kg for each analyte. The LOQ for milk was 0.01 mg/kg and for animal products (liver, kidney, muscle, eggs) 0.05 mg/kg for each analyte. Methods have been subjected to independent laboratory validation.

Fenamidone and RPA 410193 were analysed in plant material by the multi method S 19 with an LOQ of 0.01 mg/kg by GC-MS. The QuEChERS multi residue method was used for fenamidone and RPA 410193 in plant matrices as well as for fenamidone and RPA 412708 and RPA 412636 in animal matrices with LOQs of 0.01 mg/kg by LC-MS/MS for each analyte.

Stability of residues in stored analytical samples

The Meeting received storage stability studies under freezer conditions at -20 °C for fenamidone, RPA 412636, RPA 412708 and RPA 410193 for the duration of the storage of 12 months in a wide range of raw and processed crop matrices, including examples of high-water and high-starch crops and for duration of 6 months for cotton products. Furthermore, studies were conducted for fenamidone and RPA 410193 in high-water content commodities for duration of 14 months and in strawberries of 18 months.

The Meeting concluded that residues of fenamidone and RPA 410193 are stable in commodities of high-water content for at least 14 months and in strawberries for at least 18 months. Residues of fenamidone, RPA 412636, RPA 412708 and RPA 410193 are also stable for at least 6 months in high-oil content products.

Because milk and tissue samples of the ruminant feeding study were analysed within 29 days of collection, no storage stability data were submitted.

Definition of the residue

Animal metabolism studies were performed in rats, lactating goats and laying hens. The metabolic behaviour of fenamidone in the rat is summarised by the 2013 JMPR and shows pathways and major components similar to those found in ruminants and poultry. RPA 412636 and RPA 412708 are found in the rat metabolism. RPA 410193, which is a plant metabolite, was not identified in the rat ADME studies. The 2013 Meeting considered the named metabolites as toxicological relevant.

The 2014 JMPR agreed that RPA 410193 is covered by the ADI of the parent fenamidone. The toxicological relevance of RPA 412636 and its precursor RPA 412708, both detected as RPA 412636, were confirmed. RPA 412636 was considered as 10 times more toxic than the parent.

Livestock metabolism studies in goat and hen showed no major differences; the routes and products of metabolism in animals are consistent across the studies. The residues in animal products were low. Fenamidone was identified, reaching 0.013 mg/kg in ruminant fat (53% TRR) and 0.014 mg/kg in egg yolk (11% TRR). RPA 412636 was the most abundant residue in the ruminant, reaching 0.055 mg/kg in liver (5.9% TRR) and 11% TRR in milk (0.002 mg/kg). RPA 412636 was also found in the hen, at 0.011 mg/kg (74% TRR) in egg white and 0.014 mg/kg in egg yolk (11% TRR). RPA 412708 was the most abundant residue in the hen, reaching 0.028 mg/kg in egg yolk and 0.002 mg/kg in liver (25 and 1.3% TRR, respectively).

The Meeting concluded that the residue definition for MRL-setting for animal products should be parent fenamidone. For dietary intake, the residue should be defined as the sum of fenamidone, RPA 412636 and RPA 412708, expressed as fenamidone. Due to the 10-fold higher toxicity, a factor of 10 should be applied.

Fenamidone has a log P_{OW} of 2.8. No residues of fenamidone, RPA 412636 and RPA 412708 could be determined in animal products from the cattle feeding study with the exception of one milk fat sample with 0.011 mg/kg of RPA 412708. In the high dose group of the goat metabolism study, the TRR in muscle were low (0.02 mg eq/kg) and could not further identified. Fenamidone was detected in the fat (53% TRR, 0.013 mg eq/kg). In the high dose group of the egg metabolism study, fenamidone was detected in the yolk (11% TRR, 0.014 mg/kg), but not in the egg white (< 0.001 mg/kg). The Meeting decided that the residue is fat-soluble.

Plant metabolism studies for foliar spray application to the plant provide a clear understanding of the fate of the fenamidone molecule, both the C-phenyl and N-phenyl portions. The overall metabolic pathway is consistent between the different crop groups. Fenamidone forms the largest part of the residue and the only significant metabolite is RPA 410193, which reached a maximum of 17% TRR in grape. RPA 412636 and RPA 412708 reached a maximum of 6.3% TRR (0.005 mg/kg) and 6.4% TRR (0.006 mg/kg) in potato tubers. No other metabolite exceeded 5% TRR in any plant commodity.

The Meeting took into account the possibility of residues of the metabolites RPA 412708 and RPA 412636 in follow-on crops used as human food and/or animal feed. The Meeting concluded to

include both metabolites in the residue definition for estimation of the dietary intake of plant commodities. Because of the 10-fold higher toxicity, a factor of 10 should be applied.

The Meeting agreed the following residue definitions:

- Definition of the residue for compliance with the MRL for plant and animal commodities: *Fenamidone*.
- Definition of the residue for estimation of dietary intake for plant commodities: Sum of fenamidone, (S)-5-methyl-5-phenyl-3-(phenylamino)-2,4-imidazolidine-dione (RPA 410193) plus $10 \times$ the sum of both (S)-5-methyl-5-phenyl-2,4-imidazolidine-dione (RPA 412636) and (5S)-5-methyl-2-(methylthio)-5-phenyl-3,5-dihydro-4H-imidazol-4-one (RPA 412708), all calculated as fenamidone.
- Residue concentration $C_{\text{total}} = C_{\text{fenamidone}} + C_{\text{RPA 410193}} + 10 \times (C_{\text{RPA 412636}} + C_{\text{RPA 412708}})$
- Definition of the residue for estimation of dietary intake for animal commodities: *Fenamidone plus $10 \times$ the sum of both (S)-5-methyl-5-phenyl-2,4-imidazolidine-dione (RPA 412636) and (5S)-5-methyl-2-(methylthio)-5-phenyl-3,5-dihydro-4H-imidazol-4-one (RPA 412708), all calculated as fenamidone.*
- Residue concentration $C_{\text{total}} = C_{\text{fenamidone}} + 10 \times (C_{\text{RPA 412636}} + C_{\text{RPA 412708}})$

The residue is fat-soluble.

Results of supervised residue trials on crops

The Meeting received supervised residue trials data for grapes, strawberries, leek, bulb onion, spring onion, cabbage, flowerhead brassica, melons, watermelons, cucumber, summer squash, peppers, tomato, lettuce, mustard greens, spinach, carrots, potato, ginseng, Witloof chicory, celery, cotton seed, sunflower seed, common bean forage and cotton fodder. If two field samples were taken or results of two replicate plots were submitted, the mean value was calculated for estimation of maximum residue levels. For HR estimation, the highest single value of the trials according to GAP was used. From two or more trials carried out side-by-side the higher residue was chosen.

Residues are reported separately for fenamidone and RPA 410193 only because the soil metabolites RPA 412636 and RPA 412708 are not relevant for foliar treated crops. For HR and STMR estimation, the sum of fenamidone (MW 311.4 g/mol) and RPA 410193 (MW 281.3 g/mol), expressed as fenamidone (conversion factor 1.11), is needed. When residues are undetectable in a commodity, the sum of the LOQs of both components is not appropriate for all plant commodities because the days after the last treatment (DALT) differ from 2 days (e. g. lettuce) to 35 days (strawberry). The residues of RPA 410193 are found in the same order of magnitude as the parent in berries harvested 4 to 5 weeks after treatment. In other plant commodities harvested at shorter PHIs (2–21 days), the level of the metabolite is much lower than the parent in most cases. The method for calculation of the total residues of the sum of fenamidone and RPA 410193 is illustrated as follows:

- Plant commodities except grapes and strawberries

Fenamidone, mg/kg	RPA 410193, mg/kg	Total, mg/kg
< 0.02	< 0.02	< 0.02
0.05	< 0.02	0.05
0.42	0.08	0.51 ^a

Trials from the USA or Canada on carrots, potatoes, fruiting—brassica, leafy and legume—as well as stalk and stem vegetables were performed with four instead of three applications and trials on bulb vegetables as well as cucurbits were performed with six instead of four applications. The Meeting accepted the trials as matching the GAP in the USA and Canada since comparative residue trials on grapes and tomatoes as well as decline studies on vegetables indicated that the contribution of two earlier applications to the terminal residue is negligible. The Meeting agreed to use the trials to estimate maximum residue levels.

Rotational crop maximum residue levels, STMRs and HRs

The Meeting noted that no residues of parent fenamidone above the LOQ of 0.02 mg/kg are expected in follow-on crops. It was concluded that the estimation of maximum residue levels is not necessary.

The Meeting recognized that, in commodities used as human food, RPA 412636 were found. The table below shows the highest and the mean residues of two plots found in follow crops as spinach, radish roots and leaves as well as wheat grain after treatment of vegetables with fenamidone at 1.2 kg ai/ha per annum. The Meeting agreed to use the proportionality approach and scaled the residues according to the US GAP of 0.9 kg ai/ha per annum for brassica vegetables, fruiting vegetables, leafy vegetables, root and tuber vegetables and celery. The values measured as RPA 412636 (MW 190.2 g/mol) were expressed as fenamidone (MW 311.4 g/mol) multiplying by 1.64.

Treatment, kg ai/ha	Commodity	RPA 412636, highest residue, mg/kg			RPA 412636, mean residue, mg/kg		
		Measured	Scaled	Calculated as fenamidone eq	Measured	Scaled	Calculated as fenamidone eq
6× 0.2	Spinach	0.12	0.09	0.15	0.096	0.072	0.12
	Radish tops	0.044	0.033	0.054	0.033	0.0275	0.045
	Radish roots	0.039	0.029	0.048	0.03	0.0225	0.037
	Wheat grain	0.061	0.046	0.075			
1× 0.2	Wheat grain				< 0.02		< 0.033 (n = 22)

The Meeting concluded that the contribution of residues of RPA 412636 and RPA 412708 has to be considered for the STMR and HR estimation for annual crops like vegetables and cereals. A factor of 10 is used because of the 10-fold higher toxicity compared to parent.

For brassica vegetables, fruiting vegetables, leafy vegetables, fresh herbs as well as stalk and stem vegetables, the Meeting estimated a rotational crop STMR of 1.2 mg/kg and a rotational crop HR of 1.5 mg/kg, based on the residues analysed in spinach.

For bulb vegetables, root and tuber vegetables as well as their leaves/greens the Meeting estimated a rotational crop STMR of 0.4 mg/kg and an HR of 0.5 mg/kg, respectively.

For cereal grains, residues of RPA 412636 + RPA 412708 were in wheat of 22 field trials as well as of nine trials in maize < 0.033 mg eq/kg and in only one trial 0.075 mg eq/kg. The Meeting agreed to estimate an STMR of 0.33 mg/kg (10 times LOQ) for cereal grains except rice as follow-on crops.

No residues of RPA 412636 or RPA 412708 higher than the LOQ of 0.02 mg/kg occurred in strawberries, sweet corn kernels and soya bean seed grown as follow-on crops. The Meeting concluded that the uptake of substantial concentrations of RPA 412636 or RPA 412708 by strawberry, sweet corn, oil seeds and pulses is negligible. No STMR or HR was recommended.

Grapes

The GAP for fenamidone in Brazil on grapes is foliar spray treatment with 3×0.13 kg ai/ha and a PHI of 7 days. Three Brazilian trials matching the GAP were submitted. The residues in grape bunches were for parent fenamidone 0.02, 0.03, 0.03 mg/kg and for the sum of fenamidone and RPA 410193 0.04, 0.05, 0.05 mg/kg.

Fenamidone is registered for foliar spray treatment on grapes in the Czech Republic with application at 3×0.13 kg ai/ha and a PHI of 28 days. Sixteen European trials according to GAP were conducted in 2009 and 2010 in Belgium, France, Germany, Italy, Portugal and Spain. The residues in grape bunches were for fenamidone ($n = 16$) 0.04, 0.06, 0.08, 0.09, 0.09, 0.10, 0.13, 0.13, 0.17, 0.21, 0.22, 0.22, 0.26, 0.28, 0.30 and 0.33 mg/kg. The total residues (sum of fenamidone and RPA 410193) were 0.06, 0.09, 0.09, 0.11, 0.12, 0.13, 0.15, 0.16, 0.19, 0.25, 0.25, 0.25, 0.34, 0.34, 0.35 and 0.42 mg/kg.

Based on the European residue data, the Meeting estimated a maximum residue level of 0.6 mg/kg, an STMR of 0.175 mg/kg and an HR of 0.42 mg/kg for fenamidone residues in grapes.

Strawberry

The UK GAP for fenamidone in strawberries is one pre-transplantation treatment (0.18 kg ai/ha) followed by one post-transplantation drench or spray (0.27 kg ai/ha) and a PHI of 35 days.

Eight supervised residue trials were carried out in 2009 and 2012 in Europe in greenhouses. The plants were treated by a drip-irrigation with 0.16–0.18 kg ai/ha followed after 21/22 days by a foliar spray of 0.27 kg ai/ha. The residues were for parent fenamidone < 0.01, < 0.01, 0.01, 0.01, 0.01, 0.02, 0.02, 0.02 mg/kg and for the sum of fenamidone and RPA 410193 < 0.02, < 0.02, 0.02, 0.02, 0.02, 0.02, 0.03, 0.03, 0.03 mg/kg.

Fenamidone is registered in Belgium in protected strawberries with two drench treatments of 0.45 kg ai/ha and a PHI of 35 days. Seven trials according to Belgium GAP were conducted in 2010/2011. The residues were for parent fenamidone < 0.01 (3), 0.01, 0.02 (3) mg/kg and for the sum of fenamidone and RPA 410193 < 0.02, < 0.02, 0.02, 0.02, 0.03, 0.03, 0.04 mg/kg.

The Meeting agreed to use the data set according to the Belgium GAP and estimated a maximum residue level of 0.04 mg/kg, an STMR of 0.02 mg/kg and an HR of 0.04 mg/kg for fenamidone residues in strawberries.

Bulb vegetables

Fenamidone is registered for bulb vegetables in the USA and Canada with foliar application at 4×0.2 kg ai/ha and a PHI of 7 days. Field trials on bulb onion (8) and spring onion (4) were carried out in the USA. At each trial, six instead four spray applications of 0.2 kg ai/ha were made. The following residue data were received.

In bulb onion, the fenamidone residues as well as total residues (sum of fenamidone and RPA 410193) were < 0.02 (6), 0.02 and 0.10 mg/kg. The Meeting recognized that one duplicate field sample gave higher residues than the HR based on the mean residues and decided to use this value of 0.13 mg/kg as HR for the short-term dietary intake assessment instead. The Meeting agreed to extrapolate the residue data from bulb onions to garlic and shallots. Furthermore, the contribution in follow-on crops of 0.4 mg/kg has to be added to the STMR and 0.5 mg/kg to the HR.

The Meeting estimated a maximum residue level, an STMR and an HR of 0.15 mg/kg, 0.42 mg/kg and 0.63 mg/kg, respectively, for bulb onion, garlic and shallots.

In spring onion, the fenamidone residues were 0.24, 0.36, 0.94 and 0.94 mg/kg. The corresponding total residues were 0.24, 0.36, 0.94 and 1.1 mg/kg. The Meeting recognized that one duplicate field sample gave higher residues than the HR based on the mean residues and decided to use this value of 1.2 mg/kg as HR for the short-term dietary intake assessment instead. The Meeting agreed to extrapolate the residue data from spring onion to welsh onion. Furthermore, the contribution in follow-on crops of 0.4 mg/kg has to be added to the STMR and 0.5 mg/kg to the HR.

The Meeting estimated a maximum residue level, an STMR and an HR of 3 mg/kg, 1.05 mg/kg and 1.7 mg/kg, respectively, for spring onion and Welsh onion.

The GAP for leek in Switzerland is 3×0.15 kg ai/ha and a PHI of 14 days. Four supervised residue trials (France 1, Germany 2 and the Netherlands 1) with 4×0.15 kg ai/ha were submitted. At a PHI of 14 days, the residues of fenamidone as well as of the sum of fenamidone and RPA 410193 were 0.02, 0.05, 0.07 and 0.13 mg/kg. Furthermore, the contribution in follow-on crops of 0.4 mg/kg has to be added to the STMR and 0.5 mg/kg to the HR.

The Meeting considered four trials on leek as sufficient and estimated a maximum residue level, an STMR and an HR of 0.3 mg/kg, 0.46 mg/kg and 0.63 mg/kg, respectively.

Brassica vegetables

Head cabbage

Fenamidone is registered in Switzerland in head cabbages as foliar spray with 3×0.15 kg ai/ha and a PHI of 14 days. Seven European trials (France 2, Germany 4 and Portugal 1) according to the Swiss GAP were submitted. The residues of fenamidone as well as the sum of fenamidone and RPA 410193 were < 0.01 (4), 0.01, 0.02 and 0.06 mg/kg.

The GAP for Brassica vegetables in Canada and the USA is 3×0.3 kg ai/ha and a PHI of 2 days. Six trials were conducted in 2003 in the USA with 4×0.3 kg ai/ha and a PHI of 2 days. In all trials, heads with wrapper leaves were analysed. The residues were for parent fenamidone 0.10, 0.17, 0.22, 0.24, 0.35 and 0.52 mg/kg in cabbage heads with wrapper leaves. Residue data for heads without wrapper leaves were available from four of the six trials. The fenamidone residues as well as the total residues were < 0.02, < 0.02, 0.03 and 0.19 mg/kg.

The Meeting agreed to use the US residue data on cabbage heads with wrapper leaves for MRL estimation and without wrapper leaves for dietary intake purposes. Furthermore, the contribution in follow-on crops of 1.2 mg/kg has to be added to the STMR and 1.5 mg/kg to the HR.

The Meeting estimated a maximum residue level of 0.9 mg/kg, an STMR of 1.23 mg/kg and an HR of 1.69 mg/kg.

For livestock dietary burden calculation, the Meeting estimated a median residue of 0.22 mg/kg and a highest residues of 0.52 mg/kg based on the fenamidone data for head cabbage with wrapper leaves.

Flowerhead brassica

The GAP for Brassica vegetables in Canada and the USA is 3×0.3 kg ai/ha and a PHI of 2 days. Six trials were conducted in 2003 on broccoli in the USA with 4×0.3 kg ai/ha and a PHI of 2 days. The mean residues of two separate field samples were for parent fenamidone as well as the total residues 0.31, 0.51, 0.68, 1.5, 1.6 and 2.2 mg/kg.

The Meeting recognized that one duplicate field sample gave higher residues than the HR based on the mean residues and decided to use this value of 2.7 mg/kg as HR for the short-term dietary intake assessment instead. Furthermore, the contribution in follow-on crops of 1.2 mg/kg has to be added to the STMR and 1.5 mg/kg to the HR.

The Meeting estimated for fenamidone residues in flowerhead brassica a maximum residue level, an STMR and HR of 4 mg/kg, 2.29 mg/kg and 4.2 mg/kg, respectively.

Fruiting vegetables, cucurbits

The GAP for cucurbits in Canada and the USA is 4×0.2 kg ai/ha and a PHI of 14 days. Field trials on cucumber (9), summer squash (9) and cantaloupe melons (8) were carried out during 1999 in the USA. At each trial, six spray applications in the range of 0.19–0.21 kg ai/ha were made at intervals of 3–6 days. The following residue data were received:

- In cucumber, the residues of fenamidone as well as the total residues were < 0.02 (7), 0.02 and 0.04 mg/kg.
- In summer squash, the residues of fenamidone as well as the total residues were < 0.02 (8) and 0.06 mg/kg.
- In cantaloupe melon, the residues for fenamidone as well as the total residues were in whole fruits < 0.02, 0.02, 0.04, 0.06, 0.07, 0.08, 0.08 and 0.09 mg/kg. No data were submitted for the edible part.

The Brazilian GAP for the use of fenamidone in watermelon is 3×0.15 kg ai/ha and a PHI of 7 days. Three trials on watermelons were conducted in 2004 in Brazil. The residues were in whole fruits for fenamidone as well as the sum of fenamidone and RPA 410193 were 0.03, 0.04 and 0.05 mg/kg. No residue data for pulp were submitted.

Fenamidone is registered in Switzerland for cucumbers, pumpkins, melons, courgettes, patisson and rondini with three foliar spray treatments of 0.15 kg ai/ha and a PHI of 3 days. Trials on cucumber (9 indoor) and on melons (8 indoor, 8 outdoor) carried out between 2002 and 2005 in European countries according to the GAP were submitted. The following residue data were received:

- In indoor grown cucumber, the residues of fenamidone as well as the total residues were < 0.01, < 0.02, 0.04, 0.04, 0.09, 0.10, 0.10, 0.12 and 0.13 mg/kg.
- In outdoor grown melons, the residues of fenamidone in whole fruits were < 0.02, 0.03, 0.03, 0.04, 0.04, 0.05, 0.08 and 0.12 mg/kg
- In indoor grown melons, the residues of fenamidone in whole fruits were < 0.02, < 0.02, < 0.02, 0.03, 0.04, 0.07, 0.07 and 0.09 mg/kg.
- The corresponding residues of the sum of fenamidone and RPA 410193 in melon pulp were < 0.01 (6) and < 0.02 (10).

The Meeting concluded that the maximum residue level should be based on the critical Swiss GAP. It was noted, that the median of the datasets for cucumber and melons (outdoor and indoor grown) differed by less than five times and agreed to consider a group maximum residue level. In deciding on the data set to use for estimating a group maximum residue level, as a Mann-Whitney U-test indicated that the residue populations for cucumber and melons were not different, it was agreed to combine the results to give a data set for fenamidone residues in whole melons and cucumbers of ($n = 25$) < 0.01, < 0.02 (5), 0.03 (3), 0.04 (5), 0.05, 0.07, 0.07, 0.08, 0.09, 0.09, 0.10, 0.10, 0.12, 0.12 and 0.13 mg/kg. Furthermore, the contribution in follow-on crops of 1.2 mg/kg has to be added to the STMR and 1.5 mg/kg to the HR.

The Meeting estimated for fenamidone residues in fruiting vegetables, cucurbits a maximum residue level of 0.2 mg/kg. Based on the cucumber data, an STMR of 1.29 mg/kg and an HR of 1.63 mg/kg were estimated.

Fruiting vegetables other than cucurbits

The GAP for fruiting vegetables except cucurbits in the USA is 3×0.3 kg ai/ha and a PHI of 14 days.

Field US trials on sweet pepper (6), chilli pepper (3) and tomatoes (17) according to the US GAP were provided. At each outdoor trial, four spray treatments of about 0.3 kg ai/ha were applied. The following residue data were received:

- In sweet pepper, the residues were for fenamidone as well as for the sum of fenamidone and RPA 410193 0.03, 0.05, 0.07, 0.08, 0.08 and 0.19 mg/kg.
- In chilli pepper, the fenamidone residues and the total residues were 0.07, 1.3 and 1.5 mg/kg. The Meeting recognized that one duplicate field sample gave higher residues than the HR based on the mean residues and decided to use this value of 1.7 mg/kg as HR for the short-term dietary intake assessment instead.

- In tomatoes, the fenamidone residues were < 0.02, < 0.02, 0.07, 0.07, 0.09, 0.10, 0.11, 0.25, 0.33, 0.34, 0.38, 0.40, 0.42, 0.46, 0.47, 0.61 and 0.80 mg/kg. The total residues were (n = 17) < 0.02, < 0.02, 0.07, 0.07, 0.09, 0.10, 0.11, 0.25, 0.33, 0.34, 0.38, 0.45, 0.46, 0.47, 0.40, 0.61 and 0.80 mg/kg. The Meeting recognized that one duplicate field sample gave higher residues than the HR based on the mean residues and decided to use this value of 0.82 mg/kg as HR for the short-term dietary intake assessment instead.

The Meeting noted that the GAP in the USA was for fruiting vegetables other than cucurbits and considered a group maximum residue level. Furthermore, the Meeting noted that the median of the datasets for sweet pepper and tomatoes differed by less than 5-fold but the median for chilli was 17 times higher than for sweet pepper. The Meeting agreed to consider a group maximum residue level for fruiting vegetables other than cucurbits, except sweet corn, fungi and chilli pepper. In deciding on the data set to use for estimating a group maximum residue level, as a Mann-Whitney U-test indicated that the residue populations for sweet pepper and tomatoes belong to different populations with the highest residues in tomato. Furthermore, the contribution in follow-on crops of 1.2 mg/kg has to be added to the STMR and 1.5 mg/kg to the HR.

Based on the tomato residue data, the Meeting estimated a maximum residue level of 1.5 mg/kg, an STMR of 1.53 mg/kg and an HR of 2.32 mg/kg for fruiting vegetables other than cucurbits, except sweet corn, fungi and chilli pepper.

For chilli pepper, the Meeting estimated a maximum residue level of 4 mg/kg, an STMR of 2.5 mg/kg and an HR of 3.2 mg/kg.

The Meeting also decided to estimate a maximum residue for chilli pepper (dried) of 30 mg/kg following application of a default dehydration factor of 7 to the estimated maximum residue level of 4 mg/kg for chilli pepper ($7 \times 4 = 28$ mg/kg). The STMR for residues of fenamidone in chilli peppers (dry) is estimated to be 18 mg/kg ($7 \times 2.5 = 17.5$ mg/kg).

Leafy vegetables

The use of fenamidone in leafy vegetables in the USA is 3×0.3 kg ai/ha and a PHI of 2 days and the Meeting looked at the possibility to establish a group MRL. However, the Meeting recognized that the ARfD of 1 mg/kg bw was exceeded for the single commodities, if the highest residue of 32.7 mg/kg (mustard greens) is used as HR and concluded that a group MRL cannot be recommended.

Nine outdoor US trials on head lettuce according to the US GAP were provided. At each outdoor trial, four spray treatments of about 0.3 kg ai/ha were applied. The fenamidone residues, as well as the total residues, were: 0.82, 2.3, 3.3, 3.3, 3.7, 3.9, 4.4, 8.0 and 11 mg/kg. The Meeting recognized that one single sample gave higher residues than the HR based on the mean and decided to use this value of 12 mg/kg as HR for the short-term dietary intake assessment instead. Furthermore, the contribution in follow-on crops of 1.2 mg/kg has to be added to estimate the STMR and 1.5 mg/kg to the HR.

The Meeting estimated a maximum residue level of 20 mg/kg, an STMR of 4.9 mg/kg and an HR of 13.5 mg/kg for fenamidone residues in head lettuce.

Nine outdoor US trials on leaf lettuce according to the US GAP were provided. At each outdoor trial, four spray treatments of about 0.3 kg ai/ha were applied. The fenamidone residues were 1.0, 2.6, 3.4, 3.4, 6.5, 7.9, 10, 12 and 16 mg/kg. The corresponding total residues were 1.0, 2.6, 3.4, 3.4, 6.5, 8.0, 10, 12 and 16 mg/kg (residue of one duplicate field sample 17.5 mg/kg).

The Meeting noted that the ARfD of 1 mg/kg bw is exceeded for leaf lettuce by the IESTI for children (110% of ARfD) using 17.5 mg/kg as HR and decided that the US dataset is not appropriate to estimate a maximum residue level for leaf lettuce.

Alternative GAP exist for outdoor use in Switzerland with 3×0.15 kg ai/ha with a PHI of 14 days. Nine trials on leaf lettuce conducted in Europe were submitted. The fenamidone residues in outdoor leaf lettuce at a PHI of 14 days were < 0.02 (3), 0.02, 0.04, 0.06, 0.07, 0.42 and 0.48 mg/kg. The corresponding total residues were < 0.02 (3), 0.02, 0.04, 0.06, 0.07, 0.43 and 0.48 mg/kg.

Furthermore, the contribution in follow-on crops of 1.2 mg/kg has to be added to estimate the STMR and 1.5 mg/kg the HR.

The Meeting estimated a maximum residue level of 0.9 mg/kg, an STMR of 1.24 mg/kg and an HR of 1.98 mg/kg for fenamidone residues in leaf lettuce.

Eight outdoor US trials on mustard greens and six on spinach according to the US GAP were provided. At each outdoor trial, four spray treatments of about 0.3 kg ai/ha were applied.

In mustard greens, the fenamidone residues were 11, 12, 13, 17, 24, 28, 28 and 29 mg/kg. The corresponding total residues were 11, 12, 13, 17, 24, 28, 29 and 29 mg/kg (residue of one duplicate field sample 32.7 mg/kg). In spinach, the fenamidone residues were 7.2, 7.3, 11, 21, 23 and 31 mg/kg. The corresponding total residues were 7.2, 7.4, 11, 21, 23 and 31 mg/kg (residue of one duplicate field sample 32.4 mg/kg).

The similar datasets of mustard greens and spinach were combined for mutual support. The rank order of the combined fenamidone residues in spinach and mustard greens were (n = 14) 7.2, 7.3, 11, 11, 12, 13, 17, 21, 23, 24, 28, 28, 29 and 31 mg/kg. The corresponding total residues were 7.2, 7.4, 11, 11, 12, 13, 17, 21, 23, 24, 28, 29, 29 and 31 mg/kg. The Meeting recognized that one duplicate field sample gave higher residues than the HR based on the mean residues and decided to use this value of 32.7 mg/kg as HR for the short-term dietary intake assessment instead. Furthermore, the contribution in follow-on crops of 1.2 mg/kg has to be added to estimate the STMR and 1.5 mg/kg the HR.

For spinach and mustard greens, the IESTI represented 150% and 170% for children, respectively of the ARfD of 1 mg/kg bw. The Meeting noted that an alternative GAP was not available.

The Meeting estimated a maximum residue level of 60 mg/kg, an STMR of 20 mg/kg and an HR of 34 mg/kg for fenamidone residues in spinach and mustard greens.

Legume vegetables

In the USA and in Canada, fenamidone may be used as foliar spray on succulent beans with 3 × 0.3 kg ai/ha and a PHI of 3 days. Field trials using 4×0.3 kg ai/ha were carried out in the USA for lima beans (8) and seven trials on common beans (7).

In mature succulent lima beans, the fenamidone residues as well as the total residues were in seeds without pods (n = 8) < 0.02 (4), 0.03, 0.04, 0.08 and 0.08 mg/kg. Furthermore, the contribution in follow-on crops of 1.2 mg/kg has to be added to estimate the STMR and 1.5 mg/kg the HR.

The Meeting estimated for fenamidone residues in beans, shelled a maximum residue level, an STMR and an HR of 0.15 mg/kg, 1.2 mg/kg and 1.58 mg/kg, respectively.

In common beans, the fenamidone residues as well as the total residues were in Pods with seeds (n = 7) 0.10, 0.11, 0.16, 0.19, 0.23, 0.34 and 0.46 mg/kg. Furthermore, the contribution in follow-on crops of 1.2 mg/kg has to be added to estimate the STMR and 1.5 mg/kg the HR.

The Meeting estimated for fenamidone residues in beans, except broad bean and soya bean (green pods and immature seeds) a maximum residue level, an STMR and an HR of 0.8 mg/kg, 1.39 mg/kg and 1.96 mg/kg, respectively.

Root and tuber vegetables

Fenamidone is registered in the USA on the one hand for carrots, ginseng and potatoes and on the other hand for other root and tuber vegetables (garden beet, celeriac, horseradish, parsnips, parsley root, radish, salsify, swedes and turnips) except sugar beet with 3×0.3 kg ai/ha and a PHI of 14 days. Residue data were submitted for the use of fenamidone on carrots, potatoes and ginseng, dry.

Field trials (13) on carrots using approximately 4×0.3 kg ai/ha were carried out in the USA and in Canada. The fenamidone as well as the total residues were (n = 13): 0.02, 0.03, 0.03, 0.03, 0.03, 0.04, 0.05, 0.05, 0.06, 0.06, 0.07, 0.09 and 0.11 mg/kg. Furthermore, the contribution in follow-on crops of 0.4 mg/kg has to be added to estimate the STMR and 0.5 mg/kg the HR.

The Meeting estimated a maximum residue level, an STMR and an HR of 0.2 mg/kg, 0.45 mg/kg and 0.61 mg/kg respectively, for carrots.

Field trials (19) on potatoes using approximately 4×0.3 kg ai/ha were carried out in the USA and in Canada. The fenamidone as well as the total residues were < 0.02 (19) mg/kg. Furthermore, the contribution in follow-on crops of 0.4 mg/kg has to be added to estimate the STMR and 0.5 mg/kg the HR.

The Meeting estimated a maximum residue level of 0.02* mg/kg for fenamidone residues in potatoes. Taking into account the uptake of RPA 412363 from the soil by rooting vegetables grown as follow-on crops, the Meeting estimated an STMR of 0.4 mg/kg and an HR of 0.5 mg/kg for fenamidone residues in potatoes.

Six supervised trials on ginseng were carried out in 2007 in the USA and Canada. Only one trial was carried according to GAP with 3×0.3 –0.31 kg ai/ha. At five trials, nine applications with application rates in the range of 0.29–0.32 kg ai/ha were performed at intervals of 7–15 days between each foliar spray. Samples were prepared by washing the roots with water after harvest followed by drying on racks in drying chambers for 14 days at 18–46 °C. The following residue data were received:

- After a treatment with 3×0.3 –0.31 kg ai/ha, the residue of fenamidone as well as the total residue was 0.06 mg/kg.
- After treatment with 9×0.29 –0.32 kg ai/ha, the fenamidone residues were 0.03, 0.10, 0.17, 0.29 and 0.35 mg/kg. The corresponding total residues were 0.03, 0.10, 0.17, 0.31 and 0.37 mg/kg and the highest single value from a duplicate field sample was 0.55 mg/kg.

The Meeting noted that only one of the six trials matched the GAP and concluded that the data submitted are insufficient to estimate a separate maximum residue level for ginseng.

Stalk and stem vegetables

Fenamidone is registered in the USA for celery with 3×0.3 kg ai/ha and a PHI of 2 days. Six supervised trials on celery were carried out during 2003 in the USA. At each trial, fenamidone was applied by foliar spray at rates of about 0.3 kg ai/ha four times at intervals of 4–6 days. In untrimmed plants without roots, the residues of fenamidone as well as the total residues were at a 2-days PHI ($n = 6$) 2.3, 4.4, 4.5, 8.8, 15 and 18 mg/kg. In trimmed stalks, the residues were ($n = 5$) 0.06, 0.32, 1.1, 1.2 and 1.7 mg/kg. Furthermore, the contribution in follow-on crops of 1.2 mg/kg has to be added to estimate the STMR and 1.5 mg/kg the HR.

The Meeting estimated a maximum residue level of 40 mg/kg, an STMR of 2.3 mg/kg and an HR of 3.2 mg/kg for fenamidone residues in celery.

The GAP for Witloof chicory in Belgium is one dip treatment of 0.006 kg ai/hL followed by an irrigation treatment with 0.6 g ai/hL and a PHI of 18 days.

All in all, nine European indoor residue trials were submitted. In 2004 four hydroponic residue trials were conducted in Belgium, France and the Netherlands consisting of one application through the irrigation water system at a maximum rate of 0.6 g ai/hL of fenamidone and a water volume of 40 L/m², at the commencement of forcing. The fenamidone residues as well as total residues in sprouts at PHIs of 20/21 days were < 0.01 mg/kg (4).

In 2008 and 2010 five residue trials were conducted in France, Germany and the Netherlands. These trials were treated twice, one dip application for two minutes in a solution containing 6.0 g ai/hL, immediately after field sampling of the roots. After storage of the roots in a cold room for 3–8 months, a second hydroponic application was made at the commencement of forcing in the irrigation water system at a maximum rate of 0.6 g ai/hL. Sprout samples were taken on day 20/21 after the second application. The fenamidone residues as well as total residues in sprouts at PHIs of 20/21 days were < 0.01 mg/kg (5).

The Meeting estimated a maximum residue level of 0.01* mg/kg, an STMR of 0.01 mg/kg and an HR of 0.01 mg/kg for fenamidone residues in Witloof chicory.

Oilseed

Fenamidone is registered in the USA for cotton as in-furrow treatment with 1×0.3 kg ai/ha.

Twelve trials were conducted on cotton in the USA during 2003. In each trial, cotton plants were treated at-planting with a single in-furrow over-the-seed application at a rate of 0.3 kg ai/ha. Samples of mature cotton seed were harvested 127–190 days post treatment. The residues of fenamidone as well as the total residues were in seed < 0.02 mg/kg (12).

The Meeting estimated a maximum residue level of 0.02^* mg/kg and an STMR of 0.02 mg/kg for fenamidone residues in cotton seed.

The GAP for the use of fenamidone in the USA for sunflower is seed treatment with 0.19 kg/100 kg seed. Nine trials on sunflower were conducted in 2009 in the USA. In each trial, one plot was planted with sunflower seeds treated with fenamidone at a rate of 0.19 kg ai per 100 kg seed. Two trials included an additional plot planted with seed treated at an exaggerated rate of 0.95 kg ai per 100 kg seed. Samples of mature sunflower seed were harvested 104–146 days after sowing of the treated seed. The residues of fenamidone as well as the total residues were in seed < 0.02 mg/kg (9).

The Meeting estimated a maximum residue level of 0.02^* mg/kg and an STMR of zero for fenamidone residues in sunflower seed.

Legume animal feed

In the USA and Canada, fenamidone may be used as foliar spray on succulent beans with 3×0.3 kg ai/ha and a PHI of 3 days. Seven field trials with 4×0.3 kg ai/ha were carried out in the USA on common beans. The fenamidone residues were in plants with pods at a PHI of 3 days 2.3, 4.1, 5.6, 7.6, 10, 11 and 16 mg/kg (fresh weight).

For the calculation of the livestock animal dietary burden, the Meeting estimated a median residue of 7.6 mg/kg and a highest residue of 16 mg/kg bean forage (green).

Cotton fodder, dry

Fenamidone is registered in the USA for cotton as in-furrow treatment with 1×0.3 kg ai/ha. Trials were conducted on cotton in the USA during 2003. In each trial, cotton plants were treated at-planting with a single in-furrow over-the-seed application at a rate of 0.3 kg ai/ha. The harvest was 127–178 days post treatment. The residues of fenamidone as well as the total residues were in cotton gin by-products < 0.02 mg/kg (6).

For the calculation of the livestock animal dietary burden, the Meeting estimated 0.02 mg/kg as median residue and highest residue for cotton fodder, dry.

Fate of residues during processing

Nature of residues

To estimate the degradation behaviour of [C-phenyl-U- ^{14} C]-fenamidone during industrial processing or household preparation, the processes of pasteurization (90 °C, 20 min at pH 4), baking, boiling, brewing (100 °C, 60 min at pH 5) and sterilization (120 °C, 20 min at pH 6) were simulated.

Degradation of fenamidone was limited and appeared to be dependent on the conditions. The largest extent of degradation was ca. 12% TAR under pasteurisation conditions. RPA 410193 was the only degradate under these conditions. The amounts of RPA 410193 decreased with increasing pH, to 2.5% TAR at pH 6. There was additional degradation to RPA 412708 up to 3.6% TAR at higher temperature (120 °C) and pH (6). This degradation path was not seen at the lower temperatures.

The Meeting concluded that, in addition to the parent fenamidone, the only metabolite to consider for processed products is RPA 410193.

Level of residues

The Meeting received information on the fate of fenamidone residues during the processing of raw agricultural commodities (RAC) like grapes to juice, must, wine and pomace and tomatoes into juice, paste, ketchup and canned tomatoes. Because the residues of RPA 410193 are of the same order of magnitude as the parent concentrations in processed products of grapes and tomatoes, the sum of parent and RPA 410193 is calculated as follows:

Fenamidone, mg/kg	RPA 410193, mg/kg	Total, mg/kg
< 0.02	< 0.02	< 0.04
< 0.02	0.076	0.10
0.05	< 0.02	0.07
0.53	0.13	0.67 ^a
^a 0.53 + (0.13 × 1.11) = 0.6743		

Two processing studies were carried out on potatoes but were only of limited use because the residues in RAC were < LOQ. Five further studies conducted on cabbage, broccoli, peppers, mustard greens and spinach investigated the fate of fenamidone and RPA 410193 after washing and cooking. The processing factors were for washed vegetables 0.58 and for cooked vegetables 0.21.

The processing factors for the sum of fenamidone and RPA 410193 obtained in the processing studies and the estimated STMR-P values for dietary intake calculations are summarized below.

Raw agricultural commodity		Processed commodity (food)		
	STMR, mg/kg		Processing factor	STMR-P, mg/kg
Grapes	0.175	Juice	0.36 (median)	0.063
		Must	0.83 (median)	0.145
		Wine	0.71 (median)	0.124
Tomatoes	1.53	Juice	0.8 (median)	1.22
		Puree	2.1 (median)	3.21
		Ketchup	2.4 (single value)	3.67
		Paste	3.65 (mean)	5.58
		Canned fruits	0.45 (median)	0.69

In some tomato processed commodities, the residues increased during processing. For parent fenamidone, the processing factors were 2.55 for paste, 1.7 for puree and 1.6 for ketchup. Based on the recommended MRL of 1.5 mg/kg in fruiting vegetables other than cucurbits, the Meeting estimated maximum residue levels of 4 mg/kg for tomato paste and of 3 mg/kg for tomato puree as well as for ketchup.

The processing factors for parent fenamidone obtained in the processing studies and the median values of fenamidone residues in the RAC (parent only) were used to calculate the residues in the feed items grape pomace, tomato pomace and potato wet peel for animal dietary burden purposes.

Raw agricultural commodity		Processed commodity (feed)		
	Median (mg/kg)		Processing factor	STMR-P (mg/kg)
Grapes	0.15	Pomace, wet	2.0 (median)	0.3
Tomatoes	0.33	Pomace, wet	4.5 (median)	1.49
Potatoes	0.02	Wet peel	> 2.3 (single value)	0.046

The Meeting noted that fenamidone concentrated during processing in grape wet pomace, tomato wet pomace and potato wet peel. Because wet pomace and wet peel are not commodities in the international trade, no maximum residue levels are estimated.

Residues in animal commodities

Farm animal feeding studies

The Meeting received information on the residue levels arising in tissues and milk when three groups of dairy cows were fed with a diet containing 0.8, 2.4 and 8 ppm fenamidone for 35 consecutive days. At the highest dose group, no residues of fenamidone or the two major metabolites RPA 412636 and RPA 412708 were found in any of the tissue or milk fat samples higher than the LOD of 0.003 mg/kg, with the exception that in one milk fat sample, RPA 412708 was detected (0.011 mg/kg).

No poultry feeding study was submitted. In two metabolism studies laying hens were dosed at 13.8 ppm (C-phenyl label) and 9.8 ppm (N-phenyl label) fenamidone in the diet. The maximum residues (sum of fenamidone, RPA 412636 and RPA 412708) were 0.012 mg/kg in egg white, 0.05 mg/kg in egg yolk, 0.028 mg/kg in liver, 0.004 mg/kg in skin and < 0.001 mg/kg in fat.

Estimated dietary burdens of farm animals

Maximum and mean dietary burden calculations for fenamidone are based on the feed items evaluated for cattle and poultry as presented in Annex 6. The calculations were made according to the livestock diets from Australia, the EU, Japan and US-Canada in the OECD feeding table. Furthermore, the Meeting estimated the maximum highest dietary burden for the main metabolites in follow-on crops.

Parent fenamidone in primary commodities

The foliar application of fenamidone to grapes, tomatoes, cabbage, root and tuber vegetables, cotton and sunflower resulted in residues of fenamidone in the following feed items: wet grape pomace, wet tomato pomace, head cabbage, carrot culls, potato culls, potato process waste, turnip roots, swede roots, cassava/tapioca roots, cotton undelinted seed, sunflower seed and cotton fodder, dry. Residue data were also submitted for green bean forage (vines) what is listed as 60–70% of the Australian diet and for beef and dairy cattle and as 20% of the European diet for dairy cattle. Based on the named feed items, the calculated maximum animal dietary burden for dairy or beef cattle was in the USA and Canada 0.13 ppm, in the EU 10 ppm and in Australia 33 ppm. The Meeting noted that the estimated livestock dietary burden (AUS) was up to three times higher than the dose rate in the cow feeding study.

The Meeting recognized that green bean forage (vines) is not used as animal feed in the USA and in Canada but in the EU and in Australia. The Meeting was informed by an official communication of the government of Australia that no fodder crops are imported. Furthermore, the USDA Global Agricultural Trade System database indicates that no animal feed/fodder were exported from the USA to Australia and the EU in 2013. The Meeting concluded that green bean forage is not an exportable commodity and decided to make a refined calculation of the livestock dietary burden without the residues in bean vines (see Annex 6).

In the table below the estimated livestock dietary burden is presented for fenamidone after foliar treatment of plants.

	Livestock dietary burden, fenamidone, ppm of dry matter diet							
	US-Canada		EU		Australia		Japan	
	Max	Mean	Max	Mean	Max	Mean	Max	Mean
Beef cattle	0.15	0.15	1.0 ^a	0.52	1.0 ^a	0.97 ^b	0	0
Dairy cattle	0.13	0.08	0.96	0.49	0.99	0.97	0	0
Poultry–broiler	0	0	0.09	0.04	0	0	0	0
Poultry–layer	0	0	0.27 ^c	0.12 ^d	0	0	0	0

^a Suitable for MRL estimates for mammalian meat, fat, edible offal and milk.

^b Suitable for STMR estimates for mammalian meat, edible offal and milk.

^c Suitable for MRL estimates for eggs, meat, fat and edible offal of poultry.

^d Suitable for STMR estimates for eggs, meat, fat and edible offal of poultry.

Metabolites in follow-on crops

Rotational crop studies showed that in the follow-on crops an uptake from the soil of the metabolites RPA 412708 and RPA 412636 occurred. Their highest concentrations found in follow-on crops as wheat, sweet corn, maize and soya beans after the treatment of bare soil with fenamidone at 1.2 kg ai/ha per annum were scaled according to the critical US GAP of 0.9 kg ai/ha per annum for brassica vegetables, fruiting vegetables, leafy vegetables, root and tuber vegetables and celery. These residues are extrapolated to similar feed items in the OECD feeding table.

The maximum livestock dietary burden for RPA 412708/RPA 412636 in follow-on crops in the USA and Canada was estimated as follows: Beef cattle 0.088 ppm (as RPA 41236), dairy cattle 0.36 ppm (as RPA 41236), poultry broiler 0 ppm and poultry layer 0 ppm. Expressed as fenamidone equivalents, the burden was for beef cattle 0.14 ppm and for dairy cattle 0.59 ppm.

The Meeting noted that RPA 412708 and RPA 412636 are not found in milk or tissues of dairy cows dosed at 8 ppm fenamidone through normal animal metabolism routes. Therefore, the two metabolites are unlikely to be present after direct administration of much lower levels (maximum livestock dietary burden 0.59 ppm).

The Meeting concluded that it is unlikely that residues of RPA 412708 and RPA 412636 in follow on crops of the uses considered by the JMPR result in residues in animal products.

Animal commodities, MRL estimation

The feeding study with fenamidone in dairy cows was performed at actual dose levels of 0.8, 2.4 and 8 ppm in the diet. At the highest dose group, no residues of fenamidone or of the two major metabolites RPA 412636 and RPA 412708 were found in any of the tissue or milk fat samples (< 0.003 mg/kg, LOD; LOQ 0.01 mg/kg), with the exception that in one milk fat sample RPA 412708 was detected (0.011 mg/kg). The overdosing factor is calculated as about 8 ($8 \text{ ppm} \div 1 \text{ ppm}$). Therefore, residues of fenamidone, RPA 412636 and RPA 412708 in cattle tissues and milk arising from a burden of 1 ppm are not expected.

The Meeting estimated maximum residue levels of 0.01^* mg/kg for milks, meat from mammals, other than marine mammals (fat), mammalian fat (except milk fat) and edible offal (mammalian). For milk fat, a maximum residue level of 0.02 mg/kg was estimated. The STMRs for milk and milk fat were 0.01 mg/kg and the STMR/HR values for muscle, fat and edible offal were zero.

No poultry feeding study was submitted. In two metabolism studies, laying hens were dosed at 13.8 ppm (C-phenyl label) and 9.8 ppm (N-phenyl label) fenamidone in the diet. The maximum residues (sum of fenamidone, RPA 412636 and RPA 412708) were 0.012 mg/kg in egg white, 0.05 mg/kg in egg yolk and 0.028 mg/kg in liver.

Allowing for the dose rates in the metabolism studies (overdosing factors about 40–50), it can be seen that at the maximum calculated dietary burden for poultry of 0.27 ppm, no residues of fenamidone or any of its metabolites will be found in poultry commodities at or above the LOQ of 0.01 mg/kg.

The Meeting estimated maximum residue levels of 0.01^* mg/kg poultry meat, poultry fat, poultry edible offal and eggs. The STMR/HR values for poultry meat, poultry fat, poultry edible offal and eggs are zero.

RECOMMENDATIONS

On the basis of the data from supervised trials the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI and IESTI assessment.

Definition of the residue for compliance with the MRL for plant and animal commodities: Fenamidone.

Definition of the residue for estimation of dietary intake for plant commodities: Sum of fenamidone, (S)-5-methyl-5-phenyl-3-(phenylamino)- 2,4-imidazolidine-dione (RPA 410193) plus $10 \times$ the sum of both (S)-5-methyl-5-phenyl-2,4-imidazolidine-dione (RPA 412636) and (5S)-5-methyl-2-(methylthio)-5-phenyl-3,5-dihydro- 4H-imidazol-4-one (RPA 412708), all calculated as fenamidone.

Residue concentration $C_{total} = C_{fenamidone} + C_{RPA\ 410193} + 10 \times (CRPA\ 412636 + CRPA\ 412708)$

Definition of the residue for estimation of dietary intake for animal commodities: Fenamidone plus $10 \times$ the sum of both (S)-5-methyl-5-phenyl-2,4-imidazolidine-dione (RPA 412636) and (5S)-5-methyl-2-(methylthio)-5-phenyl-3,5-dihydro- 4H-imidazol-4-one (RPA 412708), all calculated as fenamidone.

Residue concentration $C_{total} = C_{fenamidone} + 10 \times (CRPA\ 412636 + CRPA\ 412708)$

The residue is fat-soluble.

DIETARY RISK ASSESSMENT

Long-term intake

The International Estimated Dietary Intakes (IEDIs) of fenamidone were calculated for the 17 GEMS/Food cluster diets using STMRs and STMR-Ps estimated by the current Meeting (Annex 3). The ADI is 0–0.03 mg/kg bw and the calculated IEDIs were 10–60% of the maximum ADI. The Meeting concluded that the long-term intake of residues of fenamidone resulting from the uses considered by the current JMPR is unlikely to present a public health concern.

Short-term intake

The International Estimated Short Term Intake (IESTI) for fenamidone was calculated for food commodities and their processed fractions for which maximum residue levels were estimated and for which consumption data were available. The results are shown in Annex 4.

The Meeting recognized that for leaf lettuce the IESTI calculated according to the maximum GAP exceeded the ARfD of 1 mg/kg bw and used an alternative GAP. For spinach and mustard

greens, the IESTI represented 150% and 170%, respectively of the ARfD of 1 mg/kg bw. The Meeting noted that an alternative GAP was not available. For the other commodities considered by the JMPR, the IESTI represented 0–30% of the ARfD. The Meeting concluded that the short-term intake of residues of fenamidone, when used in ways that have been considered by the JMPR, is unlikely to present a public health concern (except mustard greens and spinach).

FENPROPATHRIN (185)

The first draft was prepared by Professor Árpád Ambrus, temporary adviser, Hungary

EXPLANATION

Fenpropathrin is a type II pyrethroid insecticide and acaricide used for the control of a variety of arthropods including aphids, worms, moths, beetles, mites, spiders, thrips, flies, fleas and other pests in agriculture. It acts by contact and ingestion. It is also a repellent. It interferes with nerve impulse transmission by acting on sodium channels.

Fenpropathrin was first evaluated by JMPR in 1993 when an ADI of 0–0.03 mg/kg bw was established and a number of MRLs recommended. In 2006 MRL for tea was recommended. The compound was re-evaluated for toxicology within the periodic review programme in 2012 when the Meeting reaffirmed the ADI of 0–0.03 mg/kg bw and established an ARfD of 0.03 mg/kg bw.

Fenpropathrin is scheduled for periodic re-evaluation of residues in 2014. Data to support proposed Codex MRLs on a number of commodities and on animal products were submitted for review.

IDENTITY

ISO common name:

Fenpropathrin

IUPAC name:

(*RS*)- α -cyano-3-phenoxybenzyl 2,2,3,3-tetramethylcyclopropanecarboxylate

Chemical Abstract name:

cyano(3-phenoxyphenyl)methyl 2,2,3,3-tetramethylcyclopropanecarboxylate

CAS No.:

64257-84-7 (racemate);
39515-41-8 (unstated stereochemistry)

Molecular Formula:

C₂₂H₂₃NO₃

Structural Formula:

Molecular Weight:

349.43

Specifications

Specifications for fenpropathrin have not yet developed by FAO.

Physical and Chemical Properties

Technical material (90%) (Reference: JMPR, 1993)

Chemical/physical property	Results	
Physical state	Liquid	
Colour	Yellow to brown	
Odour	Faint characteristic odour	
Density	1.105	
Vapour pressure	2.15×10^{-6} Pa	
Melting range	45-50 °C	
Flammability	Flash point : 205 °C Ignition point: 325 °C	
Solubility in organic solvents (g/L, 23°C)	Acetone	> 500

Chemical/physical property	Results	
	Acetonitrile	> 500
	Cyclohexanone	> 500
	Ethyl acetate	> 500
	Methanol	216
	Xylene	> 500
Solubility in water	36.3 µg/L at 25.1 °C	
Octanol/water partition coefficient	Log $P_{O/W}$ = 6.0± 0.20	
Hydrolytic half lives	pH 5 and pH: 7 200 days pH 9: 17.1 days (calculated based on hydrolysis of cyclopropyl-1- ¹⁴ C)-fenpropathrin.	
Stability	No significant breakdown after 20 weeks storage at 60 °C	

Hydrolytic degradation

The hydrolytic degradation of fenpropathrin was examined at pH 5, 7, and 9 with [phenoxyphenyl-¹⁴C]-fenpropathrin or [cyclopropyl-1-¹⁴C]-fenpropathrin in sterile aqueous solution containing 1% acetonitrile as co-solvent (Takahashi, *et.al.*, 1983 and 1985, References FM-30-0010 and FM-50-0053; Concha, *et al*, 1992; Reference FM-21-0060).

The predominant hydrolysis reactions were cleavage of the ester linkage and hydration of the cyano group. Major hydrolysis products from cyclopropyl labelled fenpropathrin were TMPA, TMPA-carboxamide and CONH₂-fenpropathrin, while from phenoxyphenyl labelled fenpropathrin, were PBacid and CONH₂-fenpropathrin

Formulation

The emulsifiable concentrate formulation containing 300 g/L fenpropathrin was used in the residue trials submitted for evaluation.

METABOLISM AND ENVIRONMENTAL FATE

The metabolism of fenpropathrin has been investigated in apple, tomato, beans, cotton, cabbage, lactating goat and laying hens. The crops selected represent those for which supervised trials have been provided.

The fate and behaviour of fenpropathrin in plants, animals and soil were investigated using either [cyclopropyl-1-¹⁴C]-fenpropathrin, [benzyl-¹⁴C]-fenpropathrin, [phenoxyphenyl-¹⁴C]-fenpropathrin or [cyano-¹⁴C]-fenpropathrin (all with radiochemical purity >98%).

[cyclopropyl-1-¹⁴C]-fenpropathrin

[cyano-¹⁴C]-fenpropathrin

[phenoxyphenyl-¹⁴C]-fenpropathrin

[benzyl-¹⁴C]-fenpropathrin

The chemical structures and code names of metabolites and the major degradation products of fenpropathrin are shown in Table 1.

Table 1 Degradation compounds from the metabolism of fenpropathrin

Compound Name	Structure	Found in:
2'-or 4'-OH-Fenpropathrin [α -cyano-3-(2'- or 4'-hydroxyphenoxy)benzyl 2,2,3,3-tetramethylcyclopropanecarboxylate]		Plant, animal, soil
2'- or 4'-OH-Fenpropathrin-CH ₂ OH [α -cyano-3-(2'- or 4'-hydroxyphenoxy)benzyl-2-hydroxymethyl-2,3,3-trimethylcyclopropanecarboxylate]		Plant, animal
CONH ₂ -Fenpropathrin [α -carbamoyl-3-phenoxybenzyl 2,2,3,3-tetramethylcyclopropanecarboxylate]		Soil, water plant
COOH-Fenpropathrin [α -carboxy-3-phenoxybenzyl 2,2,3,3-tetramethylcyclopropanecarboxylate]		Soil, plant
Desphenyl-Fenpropathrin [α -cyano-3-hydroxybenzyl 2,2,3,3-tetramethylcyclopropanecarboxylate]		Animal, soil, plant
Fenpropathrin-CH ₂ OH [α -cyano-3-phenoxybenzyl 2-hydroxymethyl-2,3,3-trimethylcyclopropanecarboxylate]		Plant, animal
Fenpropathrin-COOH [α -cyano-3-phenoxybenzyl 2-carboxy-2,3,3-trimethylcyclopropanecarboxylate]		Animal
Fenpropathrin-(CH ₂ OH) ₂ [α -cyano-3-phenoxybenzyl 2,2-dihydroxymethyl-3,3-dimethylcyclopropanecarboxylate]		Plant
2'- or 4'-OH-Fenpropathrin-(CH ₂ OH) ₂ [α -cyano-3-(2'- or 4'-hydroxyphenoxy)benzyl 2,2-dihydroxymethyl-3,3-dimethylcyclopropanecarboxylate]		Plant
PB aldehyde (PBald) [3-phenoxybenzaldehyde]		Plant, animal, soil
PB alcohol (PBalc) [3-phenoxybenzyl alcohol]		Plant, soil
PBacid [3-phenoxybenzoic acid]		Plant, animal, soil, water

Compound Name	Structure	Found in:
2'- or 4'-OH-PBalc [3-(2'- or 4'-hydroxyphenoxy)benzyl alcohol]		Plant
2'- or 4'-OH-PBacid [3-(2'- or 4'-hydroxyphenoxy)benzoic acid]		Plant, animal, soil
3-OH-Bacid [3-hydroxy-benzoic acid]		Animal, soil
TPMA [2,2,3,3-tetramethylcyclopropane-carboxylic acid]		Plant, animal, soil, water
TPMA-CH2OH [2-hydroxymethyl-2,3,3-trimethylcyclopropanecarboxylic acid]		Plant, animal
TPMA-lactone [5,6,6-trimethyl-3-oxabicyclohexan-2-one]		Plant
TPMA-CH2OH lactone [5-hydroxymethyl-6,6-dimethyl-3-oxabicyclohexan-2-one]		Plant, animal
TPMA carboxamide [2,2,3,3-tetramethylcyclopropane-carboxamide]		Water
TPMA-COOH [2-carboxy-2,3,3-trimethylcyclopropanecarboxylic acid]		Plant, animal

Animal metabolism

Laboratory animals

Absorption by rats was rapid and excretion almost complete (97%) within 48 hours. About 56% of the administered dose was found in urine and 40% in faeces at 48 hours. The amount of radioactivity excreted via expired air was 0.005%. The low residues found in blood, liver, kidney, fat, muscle and brain 24 hours after dosing depleted rapidly over the following 7 days to barely detectable levels, and less than 1.5% of the administered dose remained in the body 8 days after treatment. The highest residue was found in the fat. About 29–53% of the parent compound was detected in the faeces and no parent compound was detected in the urine. The predominant urinary metabolites derived from the acid moiety were identified as TPMA–glucuronide and TPMA-CH₂OH (*trans*). Other metabolites identified were TPMA-COOH (*trans*) and TPMA-CH₂OH-lactone in free form or as the glucuronide conjugate. The major urinary metabolites derived from the alcohol moiety were PBacid in free form and as the glycine conjugate, 4'-OH-PBacid–sulfate and 2'-OH-PBacid–sulfate. The urinary metabolites from the alcohol moiety were similar to those from other pyrethroids. The major faecal metabolite was identified as CH₂OH *trans*-fenpropathrin, followed by COOH *trans*-fenpropathrin, 4'-

OH-fenpropathrin and 4'-OH,CH₂OH *trans*-fenpropathrin. Depending on the dose administered, 30–50% of the applied radioactivity was excreted in faeces as parent compound. Fenpropathrin and TMPA were the major components of ¹⁴C in tissues. No sex-related differences in tissue distribution were observed.

Lactating goats

The adsorption and deposition of radioactivity was studied in lactating goats (Ku and Doran, 1990, Reference FM-01-0041). Two animals per group were dosed for five consecutive days via capsules with either [phenoxyphenyl-¹⁴C]-fenpropathrin or [cyclopropyl-1-¹⁴C]-fenpropathrin at a rate equivalent to 50 ppm (based on a 2 kg diet, 100 mg per dose of test material). A single control animal was dosed, using a placebo capsule, in an identical manner. Sample collection was initiated on study day 1, with the twice daily collection of milk (morning and afternoon) until sacrifice. Urine and faeces were collected daily from study day 1 to day 4 (with cage wash conducted at study termination). Blood samples were collected at specified times during the last day of dosing. At sacrifice, and within 4 hours of the terminal dose, samples of omental and perirenal fat, kidneys, liver, gall bladder contents, heart, loin muscle and rear leg muscle were taken for analysis. Urine, milk and butterfat (obtained from the milk) were quantified directly by LSC of replicate aliquots. Faeces and non-fatty tissues were homogenized and replicate subsamples taken for combustion and radio-assay. Replicate samples of the fatty tissues were solubilised prior to radio-assay.

Milk, tissues and fat (omental and perirenal) were extracted with either acidified acetonitrile/hexane (milk) or acidified acetonitrile (fat and tissues). Extracts were combined, concentrated and partitioned with either ethyl ether or ethyl acetate with further concentration and subsequent quantification by HPLC. Aqueous fractions from the milk, tissues, urine and faeces extractions were subjected to acid hydrolysis, extracted with either ethyl acetate or ethyl ether and the organo-soluble components analysed. Non extractable residues of milk, tissues, fat and faeces were air dried prior to combustion and radio-assay. Selected non-extractable residues were subjected to acid hydrolysis with analysis of the organo-soluble components.

The mean total recovery of radioactivity following dosing with [cyclopropyl-1-¹⁴C]-fenpropathrin was 65.2% (63.9–66.5%) with 40.9% (40.0–41.8) recovered in the urine and 23.5% (23.0–24.0) in the faeces. Excretion via milk was a minor route with radioactivity accounting for *ca* 0.15% (0.73 (0.497–0.954)) mg fenpropathrin equivalents for the phenoxyphenyl label and *ca* 0.087% (0.43 (0.416–0.449)) mg fenpropathrin equivalents of total dose 500 mg for the cyclopropyl label. Total radioactive residues in the milk reached a steady state by the evening milking on the third day when average residues in the whole milk were 0.11 mg/L for [cyclopropyl-1-¹⁴C]-fenpropathrin treated animals and 0.25 mg/L for the [phenoxyphenyl-¹⁴C]-fenpropathrin treated animals. Less than 3% of the radioactivity in the milk was associated with the butterfat. Most of the retained activity was found in the liver, kidney and fat. Levels in these three organs were in the range of 0.4–0.7 mg/kg fenpropathrin equivalent for both labels. Muscle levels were in the range of 0.02–0.04 mg/kg fenpropathrin equivalent.

Between 20% and 40% of the radiocarbon in the milk from animals receiving the phenoxyphenyl label was associated with the parent compound, with nearly all of the remainder being present as the glycine conjugate of PBacid which reached levels of 0.03–0.15 mg/L (Table 3). There were minor amounts of the hydroxylated derivatives of PBacid (0.003–0.01 mg/kg) and also of fenpropathrin itself (0.02–0.12 mg/kg). With the cyclopropyl label, 57–75% of the activity was associated with the parent material with moderate amounts of TMPA (< 0.002–0.005 mg/kg), its hydroxymethyl (< 0.002–0.003 mg/kg) and carboxy (< 0.002–0.003 mg/kg) derivatives and its hydroxymethylated lactone (< 0.002–0.004 mg/kg) (Table 4). In this case, however, the total recovery was only about 70–80% and the concentration of TMPA and all its derivatives did not exceed 0.01 mg/L. The identity of the compounds associated with the radioactivity in the tissues was somewhat similar except that in the liver and kidney there were only traces left as parent material (Table 5). In the case of the phenoxyphenyl label, most of the activity was in the form of PBacid (kidney 0.22–0.34 mg/kg; liver 0.05–0.07 mg/kg) and its glycine conjugate (kidney 0.21–0.38 mg/kg; liver 0.06–0.11 mg/kg) and in the case of the cyclopropyl label TMPA and its derivatives

predominated. The hydroxymethyl TMPA-lactone (TMPA-CH₂OH lactone) was practically absent from the fat but was prominent in muscle, liver and kidney, accounting for up to 40% of the activity in the kidney, equivalent to about 0.2 mg/kg.

Table 2 Distribution of radioactive residues in milk and tissues following administration of [phenoxyphenyl-¹⁴C]-fenpropathrin or [cyclopropyl-1-¹⁴C]-fenpropathrin to lactating goats for 5 consecutive days

Laying Hens

Fenpropathrin, labelled in either the cyclopropyl or the benzyl ring was administered in capsules to laying hens daily for 10 days (Ku and Doran, 1990, Reference FM-01-0042). The group of 10 hens were dosed with [phenoxyphenyl- ^{14}C]-fenpropathrin (benzyl-label) and [cyclopropyl-1- ^{14}C]-fenpropathrin (cyclo-label) at a nominal rate of either 0.5 or 5 mg/kg body weight. Eggs were collected every morning and evening and excreta daily. The hens were all sacrificed within four hours of the last dose and kidneys, liver, heart, gizzard (washed without contents), ovaries and contents, muscle and skin were retained for analysis.

The samples were combusted and the ^{14}C activity was determined with liquid scintillation counter. Liquid samples were directly analysed with LSC. The residues in eggs and tissues were extracted with acetonitrile/1% conc. HCl. The organic phase was evaporated and the remaining aqueous phase was diluted and partitioned into ethyl acetate. The concentrated extract was analysed with HPLC. The remaining aqueous fraction was hydrolysed by refluxing it at 80–90 °C with 6N HCl overnight. The radioactivity was determined with LSC. The remaining radioactivity in PES was also determined with LSC. Portions of egg, meat, fat and liver were also analysed with gas chromatography based on acetone/hexane (1/2 v/v) extraction, silica gel clean-up. The polar metabolites were determined after methylation with diazomethane. The compounds were identified with GC/MS applying authentic analytical standards.

The recovery of total radioactivity from excreta, eggs and tissues was between 75 and 84% of the total applied dose. Between 98.9 and 99.6% of the recovered activity was found in the faeces irrespective of the label. Approximately 0.05% of the applied benzyl label was found in the eggs and 0.2% of the cyclopropyl label. The total radioactive residues expressed as fenpropathrin equivalent are summarised in Table 7.

Table 7 Total radioactive residues [mg/kg] expressed as fenpropathrin and parent fenpropathrin found following treatments with benzyl-labelled and cyclopropyl-labelled fenpropathrin at 5 ppm level

Sample	Benzyl -label		Cyclopropyl -label

Summary of animal metabolism

The major biotransformation reactions of fenpropathrin in animals consisted of oxidation at the methyl groups of the acid moiety and at the 2'- or 4'-positions of the alcohol moiety, cleavage of the ester and ether linkages and conjugation of the resultant carboxylic acids and alcohols. The proposed metabolic pathway for fenpropathrin in animals is shown in Figure 1.

equivalent to 0.45 kg ai/ha (Chen and Abell, Report FM-41-0031,1985 and Reference FM-51-0022, 1986). Samples were collected 14 days after the final application. Apple fruit was washed with methanol and separated into peel and pulp. Samples were pulverized with dry ice then extracted with acetone and methanol/water. Analysis was by autoradiography/TLC/LSC. The radioactivity remaining in un-extractable material was determined by combustion/LSC. Free metabolites were separated from conjugated metabolites by solid phase chromatography on a silica column eluted with hexane/acetone, methanol/acetone and methanol. To release aglycones, conjugated metabolites were subjected either to enzyme hydrolysis using cellulase or β -glucosidase then acidified and extracted with diethyl ether, or to chemical hydrolysis with both acid and base. Characterization of metabolites was by radio-TLC.

Table 14 Distribution of ^{14}C -fenpropathrin in apple tree samples

Sample	Benzyl-label		Cyclopropyl-label	
	mg/kg fenpropathrin equivalent	% TRR	mg/kg fenpropathrin equivalent	% TRR
Leaves	12.2	61.0	15.9	72.1
Branches	4.0	13.9	2.5	4.2
Fruit	2.11	25.1	1.40	24.7

Table 15 Extractability of ^{14}C -fenpropathrin radioactivity (%TRR)

	Leaves		Branches	Fruit	
	Benzyl-label	Cyclopropyl-label	Benzyl-label	Benzyl-label	Cyclopropyl-label
Acetone	81	87	89	94	94
Methanol/water	11	8	6	3	3
Un-extractable	8	5	5	3	3

The cyclopropyl- ^{14}C -treated branches contained only 2.5% of TRR and therefore no further analysis was carried out.

Tomatoes

In studies carried out in California, USA in 1983, greenhouse-grown tomato plants (cv. Bonny Best) were treated four times, 7–8 days apart, with [cyclopropyl-1-¹⁴C]-fenpropathrin and [benzyl-¹⁴C]-fenpropathrin (both radiochemical purity >99%) at rates equivalent to 0.224 kg ai/ha (Chen and Abell, 1985 and 1986; References FM-41-0031 and FM-51-0023). Fruit and leaves were extracted at harvest (PHI 19 days) as described for apples.

** contained at least 15 metabolites

In the fruit, the radioactivity was too low to allow full characterization, but some two thirds were present as unchanged fenpropathrin with a further 28% as conjugated metabolites. In the leaves, only 30% of the total residue was present as parent and just under 60% as conjugated metabolites. In the case of the benzyl label, the most prominent metabolites were conjugates of PBacid and its 4'-hydroxy derivative (4'-OH-PBacid), although these only constituted a minor proportion of the total radioactivity. The main metabolites reported in the case of the cyclopropyl label were conjugates of TMPA and hydroxymethyl-TMPA (TMPA-CH₂OH).

In studies carried out in California, USA in 1994, greenhouse-grown tomato plants (cv. 5715) were sprayed four times with a 2.4% EC formulation containing [cyclopropyl-1-¹⁴C]-fenpropathrin (radiochemical purity 98.7%) and [phenoxyphenyl-¹⁴C]-fenpropathrin (radiochemical purity 98.4%) at rates equivalent to 0.224 kg ai/ha (Toia, *et. al.*, 1995; Reference FM-51-0070). Fruit and leaves were collected at harvest (PHI 3 days); fruit were washed with hexane/acetone. Total radioactivity was determined by combustion/LSC. The washes were evaporated, redissolved in hexane/acetone and analysed by radio-HPLC/TLC. The major radiolabelled zone was removed from the TLC plate, dissolved in acetone, filtered, evaporated and analysed by GC-MS. Tomato fruit were extracted using acetonitrile with the supernatant being analysed using LSC. Further extractions were made using methanol and dichloromethane. Extracts were analysed using radio-HPLC with UV detection and TLC. Radioactivity in dried, un-extracted material was determined by combustion/LSC. Soil samples were analysed by combustion/LSC to determine the total radioactive residue; only small amounts of radioactivity were detected.

Table 21 Radioactive residues in tomatoes following treatment with [¹⁴C]-fenpropathrin

	Phenoxyphenyl-label		Cyclopropyl-label	
	mg/kg	%TRR	mg/kg	%TRR
Rinse	0.34	33.6	0.23	27.3
Rinsed fruit	0.68	66.4	0.62	72.8
Total	1.02	100	0.85	100

The majority of radioactivity was attributed to parent compound but small amounts of *trans*-TMPA-COOH and/or *trans*-TMPA-CH₂OH was tentatively identified.

Beans

In 1984, five pinto bean plants (cv. Idaho 111) grown in a greenhouse in California, was treated three times with [cyclopropyl-1-¹⁴C]-fenpropathrin and [benzyl-¹⁴C]-fenpropathrin (both radiochemical purity >99%) at a rate equivalent to 0.224 kg ai/ha (Chen and Abell, 1985, 1986; References FM-41-0031 and FM-51-0024). Samples were collected 15 days after the final application. Fruit and leaves were extracted at harvest as described for apples.

Cotton

Cotton pants were treated four times with [cyclopropyl-1-¹⁴C]-fenpropathrin and [phenoxyphenyl-¹⁴C]-fenpropathrin (both radiochemical purity > 99%) applying a total of *ca.* 4.7–4.8 mg ¹⁴C-fenpropathrin (Hitchings and Roberts, 1977; Reference FM-81-0005). The plant parts were extracted with acetonitrile/water and the main products in the extracts were found to be fenpropathrin itself with small amounts of TMPA and PBacid together with some polar material which is likely to have consisted primarily of conjugates of either PBacid or TMPA. In the leaves at harvest (the interval between treatment and harvest was 66 days for the benzyl label and 111 days for the cyclopropyl label) the total remaining activity included 70% parent in the case of the cyclopropyl label and 55% parent in the case of the phenoxyphenyl label. Most of the remaining activity was tentatively accounted for by PBacid and TMPA, mainly in conjugated forms. Examination of the plants grown on soils treated with 0.5 kg/ha of fenpropathrin and containing 0.86 mg/kg fenpropathrin equivalent showed only extremely low uptake of radioactivity (0.002 mg/kg in leaves and 0.01 mg/kg in bolls), demonstrating limited tendency for translocation.

In a study carried out outdoors in California in 1992, cotton plants (cv Acala Royale) were sprayed with [phenoxyphenyl-¹⁴C]- or [cyclopropyl-¹⁴C]-fenpropathrin (97.9% or > 99.9% radiochemical purity) on 4 occasions at a rate equivalent to 0.336 kg as/ha (total application rate 1.344 kg as/ha) (Kimmel, 1994, Reference FM-41-0067). Plants were harvested by hand 21 days after the final application. Seeds were delinted by hand and extracted using hexane and extracted radioactivity was analysed by LSC, TLC, HPLC-UV and GC-MS. The un-extracted material was further extracted with methanol/water, followed by diluted hydrochloric acid/methanol. Cotton lint and foliage were extracted using hexane/acetone and analysed by LSC, TLC and HPLC. Unextracted material was further extracted using methanol/water and analysed by LSC. The results are shown in Tables 27–29.

Cabbage

The metabolism of ¹⁴C-fenpropathrin was investigated in cabbages grown and treated in a greenhouse (Mikami, N. *et al.*, 1985; Reference FM-50-0044). ¹⁴C-fenpropathrin labelled at either the cyano

group (referred to as [cyano- ^{14}C]-fenpropathrin), or the $\text{C}_{(1)}$ position of the cyclopropyl ring ([cyclopropyl- ^{14}C]-fenpropathrin), or the phenoxyphenyl ring ([phenoxyphenyl- ^{14}C]-fenpropathrin) were prepared (all radio-chemical purities > 99%). Each of the preparations were dissolved in methanol and evenly applied to the upper surface of two 3rd–4th leaves of cabbage seedlings at a rate of 22 μg per leaf (ca. 25cm², equivalent to 0.09 kg ai/ha). The cabbages were sampled immediately after application and at 3, 7, 14, 21, 28, 35 and 42 days after application.

The cabbage samples were separated into the treated leaves and non-treated shoot portion. The treated leaves were rinsed twice with methanol and the leaves and the untreated shoots were separately homogenized and extracted with a solution of methanol:chloroform:distilled water (4:2:1). Each of the rinse and extract was radioassayed and analysed by TLC. 97.3% of fenpropathrin was recovered from cabbages immediately after application of [cyano- ^{14}C]-fenpropathrin. Direct TLC comparison of metabolites from three labelled preparations was used to distinguish products retaining the ester linkage from hydrolysis products. The extractable components in cabbages harvested 28 and 42 days after application are shown in Table 30.

The study demonstrated that after foliar application of ^{14}C -fenpropathrin to cabbages the radiocarbon remaining on the treated leaves (as shown by the surface wash) decreased with concomitant increase of ^{14}C in the plant tissues. Most of the recovered radiocarbon was in the treated leaves and less than 1.2% of the applied radiocarbon was found in the untreated shoots indicating that fenpropathrin and its metabolites hardly translocate from the application site to other parts of the plant.

TLC showed that in all cases the predominant radioactive component in the surface washes was the parent, fenpropathrin. Fenpropathrin underwent ester cleavage, hydrolysis of the CN group to the CONH_2 and the COOH groups, hydroxylation at either or both of the gem-dimethyl group with subsequent oxidation to carboxylic acid, and hydroxylation at the 2'- or 4'-position of the phenoxy group. Most of the resultant carboxylic acids and alcohols occurred as glycoside conjugates in plants.

Fate of hydrogen cyanide (HCN) and TMPA in abscised leaves

Mikami, N. *et al.*, also conducted work on the fate of HCN and 2,2,3,3-tetramethylcyclopropanecarboxylic acid (TMPA) in abscised leaves of apple, kidney bean, cabbage, mandarin orange, tomato and vine. 2,2,3,3-tetramethylcyclopropanecarboxylic acid labelled at the $\text{C}_{(1)}$ position of the cyclopropyl ring (^{14}C -TMPA) was prepared. Two abscised leaves from each plant were placed in 100 mL distilled water containing ^{14}C -TMPA at a concentration of 1.0 ppm. After cultivation for five days the leaves were extracted with methanol:chloroform:water (4:2:1).

In a separate experiment, abscised leaves of cabbage and bean plants were placed in a 100 ppm solution of ^{14}C -TMPA in order to obtain large quantities of metabolites for characterization. The extracts were partitioned between ethyl ether and distilled water. After acidification the aqueous layer was partitioned with ethyl acetate. The extractable components in abscised leaves of various plants over a 5 day period are shown in Table 31.

TMPA was readily converted in plants to more polar products. The metabolic pathways for TMPA varied dependent upon species of plant. The glucose ester was a main product in apple and vine plants. In orange, cabbages and bean plants, the malonylglucoside was mainly formed.

Further work was carried out using K^{14}CN . Two abscised cabbage leaves were treated for four hours with distilled water containing K^{14}CN and then transferred to K^{14}CN -free distilled water. The treated leaves were extracted at specific intervals after dosing with K^{14}CN , and the extracts were subject to TLC. There was a gradual increase in the amount of volatile ^{14}C trapped in NaOH solution, most of the radiocarbon was considered to be $^{14}\text{CO}_2$. At least six ^{14}C metabolites were present in the extracts of the abscised leaves treated with K^{14}CN . The extractable components in abscised leaves of cabbage over a 2 day period are shown in Table 32.

This study demonstrates that H^{14}CN liberated on ester hydrolysis of fenpropathrin and its derivatives would be rapidly incorporated into β -cyanoalanine, asparagines, aspartic acid and γ -glutamyl- β -cyanoalanine, with ultimate formation of $^{14}\text{CO}_2$ and unextractable ^{14}C residues.

Summary of plant metabolism

Metabolism of fenpropathrin has been studied in apples, tomatoes (fruiting crops), beans (legume crops), cotton (pulses/oilseed crops) and cabbage (leafy crops). Trials were carried out at approximately recommended rate with fenpropathrin labelled in the phenoxyphenyl, benzyl, cyclopropyl or cyano positions. The majority of radioactivity was found in leaf samples. Low levels of radioactivity were found in fruit/beans. Parent fenpropathrin was the primary component of the

residues in the fruits of the plants, but degradation products constituted the greater part of the residues present in the leaves. Breakdown products/metabolites detected in both fruits and leaves were similar to those detected in rats. It is therefore considered that crop residues are described adequately by defining them as the parent product alone.

The study on cabbage further demonstrated that after foliar application of ^{14}C -fenpropathrin the radiocarbon remaining on the treated leaves (as shown by the surface wash) decreased with concomitant increase of ^{14}C in the plant tissues. Most of the recovered radiocarbon was in the treated leaves and less than 1.2% of the applied radiocarbon was found in the untreated shoots indicating that fenpropathrin and its metabolites hardly translocate from the application site to other parts of the plant.

The general pattern of degradation in all the plant studies include breaking of the ester linkage to produce 3-phenoxybenzoic acid (PBacid) and the corresponding alcohol (PBalc) and aldehyde (PBald). From the acid side of the molecule, the main metabolite is 2,2,3,3-tetramethylcyclopropanecarboxylic acid (TMPA) which can give rise to 2-hydroxymethyl-2,3,3-trimethylcyclopropanecarboxylic acid (TMPA- CH_2OH) and 5-hydroxymethyl-6,6-dimethyl-3-oxabicyclohexan-2-one (TMPA- CH_2OH lactone). PBacid can be hydroxylated at various positions on the phenoxy ring to produce, α -cyano-3-(2'-or 4'-hydroxyphenoxy)benzyl 2,2,3,3-tetramethylcyclopropanecarboxylate (2'-or 4'-OH-fenpropathrin). The proposed metabolic pathway of fenpropathrin in plants is shown in Figure 2.

Figure 2 Metabolism and biotransformation pathway for fenpropathrin in plants

Environmental Fate in Soil

The fate and behaviour of fenpropathrin in soils was investigated using fenpropathrin labelled with ^{14}C either in the cyano group, the C-1 position of the cyclopropyl ring, the benzylic carbon or

uniformly in the phenoxyphenyl ring. The reports had been reviewed by the 1993 JMPR, no new study was submitted.

Aerobic soil metabolism

A 365-day aerobic soil metabolism study was conducted in 1989 using [benzyl-¹⁴C]-fenpropathrin (Cranor, 1990, Reference FM-91-0039). The test material was incubated in the dark at 25 °C with silt loam soil confirmed to be biologically active by plating and counting colonies. The nominal concentration of fenpropathrin was 10 µg/g soil; the measured concentration immediately after the addition was 10.2 µg/g. The soils were maintained at 70–75% field capacity throughout the study and sampled at intervals up to the end of the 365-day incubation. The samples were extracted with methanol (3–4 times) and then combusted to determine the un-extracted activity.

After 365 days, 18.4% of the dose remained as parent with accumulated volatiles accounting for 59.9% (99.8% of which was CO₂) and un-extractable residues for 17.8%.

During the whole course of the study the maximum levels of the metabolites were 1.25% PBacid (Day 1), 0.21% CONH₂-fenpropathrin (Day 122), 0.55% desphenyl-fenpropathrin (Day 122), 0.19% 4'-OH-fenpropathrin (Day 122) and 0.39% COOH-fenpropathrin (Day 61), all in terms of per cent of the initial dose. In addition there were maxima of 0.07 (Day 14), 0.28 (Day 365), 0.34 (Day 61) and 0.16% (Day 30) of unidentified products. The ¹⁴C mass balance for the whole period ranged from 98.7% to 107.1% with a mean of 102.3% and a value at the end of the study of 98.7%. The half-life was calculated, using a first order model, to be 152 days. These results were similar to those of previous degradation studies.

The production of labelled carbon dioxide was greatest from the cyano label over 208 days, and least from the phenoxyphenyl label (at day 148), indicating the relative readiness of the different parts of the molecule to mineralize. (Noble, 1976, Reference FR-61-0013).

In the soil extracts from the cyclopropyl label, the parent compound was the main component with small amounts of TMPA and unidentified polar compounds and, in one of the perfusions, the amide of fenpropathrin (CONH₂-fenpropathrin). No amide was found from the cyano label.

In the case of the phenoxyphenyl label, the liberation of carbon dioxide was much slower and the rates were erratic. Neither CONH₂-fenpropathrin nor PBacid was detected in the soils. In the perfusion mixtures, the main components isolated were the parent and unidentified hydrophilic compounds.

In the aerobic soil after 16 weeks, the most important component of the residue was the parent compound. The half-life of the fenpropathrin was about 4 weeks on moist soils (Leiston and moist Brenes) but more than 16 weeks on the drier ones (dry Brenes and Los Palacios). After 16 weeks the most prominent metabolite in drier soil was PBacid in the case of the phenoxyphenyl label and TMPA in the case of the cyclopropyl label (Roberts and Standen, 1976, Reference FR-61-0014). The other

two metabolites found were CONH₂-fenpropathrin and COOH-fenpropathrin, but these were scarcely detectable in the soils with high moisture (Brenes at 16% moisture and Leiston). In the study using Brenes soils, to detect volatile activity, the percentage of the applied radioactivity evolving as CO₂ after 26 weeks was 16.0%, with 71.8% as the intact parent compound and 11.6% as unextracted activity. Other degradation products were only present at negligible levels.

Mikami *et al.*, 1983 (Reference FM-30-0008) investigated two fresh Japanese soils, a sandy clay loam (Azuchi) and a light clay with 15% organic matter (Kodaira), under three different conditions: natural aerobic soil, anaerobic soil, and autoclaved aerobic soil. Under aerobic conditions the half-life of fenpropathrin was 11 and 17 days and after 24 weeks the level of fenpropathrin had declined from 1 mg/kg to 0.025 and 0.040 mg/kg respectively. After 8 weeks approximately 0.93 mg/kg remained under sterilized conditions. Sterilization retarded degradation, demonstrating the importance of biological processes. While there were only minor indications of degradation products in the sterile soils, at least 7 were detected in the methanol extracts of the non-sterile soil. With the cyclopropyl-labelled compound the main components of radioactivity were the parent fenpropathrin, desphenyl-fenpropathrin, 4'-OH-fenpropathrin, and small amounts of CONH₂-fenpropathrin and COOH-fenpropathrin. There were also indications of very small amounts of unidentified products. In the case of the phenoxyphenyl label, very low levels of PBacid were observed during the first 4 weeks. Un-extractable residues at the end of the study reached 44–45% of the added radioactivity in the Kodaira soil (the one containing a high proportion of organic matter), but only 24–32% in the lower-organic Azuchi soil. No TMPA was reported. A major part of the lost radioactivity was recovered as labelled CO₂ in fairly similar amounts from both labels.

Photodegradation in soil

Photodegradation studies carried out in Japan on light clay, sandy loam and sandy clay loam with fenpropathrin labelled with ¹⁴C in the cyano group, the phenoxyphenyl ring or the C-1 position of the cyclopropyl ring and applied to thin-layer soil plates (Takahashi *et al.*, 1983, 1985, Reference FM-30-0011). The fenpropathrin was applied at a rate of 1.1 µg/cm² and the plates exposed to natural sunlight for 14 days. Dark controls were run at the same time. Under irradiation, the half-lives of the CN-labelled fenpropathrin were between 1–5 days on the three soils. The mean fenpropathrin residues left in the soils at the end of the 14-day period amounted to 5.1, 29.4 and 32.9% of the amounts applied. The corresponding figures in the dark controls were 74, 84 and 96%; there was insufficient degradation for half-lives to be estimated. The main degradation product under irradiation with all three labels was CONH₂-fenpropathrin which reached a maximum in the three soils after 5, 7 and 7 days. Substantial amounts also occurred in the dark controls. For the most part, other metabolites were present in the irradiated soils in only very small amounts, except PBacid which reached a maximum of 11.4% of the total applied radioactivity after 7 days. Minor metabolites found were COOH-fenpropathrin, desphenyl-fenpropathrin, and 3-OH-Bacid. Loss of radioactivity from soils was greatly

enhanced by irradiation. The nitrile carbon was the most susceptible followed closely by the C-1 of the cyclopropyl group. The phenoxyphenyl group was a more stable part of the molecule.

Summary: Aerobic soil metabolism

Studies on the metabolism of fenpropathrin in soil demonstrated that fenpropathrin is degraded in the soil by a combination of photochemical and microbiological processes. Metabolism proceeds via cleavage of the ester bonds, hydroxylation, and hydrolysis of the cyano group to CONH_2 and COOH groups. The major products detected after aerobic metabolism were the parent fenpropathrin, CO_2 , and non-extractable residues. Metabolites included desphenyl-fenpropathrin, 4'-OH-fenpropathrin, phenoxybenzoic acid, and CONH_2 -fenpropathrin, which was further degraded to COOH -fenpropathrin. The proposed metabolic pathway of fenpropathrin in soil is shown in Figure 3.

Figure 3 Metabolism and biotransformation pathway for fenpropathrin in soil

Residues in Succeeding or Rotational Crops

The crops included in this evaluation are permanent or semi-permanent crops, for which rotational crop studies are not required. No study was submitted for evaluation.

Residue analytical methods

Analytical methods have been developed for determination of residues of fenpropathrin in plant and animal. In general, the methods involve solvent extraction, clean-up by either silica gel or Florisil column, GLC using electron capture detection. The main variations depending on the substrates are in the extraction and clean-up procedures. Fruits and vegetables may be homogenized with water, shaken with acetone, and extracted with dichloromethane, using NaCl to minimize emulsification. After drying with anhydrous sodium sulfate and clean-up by silica gel column chromatography, the solvent is evaporated at <40 °C and the residue dissolved in acetone before estimation by gas chromatography with electron capture detection. Other extraction procedures involve direct extraction of the homogenized material suspension in water or homogenization with methanol instead of water. The results of recovery studies carried out as part of method validation or concurrent recoveries obtained from supervised trial samples are summarised in Table 33.

Analytical methods for plant matrices

The base method, RM-22-4 consolidates RM-22-2 (for high moisture crops), RM-22-3 (for oily crops) and includes a procedure for processed oil and soapstock (Lai and Fujie, 1983; Reference FA-41-0040). Homogenized samples are extracted with hexane/acetone and cleaned up through silica gel and C18 solid phase extraction (SPE). Additional purification using gel permeation chromatography (GPC) are performed for oily matrices. Soapstock samples are dissolved in water, extracted with dichloromethane, before proceeding with the processed oil method which involves partition between hexane and acetonitrile and clean-up using alumina oxide. Analysis is by GC with electron capture detection (ECD) (column 3% OV 101 - high moisture and oily samples; DB-1 – processed oil and soapstock samples).

Method used for citrus fruit, pome fruit, grapes and their processed fractions

Citrus fruit samples were analysed using method RM-22-4, with modifications. Homogenized samples were extracted with hexane/acetone, partitioned into hexane and cleaned up with silica gel and C18 solid phase extraction (SPE). Residues of fenpropathrin were determined by gas chromatography with electron capture detection. The LOQ for the method was 0.01 mg/kg.

Method used for raspberry

Raspberry samples were analysed using the revised method RM-22-4 (revision May 1993), with modifications. Homogenized samples were extracted with hexane/acetone, partitioned into hexane and cleaned up with silica gel and C18 solid phase extraction (SPE). Residues of fenpropathrin were

determined by gas chromatography with mass spectrometry (MS)-SIM. The LOQ for the method was 0.02 mg/kg.

Method used for tomato and processed fractions, cucumber, melon and squash

Method RM-22-4 was used for the analysis of fenpropathrin in fruiting vegetables, cucurbits and fruiting vegetables other than cucurbits. The LOQ was 0.01 mg/kg. A revised RM-22-4 method (revision May 1993) using a DB-17 column and nitrogen phosphorus detection (NPD) was used for certain raw and processed tomato samples.

Method used for tea

Method RM-22-2 was revised for analysis of fenpropathrin in tea. Tea samples were extracted with an acetonitrile-water mixture and the extracts filtered under suction (Lavakumar, S., *et al.*, 2003; Report No. 11861 and Lavakumar, S., *et al.*, 2004; Report No.14246). The filtrate was concentrated then diluted with 5 percent aqueous sodium chloride solution and subjected to extraction with hexane-ether mixture. The combined extracts were filtered through sodium sulfate and evaporated to near dryness before being dissolved in 5 mL hexane. Clean-up was performed and the eluate evaporated and dissolved in acetone. Fenpropathrin was quantified by gas chromatography using an electron capture detector. The LOQ is 0.05 mg/kg.

Methods used for soya beans

Method RM 22-4 was modified for soya bean determination. Soya bean seeds were extracted with acetonitrile-ethyl acetate mixture, centrifuged and cleaned up through silica gel column with hexane. The extract was eluted with ethyl acetate-hexane mixture, evaporated to dryness and re-suspended in hexane. Fenpropathrin residues were determined by gas chromatography using a micro electron capture detector (Tomaz, 2013; Reference FR-0570). The LOQ for the method is 0.01 mg/kg.

In the other soya bean study, residues were extracted with acetonitrile and salt mixture and fenpropathrin analysed by liquid chromatography with mass spectrophotometric detection (LC/MS/MS) Lopez, 2012; Reference FR-0571). The LOQ for the method was 0.01 mg/kg.

Methods used for cotton matrices

Method RM 22-4 was modified for cotton matrix determination. Fuzzy seed and processing fractions were extracted with hexane-acetone and cleaned up using gel permeation chromatography or partitioned into acetonitrile for oil removal with clean up through silica gel and C-18 Sep Pak columns. For cotton seed oil, samples were dissolved in hexane, portioned into acetonitrile and cleaned up by alumina oxide column chromatography. For soapstock, samples were dissolved in water, partitioned into dichloromethane, partitioned between hexane and acetonitrile and cleaned up by alumina oxide column chromatography. Fenpropathrin residues were determined by gas

chromatography using an electron capture detector (Fujie, 1990; Reference FR-01-0306). The LOQ for the method is 0.01 mg/kg.

In the other soya bean study, residues were extracted with acetonitrile and salts mixture and fenpropathrin analysed by liquid chromatography with mass LC-MS/MS detection *utilising the transition of m/z 350→125*. The LOQ for the method is 0.01 mg/kg (Lopez, 2012; Reference FR-0571).

Method used for coffee beans

Coffee samples were extracted with water and 0.1% acetic acid in acetonitrile and a mixture of salts (anhydrous magnesium sulfate, sodium acetate and sodium chloride are added and the mixture centrifuged. An aliquot of the supernatant was transferred to a tube containing anhydrous magnesium sulfate and centrifuged. The extract was diluted in methanol:water (20:80) and residues of fenpropathrin were analysed by LC-MS/MS. The LOQ was 0.01 mg/kg (Gravena, 2013; Reference FR-0572)

Analytical methods for animal matrices

Method RM-22A-1 was used to analyse for fenpropathrin residues in milk and animal tissue samples in the feeding study (Fujie, 1986; FR-61-0174 and FR-61-0175). In summary, the method involves extraction with hexane/acetone, acetonitrile/hexane partitioning, silica gel column chromatography and measurement by gas chromatography using the electron capture detector. The method was validated with an LOQ of 0.01 mg/kg fenpropathrin. Control samples fortified with fenpropathrin were analysed together with treated samples from the feeding studies and the concurrent recoveries were within the acceptable range of 70–120%.

Multi-residue Methods

The multi-residue method DFG S19 was investigated and validated for the determination of fenpropathrin in acidic plant matrices high water content (tomatoes and oranges) (Class, 2003; Reference FA-0093). Samples were extracted with acetone/water, following neutralization of the pH in the case of oranges. Extracts were partitioned with ethyl acetate/cyclohexane in the presence of sodium chloride and cleaned up using gel permeation chromatography (GPC) and silica gel. Analysis was by GC-MS (ions m/z 181 and 265 for quantitation and 209 and 349 for confirmation). Recoveries (range and mean) and precision were within the acceptable limits. Linearity was demonstrated. There were no interfering peaks at the retention time for fenpropathrin in any of the crop matrices. The method is suitable for monitoring pesticide residues.

The multi-residue method DFG S19 was also validated for the determination of fenpropathrin in foodstuffs of animal origin (milk, bovine meat and fat, eggs) (Class, 2003; Reference FA-0094). Whole milk, egg and bovine meat samples were extracted with acetone/water and the extracts were partitioned with ethyl acetate/cyclohexane in the presence of sodium chloride. Fat samples were

extracted with ethyl acetate/cyclohexane. Extracts were cleaned up using gel permeation chromatography (GPC) and silica gel. Analysis was by GC-MS (ions m/z 181 and 265 for quantitation and 125, 152, 209 and 349 for confirmation). Recoveries (range and mean) and precision were within the acceptable limits. Linearity was demonstrated. There were no interfering peaks at the retention time for fenpropathrin in any of the animal matrices. The validated LOQ is 0.01 mg/kg for animal tissues and eggs. The method can be used for enforcement of MRLs and monitoring of residues.

A summary of recovery data from the methods used for plant and animal commodities supported in this submission are presented in the table 33.

^a Data presented are only for registered uses and from studies submitted in this document.

Storage Stability under Frozen Conditions

The stability of fenpropathrin residues in commodities under frozen conditions has been investigated in apples, orange, cotton, pears, grapes, tomato and its processed products as well as in products of animal origin.

In addition to these individual studies, storage stability determinations, together with procedural recovery analyses were also carried out concurrently with the field trial samples for strawberry, olives (fruit and oil), cucumber, squash, melon, peppers, milk, eggs and kidney. All these storage stability studies are summarized below. For samples analysed within 30 days of harvest (soya beans, coffee beans, eggs and poultry tissues), storage stability requirements have been waived. The results are summarised in Table 34.

In general, results of the storage stability tests confirmed that residues of fenpropathrin in stored frozen samples were stable within the period of storage between sampling and analyses.

Apple, orange, cotton, pears and grapes

The stability of field incurred fenpropathrin was investigated in five matrices (Fujie, 1986; Reference FR-61-0190). Samples taken from residues trials conducted with fenpropathrin 2.4 EC were stored at -20 °C and four replicate samples taken at 3, 6, 9 and 12 months during storage. Fortified control samples (0.1 mg/kg) were analysed concurrently with each set of samples to validate analytical method recovery. Homogenized samples were extracted with hexane/acetone and cleaned up through silica gel and C18 solid phase extraction (SPE) (method RM-22-4). Additional purification using gel permeation chromatography (GPC) was performed for oily matrices (method RM-22-4). Analysis was by GC with electron capture detection (ECD).

Orange oil and dried peel

The stability of field incurred fenpropathrin was investigated in orange oil and dried peel samples from a processing study (Fujie, 1990; Reference FR-01-0307). Duplicate samples taken from processing study were stored at -20 °C and samples taken after 11 months storage. Analysis was by methods RM-22-4 and RM-22-2.

Strawberry

The storage stability data for strawberries were obtained by reanalysis of retained samples from a previous field trial (Mitten, 1989; Reference FR-11-0345). Samples harvested on 07.04.89 were received frozen in the laboratory on 18.04.89, macerated on 25.04.89 and were extracted for the initial analysis on 28.04.89. After sub-sampling, the retained samples were stored at -20 °C with periodic subsampling for reanalysis using method RM-22-4. The results demonstrate that fenpropathrin is stable in strawberries up to six months in frozen storage.

Raspberry

The storage stability data for strawberries were obtained by reanalysis of retained samples from a previous field trial (Samoil, 2007; Reference FR-0560). Samples were fortified with 2 mg/kg fenpropathrin then stored frozen for 216 days. Analysis using modified method RM-22-4.

Grape products

The storage stability of fenpropathrin in samples of grape juice, dry and wet pomace, hydrated raisins and raisin waste was determined from incurred residues from the field trial sites (Fujie, 1990; Reference FR-01-0335). Samples were held in frozen storage under similar conditions to the field generated samples.

Olive fruit and olive oil

The storage stability of fenpropathrin in samples of olive fruit without pit and in olive oil was determined by fortifying samples with 2 mg/kg fenpropathrin after receipt from the field trial sites (Samoil, 2007; Reference FR-0561). Samples were held in frozen storage under similar conditions to the field generated samples. After 208 days (olive fruit without pits) and 202 days (olive oil), the storage stability samples were analysed by method RM-22-4.

Cucumber

The stability of fenpropathrin residues in cucumber samples stored frozen under the same conditions as the field trial samples, was determined as part of the field phase of the study (Samoil, 1999; Reference FR-0556). Untreated samples from two field sites were fortified at 11.4 mg/kg fenpropathrin and returned to storage at -20 °C, together with the field trials samples. After 245 and 286 days in storage, the storage stability and field samples were analysed.

Melons

Storage stability of fenpropathrin on melons was determined as part of the field trial study (Green, 1995; Reference FR-0375). Untreated samples fortified at 0.1 mg/kg fenpropathrin were stored at -20°C under the same conditions as the field trial samples. Duplicate analyses were conducted on the day of fortification and again after 187 days of storage.

Squash

Storage stability of fenpropathrin in squash samples was verified by taking untreated control samples, fortifying at 1 and 11 mg/kg with fenpropathrin, and storing in freezers under the same conditions as the field samples. Storage stability samples were analysed after 230 days in storage (Samoil, 1999; Reference FR-0557).

Tomatoes and tomato canning waste

The stability of fenpropathrin was investigated in tomatoes (fortified samples) and tomato canning waste samples (field incurred residues) from a processing study (Lai, 1990; Reference FR-21-0344). Duplicate samples taken from a processing study were stored at -20 °C and samples taken after various time periods up to 6 months storage. Analysis was by method RM-22-4.

Tomato paste, tomato juice, wet and dry tomato pomace

The stability of fenpropathrin was investigated in tomato paste, tomato juice and wet and dry tomato pomace from a processing study (Green, 1994; Reference FR-41-0360). Duplicate control samples taken from a processing study were fortified at 0.1 mg/kg, stored at -20 °C and samples taken after 5 months storage. Analysis was by methods RM-22-4.

Non-bell peppers

Samples from field trials were fortified with fenpropathrin at 10 mg/kg and stored frozen at -25 °C for 323 days (Samoil, 2001; Reference FR-0558). 323

Milk and bovine kidney

The stability of fenpropathrin in milk when stored at -20 °C was determined by fortifying control milk samples bought from a store, with 0.1 mg/kg fenpropathrin and stored at -20 °C along with the milk samples from the residue feeding study (Fujie, 1986; Reference FR-61-0174). The fortified milk samples were analysed at a time interval greater than the storage interval for milk from the feeding study.

To determine the stability of fenpropathrin in tissues, kidney samples from the feeding study were reanalysed following an appropriate interval which reflected the time interval between sacrifice and the initial analyses. The analytical method RM-22A-1 was used to analyse all samples. Reanalysis of kidney samples following an additional 71 days in storage at -20 °C resulted in a mean recovery of 104% of initial analyses results.

Eggs

The stability of fenpropathrin in eggs following storage at -20 °C was determined by fortifying control egg samples bought from the store, with 0.1 mg/kg fenpropathrin and stored at -20 °C along with the egg samples from the residue feeding study (Fujie, 1986; Reference FR-61-0175). The fortified egg

samples were analysed at a time interval greater than the storage interval for eggs from the feeding study.

Table 34 Summary of results of storage stability studies

Commodity	Spike level (mg/kg)	Storage interval (months)	Procedural recoveries (%)	Residues remaining (%)

USE PATTERN

Fenpropathrin is registered for use on a large number of crops in many countries, but only the registered use patterns for the crops for which supervised trials were provided are summarised in Table 35.

Table 35 Registered uses of fenpropathrin

Crop	Country	Formulation		Application				PHI (days)
		g ai/L or g ai/kg	type	Method	Rate kg ai/ha	Water L/ha	No or/ Season max kg ai/ ha	
Cane fruit	USA	300 g/L	EC	Foliar (by ground or aerial application)	0.22- 0.34	28-94 (aerial); 187 minimum (ground)	0.67 kg ai/ha/season 14-day intervals	3
Citrus	USA	300 g/L	EC	Foliar (by ground or aerial application)	0.22- 0.45	187 (aerial); 468- 4700 (ground)	0.9 kg ai/ha/season; 10-day intervals	1
Coffee	Brazil	300 g/L	EC	Foliar (by ground equipment)	0.06-0.12		2	14
Cotton*	USA	300 g/L	EC	Foliar (by ground or aerial application)	0.22- 0.45	28-94 (aerial); 94- 468 (ground)	0.9 kg ai/ha/season	21
Grapes	USA	300 g/L	EC	Foliar (by ground or aerial application)	0.22- 0.45	230-1870 (air or ground)	0.9 kg ai/ha/season; 7-day intervals	21
Fruiting vegetables, Cucurbits, including cucumber, muskmelon, honeydew melon, pumpkin, squash, watermelon	USA	300 g/L	EC	Foliar (by ground or aerial application)	0.22- 0.34	28-94 (aerial); 187- 935 (ground)	0.9 kg ai/ha/season; 7-day intervals	7
Fruiting vegetables other than cucurbits, including tomato, eggplant, peppers	USA	300 g/L	EC	Foliar (by ground or aerial application)	0.22	47- 94 (aerial); 234- 1122 (ground)	0.9 kg ai/ha/season; 7-days interval	3
Olive	USA	300 g/L	EC	Foliar (by ground equipment)	0.22- 0.34	935	0.9 kg ai/ha/season; 14-day intervals	7
Pome fruit	USA	300 g/L	EC	Foliar	0.22- 0.45	700- 3740	0.9 kg ai/ha/season; 10-days interval	14

Crop	Country	Formulation		Application				PHI (days)
		g ai/L or g ai/kg	type	Method	Rate kg ai/ha	Water L/ha	No or/ Season max kg ai/ ha	
Soya beans	Brazil	300 g/L	EC	Foliar (by ground equipment)	0.045		1	30
Stone fruit	USA	300 g/L	EC	Foliar (by airblast equipment)	0.22- 0.45	935- 3740	0.9 kg ai/ha/ season; 10-days interval	3
Strawberry	USA	300 g/L	EC	Foliar (by ground equipment)	0.22- 0.45	935- 2800	0.9 kg ai/ha/ season ≥30-day intervals	2
Tea	India	300 g/L	EC	Foliar (by knapsack sprayer)	0.05- 0.06 kg ai/ha (0.01- 0.015 kg ai/hL)	400- 500		7
Tree nuts	USA	300 g/L	EC	Foliar (by airblast equipment)	0.22- 0.45	468- 3740	0.9 kg ai/ha/ season; 10-days interval	3

Note: GAPs in the USA specify total seasonal rates in addition to individual application rates, therefore the seasonal maximum dose rate is considered primarily in evaluation of supervised trials.

* Do not feed gin trash or treated forage to livestock or allow animals to graze treated fields

RESIDUES RESULTING FROM SUPERVISED TRIALS

Supervised trials have been conducted to support MRLs for the following crops citrus fruits, peach, plum, strawberries, olives, cucumber, melon, squash, tomato, peppers, soya beans, tree nuts, coffee beans and tea. The results of these supervised trials are summarized in the following tables:

Crop Group	Commodity	Table No.
Citrus fruit	Orange, lemon, grapefruit	36
Pome fruit	Apple, pear	37
Stone fruit	Peach, plum, cherry	38
Berries and other small fruits	Strawberry	39
	Raspberry	40
	Grape	41
Tropical/Subtropical fruits – edible peel	Olives	42
Fruiting vegetables, cucurbits	Cucumber	43
	Melon	44
	Squash	45
Fruiting vegetables other than cucurbits	Tomato	46
	Pepper	47
Pulses	Soya beans	48
Oilseeds	Cottonseed	49

	Cottonseed hulls	53
Tree nuts	Almonds, pecans	50
	Almond hulls	54
Seeds for beverages and sweets	Coffee beans	51
Teas	Tea, green, black	52

In addition to the description and details of the field trials and analytical methods, each report includes a summary of the procedural recoveries, and in many cases, concurrent recoveries in stored frozen samples.

In the trials, where multiple samples were taken from a single plot, the average value is reported. Where results from separate plots with distinguishing characteristics such as different formulations, different crop varieties or different treatment schedules were reported, results are listed for each plot.

Results have not been corrected for concurrent method recoveries. Residues and application rates have generally been rounded to two significant figures or, for residues near the LOQ, to one significant figure. Residue values from the trials conducted according to the maximum GAP have been used for the estimation of maximum residue levels. Those results included in the tables are underlined.

Citrus fruits

A total of 31 supervised trials were conducted in the United States on citrus fruits (18 on oranges, 6 on lemons and 7 on grapefruit). The trials on oranges were carried out from 1984 to 1987 and consisted of one to four applications of an EC formulation containing 300 g/L fenpropathrin, applied at rates ranging from 0.11 to 0.45 kg ai/ha for a total seasonal rate ranging from 0.11 to 1.8 kg ai/ha (Fujie, 1990; Reference FR-01-0307). Duplicate samples of mature oranges, consisting of a minimum of 10 fruits, were collected at various PHIs (0 day to 35 days). In some trials, fenpropathrin was applied pre-planting and sampled at normal harvest, 180 days after application.

The seven supervised trials on grapefruit in 1991 were all according to the US GAP for citrus fruits. The composite samples consisted of 16 fruits.

Upon harvest, all samples were frozen and maintained frozen at -20 °C until analysis. Samples from the field trials were analysed within this demonstrated period of stability (9 months for oranges, one month for lemons, and two months for grapefruit). All samples were analysed using analytical method RM-22-4 with a limit of detection of 0.01 mg/kg.

* Report showed this value for “control samples”. Trial samples residues were reported as < 0.01 mg/kg. The report indicated mislabelling.

Pome fruits

Apple, pear

Forty-seven supervised trials on pome fruit (27 in apples and 20 in pears) were conducted in the USA in 1984–1987, using a higher number of applications compared to the GAP in the USA (up to 0.9 kg ai/ha and a PHI of 14 days) (Fujie, 1990, Fujie and Leary, 1986; Reference: FR-81-0305, FR-01-0370, FR-81-0304, FR-01-0369). The EC formulation of fenpropathrin containing 300 g/L active ingredient, was applied to treated plots at the rates of 0.9–7.2 kg ai/ha from 7 to 42 days prior to harvest.

Samples were analysed within 1 year of harvest using the methods described in section of Methods of residue analysis, which were validated to an LOQ of 0.01 mg/kg. Concurrent recoveries

from control samples fortified with fenpropathrin at levels of 0.1 and 0.2 mg/kg were within the acceptable range of 70-120%, with RSD below 20%. Results of the trials are summarized in Table 37.

Table 37 Residues of fenpropathrin in pome fruits resulting from supervised trials in the USA

*Stone fruit**Peach, plum, cherry*

Supervised trials were conducted on stone fruits in the USA during 2003. Ten of the trials were on peaches (Green, 2004; Reference FR-0384), six on cherries (Green, 2004; Reference FR-0381), and seven on plums (Green, 2004; FR-0385). All trials were according to the US GAP on stone fruit, which includes applications of fenpropathrin 300 g/L EC formulation at the rate of 0.45 kg ai/ha for a maximum seasonal application of 0.9 kg ai/ha. Duplicate samples of mature fruits were collected 3 days after the last application. Sample size for peach ranged from 2.6 to 8.5 kg, ≥ 24 fruit. Upon collection, all samples were frozen at -20 °C until extraction and analysis. All of the samples were analysed within the documented storage stability interval analysed using analytical method RM-22-4 (LOQ 0.01 mg/kg). Concurrent recoveries were within the acceptable range of 70 to 120%.

Berries and other small fruit

Strawberry

Ten supervised trials on strawberries were conducted in the US in 1987 and 1989 (Mitten, 1991; Reference FR-11-0345). Two additional trials were carried out in 1991 (Lai, 1992; Reference FR-21-0346). Eleven of the trials matched the current GAP in the US for strawberries (applications at 0.22 to 0.45 kg ai/ha for a total of 0.9 kg ai/ha per season and a PHI of 2 days). At several sites, replicate trials were carried out to study the effect of application rate and PHI on the residues in harvested samples. Mature samples were collected two days after the last application and immediately stored frozen at -20 °C until analysis. Samples from the trials were analysed within this storage stability period with method RM-22-4. Concurrent recoveries from fortified samples analysed together with field samples ranged from 81-115%, mean = 98.3%, with RSD of 8.2% (n=27).

Raspberry

Seven supervised trials on raspberries were conducted in the USA in 2005 (Samoil, 2007; Reference FR-0560) with higher rate and shorter PHI than the current GAP (applications at 0.22 to 0.34 kg ai/ha for a total of 0.67 kg ai/ha per season and a PHI of 3 days). Mature samples were collected 2–3 days after the last application and immediately stored frozen at -20 °C until analysis. Samples from the trials were analysed within this storage stability period 216 days with method RM-22-4. Concurrent recoveries ranged from 74–110%, mean = 98.3%, with SD of 8.2% (n=10).

Grapes

Twenty five supervised trials were conducted on grapes in the USA during 1983-2001. (Fujie, 1990; Fujie, 1992, Green, 2002; FR-01-0308, FR-01-0335, FR-01-0374). All trials were within the US GAP on grapes. Duplicate samples of mature fruits were collected 21 days after the last application.

All samples were analysed using analytical method RM-22-4 with an LOQ of 0.01 mg/kg within the storage stability period. Concurrent recoveries were within the acceptable range of 70 to 120%.

Assorted Tropical and Subtropical Fruits – Edible Peel

Olives

Three supervised trials were conducted on olives in the USA during 2005 (Samoil, 200; Reference FR-0561). Each trial consisted of one treated and one untreated plot, except CA64, which had two treated plots. At each trial, two applications of fenpropathrin 2.4 EC were made 7 days apart to treated plots at the rate of 0.45 to 0.48 kg ai/ha for a total of 0.9 kg ai/ha. In one plot for trial CA64, two applications at 5× rate (2.3 kg ai/ha for a total of 4.64 kg ai/ha) were made, to provide samples for processing into olive oil.

Samples of mature olive fruits were taken 7–8 and 14–15 days after the last treatment. Pits were removed from the olives. Samples were immediately frozen at -20 °C until analysis in 200 days. The samples were analysed for residues of fenpropathrin using the method “Determination of fenpropathrin in olive, Revision 0”, a method based on method RM-22-4. The method was validated with an LOQ of 0.02 mg/kg for olives. Concurrent recoveries obtained during sample analysis ranged from 69 to 103% for olive fruit without pits. Note that apparent residues at levels of 0.01–0.03 mg/kg were seen in all control samples of olives without pits. The report explained that this should have no adverse effect on the data for treated olives since the residue levels obtained were at least 40× the magnitude of those from the controls.

Fruiting Vegetables, Cucurbits

Cucumber

Six supervised trials on cucumber were conducted in the USA in 1994 and 1996 (Samoil, 1999; Reference FR-0556). The EC formulation of fenpropathrin containing 300 g/L active ingredient, was applied 3 to 5 times to treated plots at the rate of 0.21 to 0.24 kg ai/ha for a total application of 0.7 to 1.1 kg ai/ha per plot. Applications were made at weekly intervals. At maturity, 6 to 8 days after the last application, samples were harvested and immediately frozen at -20 °C. Samples were analysed within the storage stability period with RM-22-2 (LOQ of 0.01 mg/kg). Concurrent recoveries from fortified samples analysed together with the field samples ranged from 66–115% (mean = 89%, RSD= 13.8%, n=15).

Melon

Ten supervised trials on melons (cantaloupe) were conducted in the USA in 1994 (Green, 1995; Reference FR-0375). The EC formulation of fenpropathrin containing 300 g/L active ingredient, was applied 4 times to treated plots at the rate of 0.22 kg ai/ha for a total application of 0.9 kg ai/ha per plot. Applications were made at weekly intervals using tractor mounted boom sprayers or CO₂-powered backpack sprayers. At maturity, 7 days after the last application, samples were harvested and immediately frozen at -20 °C. In two trials, samples were also collected 1, 3, and 14 days, and on days 3 and 7 after application. In two trials samples of treated melons were sectioned, separating the rind from the flesh. The samples were stored up to 107 days before analysis. Samples were analysed by method RM-22-4, which was validated to an LOQ of 0.01 mg/kg. Concurrent recoveries from fortified samples analysed together with the field samples ranged from 82–98% (mean = 90%, RSD= 4.3%, n=16).

Squash

Seven supervised trials on summer squash were conducted in the US in 1994 and 1996 (Samoil, 1999; Reference FR-0557). The EC formulation of fenpropathrin containing 300 g/L active ingredient, was applied 4 times to treated plots at the rate of 0.2 to 0.25 kg ai/ha for a total application of 0.85 to 0.98 kg ai/ha per plot. Applications were made at weekly intervals. Samples were analysed with

method RM-22-2 (LOQ of 0.01 mg/kg). Concurrent recoveries from fortified samples analysed together with the field samples ranged from 80–116% (mean = 97%, RSD= 11.8%, n=11).

Fruiting Vegetables other than Cucurbits

Tomato

Nine supervised trials conducted on tomatoes in the USA in 1993 (Green, 1994; Reference FR-41-0360). Treated plots received 4 applications of an EC formulation containing 300 g/L fenpropathrin, at the rate of 0.22 kg ai/ha, for a total application of 0.88 kg ai/ha. Mature tomato samples were

collected 3 days after the last application and for decline trials, samples were also collected 1, 14, and 21 days after the last application. Upon collection, samples were stored at -20 °C until analysis. All samples from this study were analysed within this validated storage interval. Residues of fenpropathrin were determined by method RM-22-4 with modifications. Concurrent recoveries from fortified samples analysed together with the field samples were within the acceptable range of 70 to 120%.

Peppers

A total of ten supervised trials on peppers (six on bell and four on non-bell) were conducted in the US in 1996 and 1998 (Samoil, 2001; Reference FR-0558). The application rates corresponded to US GAP (0.22 kg ai/ha with a total application of 0.9 kg ai/ha per season, but samples were taken at 2 and 4 days instead of the 3 day PHI. Samples of mature peppers were immediately frozen at -25 °C to -15 °C until analysis. Samples were analysed for residues of fenpropathrin using a modification of method RM-22-4. All recoveries were conducted concurrently with the analyses of treated samples and storage stability samples. Non-bell peppers fortified with fenpropathrin at 0.02, 0.10, 0.50, and 10 mg/kg showed respective recoveries of 100-130%, 95%, 92%, and 88-104%. Bell peppers were fortified with fenpropathrin at 0.02, 0.10, 0.40, 0.50 and 1.0 mg/kg and recoveries were 100–107%, 97–101%, 94–106% and 98%, respectively.

Pulses

Soya beans

Eight supervised trials on soya beans were conducted in Brazil in 2010 and 2013 (Tomaz, 2010; Reference: FR-0570 and Lopez, 2013; Reference: FR-0571). The EC formulation of fenpropathrin containing 300 g/L active ingredient, was applied to treated plots at the rate of 0.045 kg ai/ha from 15

to 45 days prior to harvest. At maturity, 15, 30 and 45 days after the last application, samples were harvested, threshed manually, cleaned, sieved, air-dried and stored frozen at -20 °C. Samples were analysed within 30 days of harvest by GC-ECD (2010 trials) and LC-MS/MS (2013 trials) (LOQ of 0.01 mg/kg). Concurrent recoveries were within the acceptable range of 70–120%, with RSD below 20%.

Oilseeds

Cotton

Thirty-two supervised trials on cotton were conducted in the USA in 1983-1989, using a higher number of applications compared to the GAP in the USA (up to 0.9 kg ai/ha and a PHI of 21 days) (Fujie, 1990Reference: FR-01-0306). The EC formulation of fenpropathrin containing 300 g/L active ingredient, was applied to treated plots at the rates of 0.112-0.448 kg ai/ha from 18 to 35 days prior to harvest. Samples were analysed within 12–18 months of harvest. Concurrent recoveries from control

samples fortified with fenpropathrin at levels of 0.1 and 0.2 mg/kg were within the acceptable range of 70–120%, with RSD below 20%.

*Tree Nuts**Almonds and pecans*

A total of ten supervised trials on tree nuts, five on almonds and five on pecans have been conducted in the US in 2003, following the GAP for tree nuts (Green, 2004; References FR-0382 and FR-0383). Two applications of fenpropathrin 2.4 EC were made to each treated plot at the rate of 0.45 (1×) or 0.90 kg ai/ha (2×). Applications were made at 7-day intervals. Samples of almond hulls as well as almond and pecan nutmeats were collected 3 days after the last application. At one site, samples were also collected at 1, 7, and 14 days after the last application.

All samples were immediately frozen and stored at -20 °C until analysis. Residues of fenpropathrin in nutmeats were analysed using method RM-22-4. The method was modified for analysis of a 10 gram (instead of a 20 gram) sample. The LOQ remained 0.01 mg/kg. Recoveries obtained for the fortified almond and pecan nutmeat samples were between 83.5 and 119%, and 70.9 and 89.6%, respectively.

Coffee Beans

Six supervised trials on coffee were conducted in Brazil in 2013 (Gravena, 2013. Reference FR-0572). Two applications of fenpropathrin EC containing 300 g ai/L were made to each treated plot at the rate of 0.12 kg ai/ha (1×). Applications were made at 14-day intervals. Samples of coffee berries were collected 14 days after the last application. In two trials, samples were also collected at 7 and 21 days after the last application. All samples were collected manually and packed in polyethylene bags for further processing. The berries were immediately sent to the experimental station and maintained at room temperature until completion of drying. Samples were dried by opening the bags throughout the day and night, except during rainy days when the packages were sealed. After drying, the coffee beans were placed in a manual peeler and at least 1 kg of coffee beans were packed, labelled, and stored frozen at -20 °C until analysis.

All samples were analysed LC-with LC-MS/MS (LOQ of 0.01 mg/kg) within 30 days following harvest. Average recovery from control samples fortified with fenpropathrin at levels of 0.01 and 0.5 mg/kg ranged from 79–116% (n=13; mean=98%; and RSD = 15.3%).

Tea

All supervised trials on tea were conducted in India during 2002-2004 (Lavakumar, 2003 and 2006; References 1424604-2974-2002; 1424604-4190-2004). All trials were according to the GAP for tea in India, which consists of one application of fenpropathrin at the rate of 0.06 kg ai/ha and a PHI of 7 days.

In ten trials, the collected tea leaves were processed into black tea. In six trials this was achieved through withering, crush/tear/curl process, oxidation and drying while in other trials by machine drying.

In two additional trials, the collected tea leaves were air-dried to prepare green tea. Since growing conditions and application rate/method for black tea and green tea are equivalent with the only difference being in processing methods, results from both sets of trials can be combined to support an MRL and STMR for tea, green and black.

Residues of fenpropathrin were analysed by a method based on RM-22-4 with an LOQ of 0.05 mg/kg.

Animal feeds

The trial conditions are described under the corresponding food commodities.

Cottonseed hull

Samples were analysed within 12–18 months of harvest. Concurrent recoveries from control samples fortified with fenpropathrin at levels of 0.1 and 0.2 mg/kg were within the acceptable range of 70–120%, with RSD below 20%.

Almond hulls

All samples were immediately frozen and stored at -20 °C until analysis. Residues of fenpropathrin in hulls were analysed using method RM-22-4. The method was modified for analysis of a 10 gram (instead of a 20 gram) sample. The LOQ remained 0.01 mg/kg. Recoveries obtained for the fortified almond hull samples were between 90.3 and 115%, with an average recovery of 103%.

FATE OF RESIDUES IN STORAGE AND IN PROCESS

Processing studies on plums, tomato, olives, oranges, cottonseed and tea were conducted and are summarized in this section.

Processing orange into juice, oil, and other fractions

Orange samples from the following supervised trials treated at 1× or 2× the GAP application rate were sent for processing after harvest: Trials T-6389, T-6390, T-6640, T-6730, and T-6966 (Reference FR-01-0307). The study determined the magnitude of residues in raw unwashed and washed orange samples, peel, pulp, wet and dried peel, molasses, oil and juice.

Duplicate samples were harvested 1–7 days after the last application, and sent to the processor. Samples were stored frozen for up to 9 months before analysis by GC-ECD (method RM-22-4). Orange oil samples were extracted into hexane, partitioned with acetonitrile and extracts purified through alumina oxide (method RM-22-2).

Samples were variously washed by hand, separated into pulp and peel, and processed into wet and dried peel, molasses, oil and juice. Fruit was washed in an in-line foam washer with soap and rinsed with water. Juice was extracted using an automated FMC in-line extractor and the sample passed through a juice finisher with 200 mesh, the juice being collected in a holding tank.

The resulting oil, water, peel, frit emulsion from the FMC extractor was passed through an in-line FMC finisher with 200 mesh screen and collected in a holding tank. This emulsion was heated to 49°C and appropriate enzymes added. The emulsion was then centrifuged to separate out the oil. The peel, rag, frit and seeds (together called as peel) from the juice and oil finishers were deposited in a peel hopper. This was further processed by being shredded and combined with 0.3% dehydrated lime slurry.

The slurry was then pressed (4.82 bar) and molasses collected from the press. The remaining pulp from the press was dried to approximately 8% moisture content and passed through a cyclone separator and cooler and collected. Dry fines were collected from the bottom of the cyclone separator. Procedural recoveries were 77-115% (mean 95% ± 7% RSD, n=57) at fortification levels of 0.1–2.0 mg/kg.

Processing plums to dried plums/prunes

Plums from trial V-25427-F [treated twice with 1.8 kg ai/ha (2x) per application] were processed to dried plums (Reference FR-0385) by drying in a dehydrator at 187°C for approximately 18 hours. After drying, samples were frozen and analysed within 176 days of harvest of fresh plums.

In another study, fresh plum samples from Trial V-27220-A treated at the GAP rate of 0.9 kg ai/ha were dried in a drying tunnel at about 185 °C (Reference FR-0559) for approximately 18 hours. The dried prunes were pitted by hand, bagged and frozen at -20 °C until analysis within 195 days from harvest of fresh samples. The period of storage was within the demonstrated stability of plums under frozen conditions.

All samples were analysed for fenpropathrin using a modification of method RM-22-4 which is described under analytical methods. Concurrent recoveries of fortified samples ranged from 70–120%.

Table 56 Residues of fenpropathrin in fresh and dried plums

Matrix	Residues (mg/kg)	Average (mg/kg)	Processing factor	Reference (Trial No.)

Plum (RAC) – prior to processing	0.22, 0.23	0.23		FR-0559
Dried plum	0.58, 0.57	0.58	2.6	
Average			1.8	

Processing tomatoes to pomace, juice, paste and other fractions

The magnitude of residues in raw unwashed and washed tomatoes, canned and pre-canned tomatoes, wet and dry pomace and juice was determined following applications of a 2.4 EC at 1.5× GAP rate (Reference FR-21-0344). Duplicate samples of mature green fruit were sent to the processor. Certain samples were gas-ripened or vine ripened before being sampled for analysis. Samples were stored at -20 °C for up to 5 months before analysis by GC-ECD (method RM-22-4), as described above in section 3. Gas ripened fruit was held in an atmosphere of 0.008–0.015%v/v ethylene at 20 °C for 3–6 days before being sampled. Samples were variously washed in chlorine solution, waxed and/or processed into pre-canned and canned tomatoes, wet and dry pomace, juice and paste. The canning process involved washing in chlorine solution followed by a water rinse, peeling by placing in 20%

sodium hydroxide (lye) solution at 79 °C, rinsing in water, dipping in 1% citric acid solution and further rinsing. Once tomatoes were placed in the can hot (100°C) tomato juice was added and the can was sealed and heated for 55 minutes at 100 °C. Procedural recoveries were 83–112% (with the exception of one sample of green fruit at 130%) at fortification levels of 0.01–0.2 mg/kg.

In another study, the magnitude of residues in raw tomatoes, wet and dry pomace, juice and paste were determined following applications of a 2.4 EC at 7.5× GAP rates to commercial crops (Reference FR-41-0360). Duplicate samples of mature green fruit were harvested 3 days after the last application and sent to the processor. Samples were stored at -20 °C and were analysed within 5 months by GC-ECD (method RM-22-4). Samples were hand sorted and defective fruit were discarded as cannery waste. The tomatoes were then soaked in a 0.5% lye solution for 3 minutes at 54 °C and rinsed using a high pressure spray for 30 seconds. Samples were then batch steam peeled at 5.6–7 bar pressure and processed through a pulp finisher machine where the pulp/pomace was separated from juice. The wet pomace was dried to produce dry pomace and the juice concentrated in a batch vacuum concentrator to approximately 30–32% solids. 1% salt was added to the resulting paste and the temperature was raised to 90 °C before the paste was sealed in cans. The cans were subject to heating at 100 °C for 20 minutes in a water batch before being cooled under running tap water. Juice was reconstituted from the paste with water, salt and ascorbic acid, heated to 90 °C, canned, and the cans treated as for canned paste.

Procedural recoveries were 94–105% (with the exception of two samples of dry pomace at 78 and 118%) at fortification levels of 0.1 mg/kg.

Processing olive fruit to oil

Samples for processing to olive oil were obtained from trial CA64 where olive plants were treated with fenpropathrin at approximately 5× the GAP application rate (Samoil, 2007; Reference FR-0561). After harvest, the fruits were pitted and delivered at ambient temperature to the processing facility, where the olives were processed into oil. The samples were cleaned of extraneous materials and then subjected to cold water wash and crushed. After crushing, the olives were pressed by hydraulic press to produce olive oil, which was then subjected to bleaching. Processed olive oil was stored at -20 °C until analysis. The storage period was recorded as 167 days. Storage stability samples fortified with 0.2 mg/kg fenpropathrin were stored under the same conditions as the field samples and were analysed after 202 days. Recoveries ranged from 85–93% for olive oil.

Residues of fenpropathrin were determined by a method based on RM-22-4. The method was validated using store-bought oil. Recoveries ranged from 94–103%. The LOQ for olive oil was determined to be 0.02 mg/kg.

Table 58 Residues of fenpropathrin in olive oil

Processed Fractions	Residues (mg/kg)	Processing factor	Reference (Trial No.)
Olive fruit (RAC)	14.63		Trial CA64
Olive oil	15.60	1.07	(FR-0561)

Processing cottonseed to oil, meal and soapstock

Samples for processing to cottonseed oil into meal, oil and soapstock were obtained from trials M335-6070, M355-6071 and R194-6427 where cotton plants were treated with fenpropathrin using a range of application rates and timings (Fujie, 1990; Reference FR-01-0360). A Carver impact huller was used to obtain the fractions (kernels and hulls). The kernels were flaked in a Ferrell-Ross "flake-n-roll" to 0.02 mm thickness. The flakes were washed three times with hexane at a temperature of approximately 145 °C. This extraction process took 3 hours. The oil was recovered with a precision laboratory evaporator. During this process the oil reached a maximum temperature of 75 °C. Warm air was forced through the extractor to dissolve the cotton seed flakes. The oil was refined by the following steps:

1. NaOH was added to the oil while it was stirred at 250 rpm at a temperature of 20–24 °C for 15 minutes.
2. The oil was heated to 63–67 °C for 12 minutes and the stirring reduced to 70 RPM.
3. The oil was then allowed to settle for 60 minutes at a temperature of 60–65 °C.
4. The oil was refrigerated overnight or at least for 12 hours.
5. After refrigeration the oil was filtered to obtain the refined oil and soapstock fractions.

The processed samples were stored at -20 °C until analysis. Recoveries ranged from 78–99% for processed products.

Fenpropathrin residues were determined by gas chromatography using an electron capture detector (Fujie, 1990; Reference FR-01-0306). Recoveries ranged from 94–103%. The LOQ for the method was 0.01 mg/kg. Table 59 summarizes the results of the cottonseed processing study.

Table 59 Residues of fenpropathrin in cottonseed products

RESIDUES IN ANIMAL COMMODITIES

Livestock Feeding Studies

Lactating dairy cattle

Lactating Holstein cows were orally administered technical grade fenpropathrin (purity 92.5%) via gelatin capsules for 28 consecutive days (Fujie, 1986; Reference FR-61-0174). Treatment levels were equivalent to 0, 25, 75 and 250 ppm fenpropathrin based upon the daily average food consumption of 18.54 kg/cow. Each dose was administered in two equal portions at the morning and evening milkings. Each treatment group consisted of four animals, except the control group which consisted of 2 animals. Controls animals were administered empty gelatin capsules only.

Milk samples were collected from individual animals in two portions corresponding to the morning and evening milkings on the days -1, 0, 3, 5, 8, 12, 16, 20, 24 and 28. Milk from days 26 and 27 (250 ppm and control groups) were pooled and processed to obtain pasteurized milk, milk fat solids (cream), milk sugars and protein concentrate. At day 28, three animals from each treatment group were sacrificed and samples of liver, kidney, fat and muscle were collected and frozen for analysis. Administration of fenpropathrin then ceased and the animals received untreated diet. At day 31, the remaining animal from each dose group and one of the control animals were sacrificed and tissues sampled accordingly.

Samples of control milk were fortified with fenpropathrin, stored and analysed to confirm the stability of fenpropathrin over the sample storage period (78 days). An average recovery of 105% indicated stability of fenpropathrin in milk samples. Milk samples in the study were stored from 37 to 73 days at -20 °C prior to analysis.

All samples were analysed for fenpropathrin using method RM-22A-1 within the test period of storage stability. Residues of fenpropathrin in the milk reached a plateau after three days. Average residues in the whole milk of the four cows of each group on Day 3 were 0.04, 0.17, and 0.33 mg/kg for the three dose levels.

Fenpropathrin residues in milk and tissues from animals sacrificed at days 28 and 31 are summarized in Tables 61–63. Residue levels were found to be dose related.

Table 61. Residues of fenpropathrin in milk (mg/L) following administration of fenpropathrin to dairy cows for periods of up to 28 days followed by a 3 day depuration phase

Dose Level (mg/kg)	Day/residue (mg/kg)														Mean

Milk from sampling days 26 and 27 of the highest dose group were pooled and processed to obtain pasteurized milk, milk fat solids (cream), milk sugars and protein concentrate. The results show that pasteurization does not significantly reduce fenpropathrin residues in milk. Fenpropathrin concentrates in milk fat by a factor of about 10× (from mean of 0.34 mg/kg in whole milk to 3.7 mg/kg in milk fat). There is no concentration of fenpropathrin in milk sugars and protein concentrate (Table 64).

Laying Hens

Groups of 20 White Leghorn laying hens were fed a diet containing technical grade fenpropathrin (purity 94.5%) at a nominal concentration of 0, 2.5, 7.5 and 25 ppm (measured concentrations: 2.45, 7.10 and 23.6 ppm) for a period of 28 days (Fujie, 1986; Reference FR-61-0175). The number and weight measurements of body weight and feed consumption were taken at regular intervals during the study.

At study termination, all birds were examined macroscopically. Composite samples of liver, gizzard, fat and muscle were prepared for analysis. Eggs from days 1, 2, 4, 7, 21 and 28 were analysed as whole eggs minus shell. Stability samples of treated diet were taken for analysis during the study. To determine the stability of fenpropathrin in stored eggs, control samples were fortified with fenpropathrin, stored and analysed at a time interval greater than the storage interval for eggs from the feeding study. An average recovery of 92% of fenpropathrin was obtained after 156 days of storage at -20 °C. All samples were analysed within 30 days of collection and storage.

Eggs and tissues were analysed for fenpropathrin. The method involved extraction with hexane/acetone, acetonitrile/hexane partitioning, silica gel chromatography and analysis by GC-ECD. Residues were found in the eggs only at the highest feeding level. A level of 0.02 mg/kg was reached on the seventh day and remained essentially constant until the end of the study. Average levels of fenpropathrin in the fat reached 0.02, 0.05 and 0.14 mg/kg for the three feeding levels. Residues in all tissues except fat were below the lower limit of determination, 0.01 mg/kg, at the end of the study. Metabolites could only be detected in liver after dosing with 25 ppm were TMPA (0.05 mg/kg) and PBA-glycin (0.03 mg/kg). The distribution of residues between white and yolk was not studied.

Fenpropathrin residues in eggs and poultry tissues from hens sacrificed at day 28 are summarized in Tables 65 and 66. Residue levels were found to be dose related.

APPRAISAL

Fenpropathrin is a type II pyrethroid insecticide and acaricide used for the control of a variety of arthropods including aphids, worms, moths, beetles, mites, spiders, thrips, flies, fleas and other pests in agriculture.

Fenpropathrin was first evaluated by JMPR in 1993 when an ADI of 0–0.03 mg/kg bw was established and a number of MRLs recommended. In 2006 MRL for tea was recommended. The compound was re-evaluated for toxicology within the periodic review programme in 2012 when the Meeting reaffirmed the ADI of 0–0.03 mg/kg bw and established an ARfD of 0.03 mg/kg bw.

The Forty-fifth Session of the CCPR scheduled fenpropathrin for periodic re-evaluation of residues by the 2014 JMPR. Data to support proposed Codex MRLs on a number of commodities and on animal products were submitted for review.

The structural formulae and IUPAC name of fenpropathrin are:

(*RS*)- α -cyano-3-phenoxybenzyl 2,2,3,3-tetramethylcyclopropanecarboxylate.

METABOLISM AND ENVIRONMENTAL FATE

The metabolism of fenpropathrin has been investigated in apple, tomato, beans, cotton, cabbage, lactating goat and laying hens. The crops selected represent those for which supervised trials have been provided.

The fate and behaviour of fenpropathrin in plants, animals and soil were investigated using either [cyclopropyl-1-¹⁴C]-fenpropathrin, [benzyl-¹⁴C]-fenpropathrin, [phenoxyphenyl-¹⁴C]-fenpropathrin or [cyano-¹⁴C]-fenpropathrin (all with radiochemical purity >98%).

[cyclopropyl-1-¹⁴C]-fenpropathrin

[cyano-¹⁴C]-fenpropathrin

[phenoxyphenyl-¹⁴C]-fenpropathrin

[benzyl-¹⁴C]-fenpropathrin

The chemical and code names and structure of the major degradation compounds, referred to hereunder, are:

Compound Name	Structure	Found in:
2'-or 4'-OH-Fenpropathrin [α -cyano-3-(2'- or 4'-hydroxyphenoxy)benzyl 2,2,3,3-tetramethylcyclopropanecarboxylate]		Plant, animal, soil
2'- or 4'-OH-Fenpropathrin-CH ₂ OH [α -cyano-3-(2'- or 4'-hydroxyphenoxy)benzyl-2-hydroxymethyl-2,3,3-trimethylcyclopropanecarboxylate]		Plant, animal
CONH ₂ -Fenpropathrin [α -carbamoyl-3-phenoxybenzyl 2,2,3,3-tetramethylcyclopropanecarboxylate]		Soil, water plant
COOH-Fenpropathrin [α -carboxy-3-phenoxybenzyl 2,2,3,3-tetramethylcyclopropanecarboxylate]		Soil, plant
Desphenyl-Fenpropathrin [α -cyano-3-hydroxybenzyl 2,2,3,3-tetramethylcyclopropanecarboxylate]		Animal, soil, plant
Fenpropathrin-CH ₂ OH [α -cyano-3-phenoxybenzyl 2-hydroxymethyl-2,3,3-trimethylcyclopropanecarboxylate]		Plant, animal
Fenpropathrin-COOH [α -cyano-3-phenoxybenzyl 2-carboxy-2,3,3-trimethylcyclopropanecarboxylate]		Animal
Fenpropathrin-(CH ₂ OH) ₂ [α -cyano-3-phenoxybenzyl 2,2-dihydroxymethyl-3,3-dimethylcyclopropanecarboxylate]		Plant
2'- or 4'-OH-Fenpropathrin-(CH ₂ OH) ₂ [α -cyano-3-(2'- or 4'-hydroxyphenoxy)benzyl 2,2-dihydroxymethyl-3,3-dimethylcyclopropanecarboxylate]		Plant
PB aldehyde (PBald) [3-phenoxybenzaldehyde]		Plant, animal, soil
PB alcohol (PBAlc) [3-phenoxybenzyl alcohol]		Plant, soil
PBacid [3-phenoxybenzoic acid]		Plant, animal, soil, water

Compound Name	Structure	Found in:
2'- or 4'-OH-PBalc [3-(2'- or 4'-hydroxyphenoxy)benzyl alcohol]		Plant
2'- or 4'-OH-PBacid [3-(2'- or 4'-hydroxyphenoxy)benzoic acid]		Plant, animal, soil
3-OH-Bacid [3-hydroxy-benzoic acid]		Animal, soil
TMPA [2,2,3,3-tetramethylcyclopropane-carboxylic acid]		Plant, animal, soil, water
TMPA-CH2OH [2-hydroxymethyl-2,3,3-trimethylcyclopropanecarboxylic acid]		Plant, animal
TMPA-lactone [5,6,6-trimethyl-3-oxabicyclohexan-2-one]		Plant
TMPA-CH2OH lactone [5-hydroxymethyl-6,6-dimethyl-3-oxabicyclohexan-2-one]		Plant, animal
TMPA carboxamide [2,2,3,3-tetramethylcyclopropane-carboxamide]		Water
TMPA-COOH [2-carboxy-2,3,3-trimethylcyclopropanecarboxylic acid]		Plant, animal

Animal metabolism

Laboratory animals

The toxicological evaluation fenpropathrin was carried out by the 2012 JMPR. Absorption by rats was rapid and excretion was almost complete (97%) within 48 hours. About 56% of the administered dose was found in urine and 40% in faeces after 48 hours. The amount of radioactivity excreted via expired air was 0.005%. The low residues found in blood, liver, kidney, fat, muscle and brain 24 hours after dosing depleted rapidly over the following 7 days to barely detectable levels, and less than 1.5% of the administered dose remained in the body 8 days after treatment. The highest residue was found in the fat. About 29–53% of the parent compound was detected in the faeces and no parent compound was detected in the urine. The predominant urinary metabolites derived from the acid moiety were identified as TMPA–glucuronide and TMPA-CH₂OH (*trans*). Other metabolites identified were

TMPA-COOH (*trans*) and TMPA-CH₂OH-lactone in free form or as the glucuronide. The major urinary metabolites derived from the alcohol moiety were PBacid in free form and as the glycine conjugate, 4'-OH-PBacid-sulfate and 2'-OH-PBacid-sulfate. The urinary metabolites from the alcohol moiety were similar to those from other pyrethroids. The major faecal metabolite was identified as CH₂OH *trans*-fenpropathrin, followed by COOH *trans*-fenpropathrin, 4'-OH-fenpropathrin and 4'-OH,CH₂OH *trans*-fenpropathrin. Fenpropathrin and TMPA were the major components of ¹⁴C in tissues. No sex-related differences in tissue distribution were observed.

Lactating goats

Two lactating goats per group were dosed for five consecutive days via capsules with either [phenoxyphenyl-¹⁴C]-fenpropathrin or [cyclopropyl-1-¹⁴C]-fenpropathrin at a rate equivalent to 50 ppm. Milk samples were collected at the morning and afternoon and urine and faeces once a day.

The mean average total radioactivity recovered following dosing with both labelled compounds was about 65.8% with 40% recovered in the urine and 25% in the faeces.

Excretion via milk was a minor route with radioactivity accounting for approximately 0.15% of the applied phenoxyphenyl labelled and approximately 0.087% for the cyclopropyl labelled compound. Total radioactive residues in the milk reached a steady state by the evening milking on the third day.

Following the treatments with 50 ppm [phenoxyphenyl-¹⁴C]-fenpropathrin, the maximum total residue in milk was 0.25 mg/L. The major residue components were the parent fenpropathrin 78% TRR, (0.02 mg/kg). At around the plateau, the average concentration of the parent compound was 0.05 mg/kg (29%TRR) and PBacid-glycine 0.076 mg/kg (46%TRR). The other metabolites were < 10% TRR.

At sacrifice, the average residues were: in fat: fenpropathrin (0.50 mg/kg, 78%TRR), all metabolites were present at lower than 5%TRR; in muscle: fenpropathrin (0.011 mg/kg, 45%TRR), PBacid-glycine (22.4% TRR), PBacid (10.9% TRR) the other metabolites were below 3%; in liver: fenpropathrin (0.014 mg/kg, 3.2% TRR), PBacid-glycine (20%TRR), PBacid (14% TRR), 4'-OH-PBacid (11%TRR), the other metabolites were below 10% TRR; in kidney: fenpropathrin (0.01 mg/kg, 1.24%TRR), PBacid-glycine (39%TRR), PBacid (38%TRR) and the other metabolites were below 10%.

After the goats were administered with [cyclopropyl-1-¹⁴C]-fenpropathrin, the average total residue in milk was 0.11 mg/L. The parent compound in milk amounted to maximum 70% TRR (0.086 mg/kg). All metabolites amounted to maximum 4% TRR.

At sacrifice, the average residues were: in fat: fenpropathrin (0.55 mg/kg, 81% TRR), all metabolites were present at lower than 3%TRR; in muscle: fenpropathrin (0.005 mg/kg, 11.3% TRR), TMPA-CH₂OH-lactone (19.4% TRR) andTMPA-CH₂OH (11%TRR); in liver: fenpropathrin

0.011 mg/kg (2.45% TRR), TMPA (18.2%TRR), TMPA-CH₂OH (15.8%TRR) and TMPA-CH₂OH lactone (12.5% TRR); in kidney: fenpropathrin 0.0076 mg/kg (1.48% TRR), TMPA-CH₂OH-lactone (40.8% TRR) and TMPA-CH₂OH (14.5% TRR) .

The other metabolites in muscle, liver and kidney were below 5%TRR.

Laying hens

Fenpropathrin, labelled in either the cyclopropyl or the phenoxyphenyl ring was administered in capsules to laying hens daily for 10 days at a nominal rate of either 0.5 or 5 mg/kg body weight.

The recovery of total radioactivity from excreta, eggs and tissues was between 75 and 84% of the total applied dose. Between 98.9 and 99.6% of the recovered activity was found in the faeces irrespective of the label.

Approximately 0.05% of the applied phenoxyphenyl- and 0.2% of the cyclopropyl-labelled compound was found in the eggs. At about the 6th or 7th day of the study residue levels in the eggs reached a plateau of about 0.05 and 0.2 mg/kg fenpropathrin equivalent for the two doses of the phenoxyphenyl-labelled and about 0.2 and 0.5 mg/kg for those of the cyclopropyl-labelled compounds.

In case of high dose group treated with phenoxyphenyl-labelled compound, the average concentration of parent fenpropathrin amounted to 31% of TRR (0.043 mg/kg) in eggs and all identified metabolites were present at less than 10%TRR. In breast and thigh muscle, the average proportions of residues (%TRR) were: parent compound 19% (0.02 mg/kg), PBacid (22%), 3-OH-BAcid (13%). In liver and kidney the average percentage distributions of TRR were, respectively: parent (0.98%, 2.11%; 0.014 mg/kg, 0.096 mg/kg), 3-OH-BAcid (29%, 35%), 4-OH-PBacid (16%, 26%) and PBacid (14.7%, 8.7%). The other metabolites were <10% TRR in all tissues.

In case of cyclopropyl label the average concentration of parent fenpropathrin amounted to 9.8% TRR (0.038 mg/kg) in eggs, and one major metabolite, TMPA-CH₂OH, was present at 11.7% TRR. All other metabolites amounted to <10% TRR and their concentrations were < 0.03 mg/kg. In muscle, the average proportions of residues (%TRR) were: parent compound 6% (0.033 mg/kg), TMPA-CH₂OH (16%), TMPA (15.7%), TMPA-CH₂-OH-lactone (12.3%. All other metabolites amounted to <10% TRR and their concentrations were < 0.03 mg/kg. In liver and kidney the average percentage distributions of TRR were, respectively: parent (1.2%, 0.04 mg/kg; 5.1%; 0.24 mg/kg), TMPA (26.4%, 47.5%), TMPA-CH₂OH (14.7%, 7.7%), TMPA-CH₂-OH-lactone (14.8%, 5.3%), TMPA-COOH (11.4%, 15.3%). The other metabolites were present at < 1.8%TRR.

The metabolic pattern in fat was similar in case of both labels. The fat contained maximum 0.90 mg/kg total residue of which the parent compound amounted to 64%TRR (0.58 mg/kg). The most prominent metabolite was TMPA (14%TRR), the other metabolites occurred at < 6% TRR.

In summary, the major biotransformation reactions of fenpropathrin in animals consisted of oxidation at the methyl groups of the acid moiety and at the 2'- or 4'-positions of the alcohol moiety, cleavage of the ester and ether linkages and conjugation of the resultant carboxylic acids and alcohols.

The parent compound was detected in milk, eggs and tissues, and it was the main residue in fat about 80%TRR. The major metabolites >10% TRR following the treatment with phenoxyphenyl-labelled fenpropathrin were PBacid-glycine, PBacid and 3-OH-BAcid, and after dosing with cyclopropyl-labelled compound the major metabolites were TMPA-CH₂OH, TMPA, TMPA-CH₂-OH-lactone and TMPA-COOH.

Plant metabolism

Apples

One apple tree was treated 3 times with [cyclopropyl-1-¹⁴C]-fenpropathrin and [benzyl-¹⁴C]-fenpropathrin at a rate equivalent to 0.45 kg ai/ha. Samples were collected 14 days after the final application. Un-extractable residues ranged from 3% (both labels in fruit) to 8% (benzyl label in leaves).

Practically, the entire residue found in the fruit (92-94% TRR) was present as the parent compound. The parent compound was also the major component in the rest of the plant (61–66%TRR). All metabolites were < 5%TRR.

Tomatoes

Greenhouse-grown tomato plants were treated four times, 7–8 days apart, with [cyclopropyl-1-¹⁴C]-fenpropathrin and [benzyl-¹⁴C]-fenpropathrin at rates equivalent to 0.224 kg ai/ha. Fruit and leaves were extracted at harvest 19 DALT).

The total radioactive residues were 0.1 mg/kg and 0.4 mg/kg in fruits after treatments with benzyl and cyclopropyl labelled compound and consisted of the parent compound in about 66% of the benzyl label and 28% of conjugated metabolites. Their proportion was about the opposite for cyclopropyl label. The non-extractable residues were between 5.5% and 6.7%. Because of their low level, the radioactivity could not be fully characterised.

In tomato plants, the parent compound was present in 36–39% of TRR (0.1-0.04 mg/kg). Of the identified metabolites only fenpropathrin-(CH₂OH)₂ was present in free form (2.7–3.1% TRR). Numerous other metabolites were in conjugated forms. Non-extractable residues amounted to 7.4–9.3%.

In another study where tomato plants were treated in greenhouse four times with [cyclopropyl-1-¹⁴C]-fenpropathrin and [phenoxyphenyl-¹⁴C]-fenpropathrin at a rate equivalent to 0.224 kg ai/ha. Fruits and plant materials, sampled 3 days after last application, contained the parent

compound in 96–98% of TRR. Polar metabolites amounted to 1.3% of TRR. The surface rinses contained 98–99% of the parent compound determined in the fruits.

Beans

Pinto bean plants grown in greenhouse were treated three times with [cyclopropyl-1-¹⁴C]-fenpropathrin and [benzyl-¹⁴C]-fenpropathrin at a rate equivalent to 0.224 kg ai/ha. Samples were collected 15 days after the final application. Leaves and plant parts contained 98.8%, bean pods and seeds contained 1.1% and 0.1% of the residue. In beans treated with benzyl- and cyclopropyl-labelled compound, the residue in seed was composed of the parent compound (4.1% and 0.1% of TRR), conjugated metabolites (61–51% TRR) free metabolites (17–4%TRR) and un-extractable residues 18.2%–45% TRR. The bean leaves contained 46.7% parent compound and conjugates of PBald (19.5%TRR) after treatment with benzyl labelled compound. After treatment with cyclopropyl-labelled compound the residue composed of 46.4% parent fenpropathrin and conjugates of TMPA-CH₂OH (16.7%TRR). The other metabolites were present at < 10% TRR.

Cotton

Two studies were conducted treating cotton plants with [phenoxyphenyl-¹⁴C]-fenpropathrin and [cyclopropyl-1-¹⁴C]-fenpropathrin.

In the first study the plants were treated in greenhouse four times with syringe applying a total of ca. 4.7–4.8 mg ¹⁴C-fenpropathrin. In the leaves at harvest 66 and 111 days after treatments with phenoxyphenyl- or cyclopropyl labelled compound the total remaining radio activity included 70% TRR and 55% TRR parent compound, respectively. Most of the remaining radio activity was tentatively accounted for PBacid (2.% TRR) and trans-TMPA-COOH (11%TRR) mainly in conjugated forms. All other metabolites were below 2%TRR.

Plants grown on soils treated with 0.5 kg/ha of fenpropathrin contained ¹⁴C residues in very low concentration (0.002 mg/kg in leaves and 0.01 mg/kg in bolls), demonstrating limited tendency for translocation.

In the second study outdoor cotton plants were treated four times at a rate equivalent to 0.336 kg ai/ha. Seeds collected 21 day after last treatment contained total radioactivity 1.14 mg/kg and 1.59 mg/kg, while the foliage contained 78.6 mg/kg and 67.7 mg/kg fenpropathrin equivalent after treatment with phenoxyphenyl- and cyclopropyl-labelled fenpropathrin, respectively. The seed, lint and foliage contained the parent fenpropathrin in 93.8%, 96.2% and 69.2% TRR, respectively, after treatment with phenoxyphenyl -labelled compound. The seed contained 12 metabolites each at < 0.005 mg/kg concentration. Following the application of cyclopropyl-labelled fenpropathrin the parent compound amounted to 85.6%, 100% and 67.4% TRR in seed, lint and foliage, respectively. A small number of metabolites were also detected, but not identified.

Cabbage

Cabbage plants were treated on the 3rd-4th leaves with [cyano- ^{14}C]-fenpropathrin), [cyclopropyl- ^{14}C]-fenpropathrin and [phenoxyphenyl- ^{14}C]-fenpropathrin at a rate equivalent to about 0.09 kg ai/ha. The cabbages were sampled immediately after application and at 3, 7, 14, 21, 28, 35 and 42 days after application. The proportions of parent fenpropathrin in 28-day samples after treatment with cyano-, cyclopropyl- and phenoxyphenyl-fenpropathrin were 16.9%, 15.8% and 12.9% of the applied dose, respectively, and it was present at somewhat lower proportion in 48-day samples. The major part of the residue (23-26% AD) composed of the conjugates of 2'-OH-fenpropathrin- CH_2OH , 4'-OH-fenpropathrin- CH_2OH , 2'-OH-fenpropathrin- $(\text{CH}_2\text{OH})_2$ and 4'-OH-fenpropathrin- $(\text{CH}_2\text{OH})_2$ and TMPA- CH_2OH -lactone-conjugate (11%). The other metabolites were present at $\leq 10\%$ TRR after treatments with cyclopropyl- and phenoxyphenyl-labelled compounds.

Most of the recovered radiocarbon was in the treated leaves and less than 1.2% of the applied radiocarbon was found in the untreated shoots indicating that fenpropathrin and its metabolites hardly translocate from the application site to other parts of the plant.

Fate of hydrogen cyanide (HCN) and TMPA in abscised leaves

The fate of HCN and TMPA in abscised leaves of apple, kidney bean, cabbage, mandarin orange, tomato and vine was studied. Two abscised leaves from each plant were placed in 100 mL distilled water containing ^{14}C -TMPA at a concentration of 1.0 ppm. After cultivation for five days the leaves were extracted with methanol:chloroform:water (4:2:1).

TMPA was readily converted in plants to more polar products. The metabolic pathways for TMPA varied dependent upon species of plant. The glucose ester was a main product in apple and vine leaves. In orange, cabbages and bean leaves, the malonylglucoside was mainly formed.

Further on, two abscised cabbage leaves were treated for four hours with distilled water containing K^{14}CN and then transferred to K^{14}CN -free distilled water. The study demonstrated that if hydrogen cyanide were liberated during the hydrolysis of fenpropathrin, it would be rapidly converted to natural products.

Summary of plant metabolism

Metabolism of fenpropathrin has been studied in apples, tomatoes, beans, cotton and cabbage.

The general pattern of degradation in all the plant studies include break of the ester linkage to produce 3-phenoxybenzoic acid (PBacid) and the corresponding alcohol (PBalc) and aldehyde (PBald). From the acid side of the molecule, the main metabolite is TMPA which can give rise to TMPA- CH_2OH and TMPA- CH_2OH lactone. PBacid can be hydroxylated at various positions on the phenoxy ring to produce, 2'-or 4'-OH-PBacid.

The majority of radioactivity was found in leaf samples. Low levels of radioactivity were found in fruit/beans. The parent fenpropathrin amounted to the major part of the residue. Fenpropathrin and its metabolites hardly translocate from the application site to other parts of the plant.

Environmental fate

In soil

Studies on the metabolism of fenpropathrin in aerobic soil carried out with [phenoxyphenyl-¹⁴C]-fenpropathrin demonstrated that fenpropathrin is degraded in the soil by a combination of photochemical and microbial processes. After 365 days, 18.4% of the dose remained as parent with accumulated volatiles accounting for 59.9% (99.8% of which was CO₂) and un-extractable residues for 17.8%. Metabolism proceeds via cleavage of the ester bonds, hydroxylation, and hydrolysis of the cyano group to CONH₂ and COOH groups. Metabolites included desphenyl-fenpropathrin, 4'-OH-fenpropathrin, phenoxybenzoic acid, and CONH₂-fenpropathrin, which was further degraded to COOH-fenpropathrin. The estimated half-life was about 4 weeks in moist soil (70–75% field capacity) and 16 weeks in a dryer soil with 16% water content.

Photodegradation studies were carried out with fenpropathrin labelled with ¹⁴C in the cyano group, the phenoxyphenyl ring or C-1 position of the cyclopropyl ring. Irradiation greatly enhanced degradation of the fenpropathrin. The main degradation product under irradiation with all three labels was CONH₂-fenpropathrin which reached a maximum in the three soils after 5–7 days during the 14-day exposition.

Fenpropathrin is moderately stable in soil under aerobic condition. The photolysis increased the degradation of the surface residues.

Hydrolytic degradation

Fenpropathrin is stable to hydrolysis in water at pH 5 and pH 7 but it is hydrolysed at a moderate rate at pH 9.

Rotational crops

No study was submitted on rotational crops.

Methods of analysis

Analytical methods have been developed for determination of residues of fenpropathrin in plant and animal matrices. In general, the methods involve solvent extraction, clean-up by either silica gel or Florisil column, GLC using electron capture detection. Additional purification using gel permeation chromatography (GPC) was performed for oily matrices. The main variations depending on the substrates are on extraction and clean-up procedures. Fruits and vegetables may be homogenized with

water, shaken with acetone, and extracted with dichloromethane, using NaCl to minimize emulsification. After drying with anhydrous sodium sulphate and clean-up by silica gel column chromatography, the solvent is evaporated at $< 40^{\circ}\text{C}$ and the residue dissolved in acetone before determination by gas chromatography with electron capture detection. Other extraction procedures involve direct extraction of the homogenized material suspension in water or homogenization with methanol instead of water. The methods were generally validated at 0.01 mg/kg LOQ level. The RSD of recoveries was $< 20\%$

A multi residue method (DFG S19) was validated for the determination of fenpropathrin in plant materials of high water content and acidic plant matrices applying GC-MS detection (m/z 181 and 265 for quantification and 125, 152, 209 and 349 for confirmation).

In a supervised trial on soya bean, the residues were determined with LC-MS/MS utilising the transition of m/z 350 $\rightarrow$ 125. The LOQ was 0.01mg/kg.

Stability of residues in stored analytical samples

The stability of fenpropathrin residues in commodities under frozen conditions has been investigated in apples, orange, cotton, pears, grapes, tomato and its processed products as well as in products of animal origin.

Fenpropathrin was shown to be stable at least for the indicated periods (month) in: apple, orange, cotton, pears and grapes (12);cucumber (8); grape juice, dry pomace (14) wet pomace (12), hydrated raisins and raisin waste (11); melons (6); non-bell peppers (10); olives, olive oil (~ 7); orange oil and orange dried peel (11); raspberries (7); squash (7.5); strawberries (6); tomato (6), tomato paste (5), tomato juice (5) and wet and dry tomato pomace (5) tomato waste (5).

The residues were stable in eggs for 5 months, and milk and kidney at least for 2.5 months.

Definition of the residue

Livestock animal metabolism studies were conducted on lactating goats (50 ppm in feed) and laying hens (0.5 and 5 mg/kg body weight) applying [phenoxyphenyl- ^{14}C]- and [cyclopropyl-1- ^{14}C]-fenpropathrin.

In milk, at around the plateau at 3–5 days, the parent compound amounted to the major part of residues 28% TRR, (0.02 mg/kg) and 66% TRR, (0.086 mg/kg), respectively. The major metabolites were PBacid-glycine (46% TRR) from phenoxy label and all other metabolites were below 3%TRR from cyclohexyl label.

Following the treatments with 50 ppm [phenoxyphenyl- ^{14}C]-fenpropathrin the average residues of the parent fenpropathrin amounted to 0.50 mg/kg (78%TRR) in fat, 0.011 mg/kg (45% TRR) in muscle, 0.14 mg/kg (3.2% TRR) in liver and 0.01 mg/kg (1.2% TRR) in kidney. The major

metabolites in these tissues were PBacid-glycine (20–39% TRR), PBacid (11–38% TRR) and 4'-OH-PBacid (11% TRR). The other metabolites were present at lower than 10% TRR.

After the goats were administered with [cyclopropyl-1-¹⁴C]-fenpropathrin, the average residues comprised of the parent compound 0.55 mg/kg (81% TRR) in fat, 0.005 mg/kg (11% TRR) in muscle, 0.11 mg/kg (2.5% TRR) in liver and 0.0076 mg/kg (1.5% TRR) in kidney. The major metabolites in these tissues were TMPA-CH₂OH-lactone (19–41% TRR), TMPA (18%TRR), TMPA-CH₂OH (11–16%TRR). The other metabolites were below 5%TRR.

In hens, the parent fenpropathrin was a major residue 0.043 mg/kg (31%TRR) and 0.038 mg/kg (9.7%TRR) in eggs following treatments with benzyl- and cyclopropyl-labelled compounds. The only metabolite exceeding 10% TRR was TMPA-CH₂-OH from cyclopropyl label. Following dosing with benzyl label, the average concentration of parent compound was 0.43 mg/kg (29%TRR) in fat, 0.029 mg/kg (1.6% TRR) in muscle, 0.096mg/kg (7%TRR) in kidneys and 0.014 mg/kg (1% TRR) in liver. After dosing with cyclopropyl label, the average concentration of parent compound was 0.033 mg/kg, (1.55%TRR) in muscle, 0.21 mg/kg (10% TRR) in kidneys, 0.036 mg/kg (2% TRR) in liver. The main metabolites from hens dosed with the benzyl-labelled compound were 3-OH-Bacid (4–29%TRR) or 4'-OH-PBacid (4–16% TRR and PBacid 3.2–24% TRR). While from the cyclopropyl-labelled group the TMPA (6–26% TRR) and its CH₂-OH, COOH, CH₂-OH-lactone derivatives (9–41%TRR) were the major metabolites. Several of these metabolites are also formed from other pyrethroid insecticides.

The parent fenpropathrin was the major residue in milk, meat and eggs and it was detected at low concentrations in liver and kidney. The polar metabolites listed above and the minor ones identified are of no toxicological significance.

The Meeting concluded that the parent fenpropathrin is a suitable marker for animal commodities for both enforcement and dietary risk assessment.

As the fenpropathrin residue concentrates in the fat, based on the distribution of residues in various tissues, supported by the logP_{ow} of 6.0 for fenpropathrin, the Meeting concluded that the fenpropathrin residue is fat soluble.

The fate of fenpropathrin residues was studied in apples, beans, cabbages, cotton and tomatoes. The parent fenpropathrin is the major residue in apple fruits (92–94% TRR), tomato fruits (30–66% TRR), in bean leaves (46% TRR), bean seeds (up to 4.1% TRR), in cabbage leaf extract (up to 16% TRR) and cotton seed (up to 94% TRR). The major metabolites were the conjugates of 2'-OH-fenpropathrin-(CH₂OH)₂ and of 4'-OH-fenpropathrin-(CH₂OH)₂ (max 19–22% TRR in cabbage), all other metabolites (1.3–9.8%TRR) were < 10% TRR in case of all labelled compounds.

The nature of metabolites is similar to that goats and hens. The polar metabolites listed above are of no toxicological significance.

The Meeting concluded that the parent fenpropathrin is suitable marker for plant commodities for both enforcement and dietary risk assessment.

Validated analytical methods, suitable for enforcement, are available for detecting fenpropathrin in various matrices.

The Meeting agreed in the following residue definition:

Definition of residue for compliance with MRL and for estimation of dietary intake for animal and plant commodities is the parent fenpropathrin.

The residue is fat soluble.

Results of supervised residue trials on crops

The Meeting received supervised trial data on citrus fruits, pome fruits, stone fruits, berries and small fruits, fruiting vegetable, cucurbits, olives, soya beans, cotton, tree nuts, coffee beans and tea.

The HR values were estimated based on the residues measured in single samples.

Citrus fruits

A total of 31 supervised trials were conducted in the United States on citrus fruits (18 on oranges, 6 on lemons and 7 on grapefruit). The current maximum GAP for citrus in the USA consists of two applications at 0.45 kg ai/ha with a total seasonal rate of 0.90 kg ai/ha and a PHI of 1 day.

The average residues in duplicate composite samples derived from treatments corresponding to US GAP were: in oranges: 0.05, 0.07, 0.12, 0.18, 0.25, 0.26, 0.27, 0.33, 0.33, 0.46, 0.53, 0.96, 1.2 mg/kg; in lemons: 0.51, 0.56, 1.2 mg/kg; in grapefruits: 0.12, 0.18, 0.2, 0.34, 0.34, 0.37, 0.47 mg/kg.

The Meeting noted that the GAP in USA is for citrus fruits, that the residue populations were not significantly different (Kruskal-Wallis H-test) and the median residues were within the 5 times range. Furthermore, the Meeting concluded that the residue data sets for lemons, oranges and grapefruits are suitable for estimation of residue levels for the citrus group. The meeting agreed to combine the datasets which in rank order were: 0.05, 0.07, 0.12, 0.12, 0.18, 0.18, 0.2, 0.25, 0.26, 0.27, 0.33, 0.33, 0.34, 0.34, 0.37, 0.46, 0.47, 0.51, 0.53, 0.56, 0.96, 1.2, 1.2 mg/kg.

The Meeting estimated a maximum residue value of 2mg/kg and, based on the processing factor of 0.065, HR of 0.098 mg/kg and STMR values 0.02 mg/kg for citrus fruit group.

Pome fruits

Forty-seven supervised trials on pome fruit (27 in apples and 20 in pears) were conducted in the USA in 1984-1987, using a higher number of applications and total seasonal rates compared to the GAP in the USA (up to 0.9 kg ai/ha and a PHI of 14 days).

Four trials in apple and pear complied with current US GAP. The residues were: in apple: 0,48, 0.58, 0.88 and 1.1 mg/kg; and in pear: 0.27, 0.3, 1.2 and 1.8 mg/kg.

The Meeting noted that the GAP in USA is for pome fruit, that the residue populations were not significantly different and that the median residues were within the 5 times range.

The Meeting concluded that the residues in apples and pears could be combined: 0.27, 0.3, 0,48, 0.58, 0.88, 1.1, 1.2 and 1.8 mg/kg.

The Meeting noted that in one of the pear samples the residue was 2 mg/kg, and estimated a maximum residue level of 3 mg/kg, HR of 2 mg/kg and STMR of 0.73 mg/kg

The Meeting withdraws its previous recommendation for maximum residue levels of 5 mg/kg

The meeting noted that the short-term intakes of apples and pears for children are 390% and 280% of ARfD, respectively.

There is no alternative GAP available to be considered.

Stone fruits

Supervised trials were carried out in USA on peaches (10), cherries (6) and plums (7) according to US GAP (2×0.45 kg ai/ha, 3 days PHI).

The average residues in duplicate composite samples derived from treatments corresponding to US GAP were: in peach: 0.44, 0.58, 0.65, 0.66, 0.70, 0.71, 0.73, 0.92, 1.0, 1.0 mg/kg; in plums; 0.18, 0.22, 0.23, 0.25, 0.32, 0.35, 0.67 mg/kg; and in cherries: 1.4, 1.5, 1.8, 1.9, 3.3, 3.4 mg/kg.

Since the residue populations are not similar, residue levels were estimated separately for each commodity.

The meeting estimated maximum residue, HR and STMR values for subgroups of: peaches 3 mg/kg, 1.1 mg/kg and 0.71 mg/kg; plums 1 mg/kg, 0.71 mg/kg and 0.25 mg/kg; and cherries 7 mg/kg, 3.53, and 1.85 mg/kg, respectively.

The meeting noted that the short-term intakes of peaches and cherries are 190% and 140% of ARfD for children, respectively.

There is no alternative GAP to be considered.

Berries and other small fruits

Strawberry

Eleven out of 12 trials conducted on strawberry in USA matched the US GAP (applications at up to 0.45 kg ai/ha for a total of 0.9 kg ai/ha per season and a PHI of 2 days).

The average residues in duplicate composite samples derived from treatments corresponding to US GAP were: 0.26, 0.38, 0.39, 0.48, 0.48, 0.55, 0.63, 0.65, 0.69, and 1.2 mg/kg.

The Meeting estimated maximum residue level, HR and STMR values of 2 mg/kg, 1.2 mg/kg and 0.515 mg/kg, respectively.

Raspberry

Seven supervised trials on raspberries were conducted in the USA in 2005 with higher rate and shorter PHI (total 0.9 kg/ha with 2 days PHI) than the current GAP for caneberries (applications at up to 0.34 kg ai/ha for a total of 0.67 kg ai/ha per season and a PHI of 3 days).

As no trial matched the GAP, recommendation cannot be made.

Grape

Twenty five supervised trials were conducted on grapes in the USA during 1983–2001 ($2 \times$ maximum rate of 0.45 kg ai/ha, the maximum seasonal rate of 0.9 kg/ha with 21 days PHI).

The trial data did not match the critical GAP of the USA. As a result no recommendations could be made.

The Meeting withdraws its previous recommendation of 5 mg/kg.

Assorted tropical and subtropical fruits – Edible peel

Olives

Three supervised trials were conducted on olives in the USA during 2005 matching US GAP ($3 \times$ 0.34 kg ai/ha with total seasonal application rates of about 0.9 kg ai/ha and 7 days PHI).

The average residues in pitted olives from two composite samples derived from treatments corresponding to maximum application rates were in rank order: 1.9, 2.2, and 3.6 mg/kg.

Three residue values were not considered sufficient for the estimation of maximum residue levels in olives.

Fruiting Vegetables, Cucurbits

Cucumber

Six supervised trials on cucumber were conducted in the USA in 1994 and 1996, following the GAP in the USA for cucurbit vegetables (applications at the rate of up to 0.34 kg ai/ha at 7 days intervals for a total of 0.9 kg ai/ha/season; PHI is 7 days).

The Meeting noted that the trials were not conducted at maximum GAP. For multiple treatments proportionality could be applied. As a result no recommendations could be made.

Melon

Ten supervised trials on cantaloupe were conducted in the USA in 1994 following the GAP in the USA for cucurbits (applications at the rate of up to 0.34 kg ai/ha for a total of 0.9 kg ai/ha/season; PHI is 7 days).

The Meeting noted that the trials were not conducted at maximum GAP. As the number of applications and or the applied dosage rate differed from maximum GAP, the proportionality could not be applied. As a result no recommendation could be made.

Summer squash

Seven supervised trials on summer squash were conducted in the US in 1994 and 1996, following the GAP in the US for cucurbits (applications at the rate of up to 0.34 kg ai/ha for a total of 0.9 kg ai/ha/season; PHI is 7 days)

The Meeting noted that the trials were not conducted at maximum GAP. As the number of applications and or the applied dosage rate differed from maximum GAP, the proportionality could not be applied. As a result, no recommendation could be made.

*Fruiting vegetables other than Cucurbits**Tomato*

Nine supervised trials conducted on tomatoes in the USA in 1993 matching the US GAP for fruiting vegetables other than cucurbits (applications at the rate of 0.22-kg ai/ha at 7 days intervals but not more often than 7 days, PHI is 3 days) were received.

The average residues in two composite samples derived from treatments corresponding to maximum application rates, in ranked order, were: 0.05, 0.08, 0.11, 0.18, 0.19, 0.21, 0.27, 0.30, and 0.55 mg/kg.

Peppers

Ten supervised trials on peppers (6 on bell and 4 on non-bell) were conducted in the USA in 1996 and 1998. The application rates corresponded to US GAP (0.22 kg ai/ha up to 0.9 kg ai/ha, 3 days PHI), but samples were taken at 2 and 4 days instead of the 3 day PHI.

The average residues in two composite samples were: in Bell pepper: 0.10, 0.34, 0.37, 0.37, 0.50, 0.67 mg/kg; and Chili pepper: 0.24, 0.31, 0.38, 0.40 mg/kg

The Meeting noted that the residues obtained 2–4 days after last application were in a relatively narrow residue range (2×median) leading to lower maximum residue estimate than would be generally expected. Therefore the residue values obtained at day 2 (-33% of PHI) were considered acceptable. (Only one residue data (0.50 mg/kg) was obtained at day 3 and one at day 4 (0.10 mg/kg).

The Mann-Whitney U-test confirmed that the above data could be combined for the estimation of the maximum residue level and STMR. The ranked order of residues from supervised trials on peppers were: 0.10, 0.24, 0.31, 0.34, 0.37, 0.37, 0.38, 0.40, 0.50, and 0.67 mg/kg.

The Meeting noted that the GAP in USA is for fruiting vegetables, other than cucurbits and the residue populations were not significantly different (Kruskal-Wallis H-test) and the median residues were within 5 times range. However, the short-term intake for eggplants would exceed the ARfD by 110% for adults. Consequently, a recommendation for the fruiting vegetables crop group could not be made.

No alternative GAP was available for fruiting vegetables other than cucurbits.

The Meeting therefore agreed to estimate residue levels for individual commodities:

Tomato: maximum residue level of 1 mg/kg, HR of 0.64 mg/kg, STMR of 0.19 mg/kg.

Peppers including chili pepper: maximum residue level of 1 mg/kg, HR of 0.70 mg/kg, STMR of 0.37 mg/kg.

Chili peppers, dried (based on concentration factor of 7): maximum residue level of 7 mg/kg, HR of 4.9 mg/kg mg/kg, STMR of 2.59 mg/kg.

The meeting confirms its previous recommendation for maximum residue level of 1 mg/kg for tomatoes.

Pulses

Soya beans

Eight supervised trials on soya beans were conducted in Brazil in 2010 and 2013, following the GAP in Brazil (one applications at the rate of 0.045 kg ai/ha and a PHI of 30 days). Residues in all samples were below the limit of quantification (< 0.01 mg/kg).

The Meeting estimated a maximum residue and STMR values of 0.01 mg/kg.

Cotton

Thirty-two supervised trials on cotton were conducted in the USA in 1983–1989 with application rates up to 0.9 kg ai/ha and a PHI of 21 days. The current US GAP is up to 0.45 kg ai/ha with a seasonal maximum rate of 0.9 kg/ha and a PHI of 21 days.

As 5–10 applications were made with low dose rates, which do not represent the critical GAP, no recommendations could be made.

The Meeting withdraws its previous recommendation of 1 mg/kg.

Tree nuts

A total of ten supervised trials on tree nuts, 5 on almonds and 5 on pecans have been conducted in the US in 2003, with application rates of 0.45 and 0.9 kg ai/ha at 7 days intervals instead of the minimum 10 days specified on the label.

The following average residue levels in two composite samples were obtained from the trials on almonds and pecans:

Almond nutmeat: < 0.01(4), 0.03 mg/kg; and in pecans: < 0.01, 0.01, 0.02, 0.05, 0.06 mg/kg.

The Meeting noted that the GAP in USA is for tree nuts and the residue populations were not significantly different (Mann-Whitney U-test) and the median residues were within 5 times range. The Meeting agreed to combine the datasets for almonds and pecans which, in ranked order, were: < 0.01(4), < 0.01, 0.01, 0.02, 0.03, 0.05, and 0.06 mg/kg.

As the highest residue in an individual samples was 0.1 mg/kg, the Meeting estimated a maximum residue level of 0.15 mg/kg, HR of 0.1 mg/kg and STMR value of 0.01 mg/kg.

Coffee Beans

Six supervised trials on coffee were conducted in Brazil in 2013 following the current GAP there (two applications at a maximum rate of up to 0.12 kg ai/ha and a PHI of 14 days).

Residues in composite samples, in ranked order, were: < 0.01(4), 0.01, and 0.02 mg/kg.

The Meeting estimated a maximum residue level of 0.03 mg/kg and STMR value of 0.01 mg/kg.

Tea

All supervised trials on tea were conducted in India during 2002-2004. The compound was applied according to the GAP in India (0.05-0.06 kg ai./ha with a PHI of 7 days) and with double rate.

Six trials on black tea and in one trial green tea leaves (0.13 mg/kg) were analysed

The residues in composite samples following application at the GAP rate were: < 0.05, 0.13, 0.14(2), 0.17, 0.18, and 1.38 mg/kg.

The Meeting estimated a maximum residue level for green and black tea of 3 mg/kg and STMR value of 0.14 mg/kg.

The Meeting withdrew its previous recommendation of 2 mg/kg for maximum residue level for tea.

Animal feeds

Almond hulls

The US GAP specifies application rates of up to 0.45 kg ai/ha with a seasonal maximum of 0.9 kg ai/ha at 10 days intervals, and a PHI of 3 days.

In almond hulls, the ranked order of residue concentrations was 2.7, 2.9, 3.1, 3.5, and 3.6 mg/kg. The Meeting estimated a maximum residue level of 10 mg/kg, the highest residue is 3.6 mg/kg and the median residue is 3.1 mg/kg.

Cottonseed hull

The trial conditions did not match US GAP (2×0.45 , max seasonal rate 0.9 mg/kg, PHI 21 days), no recommendations could be made.

Fate of residues during processing

Processing studies were carried out on plums, tomato, olives, oranges, cottonseed and tea.

The processing factors calculated and STMR-P values estimated are summarized below.

Summary of selected processing factors and STMR-P values for fenpropathrin

RAC/processed fraction	Processing factors					PF estimated	STMR-P (mg/kg)
RAC: Whole orange	-						
Juice	< 0.02	< 0.22				< 0.02	0.007
Oil	78.7	21.56				50.1	16.5
Wet peel	0.6	0.78	2.76		2.86	2.82	0.93
Dried peel	1.6	2.67				2.1	0.70
Pulp			0.06		0.07	0.065	0.021
RAC: Plum							
Dried plum	2.56					2.56	0.639
RAC: Tomato							
Canned	0.077	0.071	0.077			< 0.075	0.021
Wet pomace				9.9	9.8	9.8	1.867
Dry pomace				46	45.0	45	8.618
Tomato paste				0.78	0.75	0.77	0.145
Tomato juice				0.12	0.1	0.12	0.023

Note: The residues measured in RAC samples taken at the processing plants are considered as they better reflect the residues in unprocessed commodities than these measured in field samples

There is no concentration of residues in juice and molasses. Residues concentrate in oil (Pf=50.1), and dried peel (Pf=2.1).

The Meeting estimated a maximum residue level of 100 mg/kg and STMR-P of 16.5 mg/kg for citrus oil,

Drying concentrates the residues of fenpropathrin in plums by a factor of 2.6×; The Meeting estimated a maximum residue level of 3 mg/kg, HR-P of 1.85 mg/kg and STMR-P of 0.65 mg/kg for dried plums (or prunes).

As no MRL could be estimated, the Meeting withdrew its previous recommendation of 3 mg/kg for cottonseed oil.

Residues in animal commodities

Estimation of dietary burden

The maximum and mean dietary burdens were calculated using the highest residues or median residues of fenpropathrin estimated at the current Meeting on a basis of the OECD Animal Feeding Table. Only almond hull, citrus pulp and tomato wet pomace can be used as animal feed based on recommended uses. The calculated maximum and mean animal burdens are summarised below

Summary of livestock dietary burdens (ppm of dry matter diet)

	US-Canada		EU		Australia		Japan	
	max	mean	max	Mean	max	mean	Max	mean
Beef cattle	0.09	0.09	0.045	0.045	1.46 ^a	1.46 ^b	0	0
Dairy cattle	0.43	0.04	0.18	0.18	1.46	1.46	0	0
Broilers	0	0	0	0	0	0	0	0
Layers	0	0	0	0	0	0	0	0

^a Suitable for estimating maximum residue levels for milk, meat, fat and edible offal of cattle.

^b Suitable for estimating STMRs for meat, fat and edible offal of cattle.

Farm animal feeding studies

Lactating Holstein cows were orally administered technical grade fenpropathrin (purity 92.5%) via gelatin capsules for 28 consecutive days in two equal portions at the morning and evening milkings. The treatment levels were 0, 25, 75 and 250 ppm fenpropathrin based upon the daily average food consumption.

Residues of fenpropathrin in the milk reached a plateau after three days. Average residues in the whole milk of the four cows of each group on Day 3 were 0.04, 0.17 and 0.33 mg/kg for the three dose levels. On Day 28, these levels were 0.04, 0.13 and 0.32 mg/kg. At the end of the three-day depuration period, residues had fallen to < 0.01, 0.02 and 0.04 mg/kg for the three levels. Pasteurization did not significantly reduce fenpropathrin residues in milk. The residues concentrated in milk fat by a factor of about 10 (from mean of 0.32 mg/kg in whole milk to 3.7 mg/kg in milk fat)

After 28 days of dosing, maximum and (average) residues, expressed in mg/kg, in muscle, kidney, liver and fat were 0.33 (0.2), 0.2 (0.16), 0.01 (0.01), and 4.1 (3.8) mg/kg, respectively, at the maximum 250 ppm dose level. The residues determined after feeding with 25 ppm fenpropathrin in

feed, and the corresponding residues in tissues and milk resulted from the calculated mean and max dietary burden (1.46 ppm) are summarised below.

Dietary burden	Fat		Meat		Liver		Kidney		Milk
	Max	Mean	Max	Mean	Max	Mean	Max	Mean	Mean
25 ppm	0.44	0.33	0.04	0.02	< 0.01	< 0.01	0.05	0.03	0.04
1.46 ppm	0.026	0.018	0.002	0.001	< 0.0006	< 0.0006	0.003	0.002	0.002

Based on the data available the Meeting estimated maximum residue levels of 0.03 mg/kg, HR value of 0.026 mg/kg and STMR value of 0.018 mg/kg for mammalian fat except milk fat.

The Meeting estimated, at the LOQ of 0.01 mg/kg, maximum residue level of 0.01 mg/kg for mammalian meat and edible offal and 0.01 mg/kg for milk. The HR values for meat and edible offal are 0.002 mg/kg and 0.003 mg/kg, respectively

The Meeting estimated STMR values of 0.001 mg/kg for mammalian meat, 0.002 mg/kg for mammalian, edible offal of, and 0.002 mg/kg for milk.

The Meeting withdraws its previous recommendations for cattle meat, edible offal and milk.

Laying hens

Laying hens were dosed at nominal concentrations of 0, 2.5, 7.5 and 25 ppm levels for a period of 28 days. The fenpropathrin residues were below 0.01 mg/kg in case of dose groups 2.5 and 7.5 ppm over the study period. Eggs derived from 25 ppm dose contained 0.02 mg/kg fenpropathrin from day 7. Residues in muscle, gizzard and liver samples were below the LOQ of 0.01 mg/kg in all dose groups. The fenpropathrin residue in fat was 0.02, 0.05 and 0.14 mg/kg for dose groups of 2.5, 7.5 and 25 ppm. Metabolites could only be detected in liver after dosing with 25 ppm were TMPA (0.05 mg/kg) and PBA-glycin (0.03 mg/kg). The distribution of residues between white and yolk was not studied.

Taking into account that poultry feed is not treated with fenpropathrin according to the uses evaluated by the present Meeting, the Meeting estimated maximum residues levels in poultry meat, fat, edible offal and eggs of 0.01 mg/kg*.

The Meeting estimated STMR values of 0 for poultry products

The Meeting withdraws its previous recommendations for poultry products.

RECOMMENDATIONS

On the basis of the data from supervised trials, the Meeting concluded that the residue levels listed below are suitable for establishing maximum residue limits and for IEDI assessment.

Definition of residue for compliance with MRL and for estimation of dietary intake for animal and plant commodities is fenpropathrin.

The residue in fat soluble.

CCN	Commodity Name	Recommended MRL, mg/kg		STMR/STMR-P mg/kg	HR/HR-P mg/kg

DIETARY RISK ASSESSMENT

Long-term intake

The evaluation of fenpropathrin resulted in recommendations for MRLs and STMR values for 24 raw and processed commodities. Where data on consumption were available for the listed food commodities, dietary intakes were calculated for the 17 GEMS/Food Consumption Cluster Diets. The results are shown in Annex 3 to the 2014 Report.

The IEDIs in the seventeen Cluster Diets, based on the estimated STMRS were 1-10% of the maximum ADI (0.03 mg/kg bw). The Meeting concluded that the long-term intake of residues of fenpropathrin from uses that have been considered by the JMPR is unlikely to present a public health concern.

Short-term intake

The International Estimated Short-term Intake (IESTI) for fenpropathrin was calculated for 24 raw and processed commodities for which maximum residue levels and STMR values were estimated. The results are shown in Annex 4 to the 2014 Report.

For cherries, peaches, and pome fruits the IESTI represented 140%, 180% and 390% of the ARfD of 0.03 mg/kg bw, respectively. No alternative GAP was available. On the basis of information provided to the JMPR it was not possible to conclude that the estimate of short-term intake of fenpropathrin, from the consumption of cherries, peaches and pome fruits, was less than the ARfD.

The other commodities considered by the JMPR were within 0–80% of ARfD. The Meeting concluded that the short-term intake of fenpropathrin when used in ways that have been considered by the MPR is unlikely to present public health concern.

FLUOPICOLIDE (235)

see also DICHLOBENIL (274)

APPRAISAL

Fluopicolide was first evaluated for residues and toxicological aspects by the 2009 JMPR.

A residue definition of *fluopicolide* was established for compliance with the MRL for both plant and animal commodities, with a residue definition of *fluopicolide* and *2,6-dichlorobenzamide*, measured separately, for dietary risk assessment. A number of maximum residue levels were estimated by the 2009 Meeting.

Dichlobenil was evaluated by the present Meeting for both toxicological and residues aspects. The Meeting established an ADI of 0–0.05 mg/kg bw and ARfD of 0.3 mg/kg bw for 2,6-dichlorobenzamide. The only significant residue of dichlobenil in both plant and animal commodities was 2,6-dichlorobenzamide. The Meeting recommended a residue definition for dichlobenil of 2,6-*dichlorobenzamide* in plant and animal commodities, for both compliance with the MRL and dietary risk assessment.

The Meeting noted that 2,6-dichlorobenzamide residues can arise from use of either fluopicolide or dichlobenil, and that there were a number of crops for which there are fluopicolide use, but no dichlobenil use. The Meeting noted that maximum residue levels were required to accommodate residues of 2,6-dichlorobenzamide arising from use of fluopicolide. See dichlobenil.

FLUENSULFONE (265)

The first draft was prepared by Dr Michael Doherty, United States Environmental Protection Agency, Washington, DC, USA

EXPLANATION

Fluensulfone is a non-fumigant, fluoroalkenyl nematicide used to control nematode pests in cucurbit vegetables, eggplant, peppers, and tomatoes. Fluensulfone shows activity in multiple nematode physiological systems; however, its specific nematicidal activity is not known at this time. Fluensulfone was considered for the first time for toxicology by the 2013 JMPR and for residues by the 2014 JMPR.

IDENTITY

ISO common name	Fluensulfone (provisionally approved)
Chemical Name	
IUPAC	5-chloro-1,3-thiazol-2-yl 3,4,4-trifluorobut-3-en-1-yl sulfone
CAS	5-chloro-2-[(3,4,4-trifluoro-3-buten-1-yl)sulfonyl]thiazole
CIPAC No.	Not Listed
CAS No.	318290-98-1
Synonyms	MCW-2
Structural Formula	
Molecular formula	C ₇ H ₅ ClF ₃ NO ₂ S ₂
Molecular mass	291.7

DT ₅₀ irr. = < 11 hours of continuous sun test irradiation, when extrapolated to environmental conditions results in a DT ₅₀ < 1 day for all latitudes.	Schick, M 2011 R-23322

Fluensulfone is registered as an emulsifiable concentrate (EC) formulation containing 480 g ai/L.

METABOLISM AND ENVIRONMENTAL FATE

Metabolism and environmental fate studies were conducted with [thiazole-4-¹⁴C]fluensulfone and [trifluorobutene-1,2-¹⁴C]fluensulfone (Figures 1 and 2).

Figure 1 [thiazole-4-¹⁴C]fluensulfone

Figure 2 [trifluorobutene-1,2-¹⁴C]fluensulfone

Chemical names, structures, and code names of metabolites and degradation products of fluensulfone are shown below.

Known metabolites and degradation products of fluensulfone

Code Names	Chemical name, molecular formula, molar mass	Structure	Where found
Fluensulfone (parent compound) MCW-2	CAS: 5-chloro-2-(3,4,4-trifluoro- but-3-ene-1-sulfonyl)-thiazole CAS No. 318290-98-1 IUPAC: 5-chloro-1,3-thiazol-2-yl 3,4,4-trifluorobut-3-en-1-yl sulfone $C_7H_5ClF_3NO_2S_2$ 291.70 g/mol		Soil, poultry, rotational crops (minor)
M-3625 Thiazole sulfonic acid TSA	IUPAC: 5-chloro-1,3-thiazole-2- sulfonic acid $C_3H_2ClNO_3S_2$ 199.64 g/mol		Soil, crops, rotational crops, rat (minor)
M-3626 Thiazole methyl sulfone MeS	IUPAC: 2-methylsulfonyl-1,3- thiazole $C_4H_5NO_2S_2$ 163.22 g/mol		Soil, ruminant, rat (minor)
M-3627 Butene sulfonic acid BSA	IUPAC: 3,4,4-trifluorobut-3-ene- 1-sulfonic acid $C_4H_5F_3O_3S$ 190.14 g/mol		Soil, crops, rotational crops, rat (minor)
Butene sulfinic acid	IUPAC: 3,4,4-trifluorobut-3-ene- 1-sulfinic acid $C_4H_5F_3O_2S$ 174.14 g/mol		Rat, ruminant
thiazole mercapturate	IUPAC: 2-acetamido-4-(1,3- thiazole-2-sulfonyl)butanoic acid $C_9H_{12}N_2O_5S_2$ 292.33		Rat
MW-327-I and MW-327-II Thiazole glucuronides (α and β isomers)	Structure not specified $C_9H_{12}NO_6S$ 262.26		Rat

Animal Metabolism

The Meeting received metabolism studies on laboratory animals (2013 Meeting), lactating goats, and laying hens. Note that in the tables below, all data are reported to the level of precision specified in the study reports. All of the studies were conducted with fluensulfone which was radio-labelled,

separately, in the thiazole ring [Thiazole-4- ^{14}C ; Th- ^{14}C] and the ethane bridge between the sulfonyl and trifluorobutene moieties [Trifluorobutene-1,2- ^{14}C ; Bu- ^{14}C].

In animals, fluensulfone is cleaved at the sulfonyl bridge, apparently via glutathione conjugation, to yield products based on the thiazole and trifluorobutene halves of the parent molecule, with each half having the SO_x moiety. No parent fluensulfone was detected in any rat or lactating goat matrix, whereas parent fluensulfone was a major residue ($> 10\%$ of the total radioactive residue, TRR) in poultry fat. In both lactating goat and laying hen, radiolabel from fluensulfone was incorporated into natural products (lactose/glucose in the goat study; sugars, fatty acids, and proteins in the hen study).

Laboratory animals

Fluensulfone was rapidly absorbed at a dose level of 5 mg/kg bw, but the absorption phase was significantly longer at 500 mg/kg bw. The recovery of excreted radiolabel was 94–99% for individual rats. Radiolabel was found mainly in urine (71–83%), faeces (9–11%) and the cage wash (6–16%). One day after dosing with radiolabelled fluensulfone, an average of 0.6–0.8% of the administered radiolabel was in liver and 0.1% in kidney, with 1.7–2.1% in the carcass and 4.5–4.7% remaining in the gastrointestinal tract. By 7 days after treatment with radiolabelled fluensulfone, an average of 0.1–0.2% of the administered radiolabel remained in liver, and 0.03% in kidney.

The majority of the faecal radioactivity was not identified. It consisted of a number of peaks, each representing less than 2% of the administered dose; the only faecal metabolite representing more than 5% of the administered dose was thiazole sulfonic acid. In urine, there were no metabolites common to both radiolabels, which indicate that the initial step is cleavage at the sulfonyl bond. The initial reaction is probably with glutathione to release the trifluorobutene group and conjugation of the thiazole moiety.

Lactating goats

The metabolism of fluensulfone in lactating goats was investigated by LaMar and Quistad (2010, Study R-25458). For each radiolabel position, a single goat was dosed for five days at ca. 29 mg/day (equivalent to 10 ppm in the diet). Milk was collected twice daily and excreta were collected once daily throughout the study. Goats were sacrificed 20–22 hours after the final dosing, at which point tissues, bile, blood, and GI tract (with contents) were collected for analysis.

Total radioactive residues were determined by liquid scintillation counting (LSC) of solubilized tissues (liver, kidney, muscle, blood, bile, and fat), combusted samples (faeces, GI tract), or direct counting (urine). Samples of liver, kidney, and muscle were extracted with twice with acetonitrile:water (ACN:H₂O, 1:1, v/v) and once by ACN (neat) for extraction of residues for characterization and identification. Samples of flank muscle from the butene-label treated goat were additionally extracted with hexane:acetone (4:1, v/v) followed by acetone (neat) prior to alkaline

treatment of the post-extraction solids (PES). Residue analysis for these extracts was by high-performance liquid chromatography (HPLC) and, in some cases, thin-layer chromatography (TLC). For milk, the fat component was separated by centrifugation and extracted with acetone:hexane (1:4, v:v) and then once with acetone. The non-fat milk portion was extracted with acetone to precipitate milk proteins, which were then extracted with acetone:water (1:1, v:v). The resulting extract was added back to the skim milk for direct analysis by HPLC and TLC. Post-extraction solid fractions of all matrices except skim milk and poultry fat underwent further treatment, including alkaline digestion which was followed by acid digestion for liver and kidney (butene label only). Numerous HPLC systems with varying stationary and mobile phases were investigated to achieve satisfactory separation of the radiolabelled components, with detection by UV absorption or mass spectrometry (MS). Identification of metabolites was by co-chromatography with known standards and/or by mass spectral analysis.

The total recovery of radioactivity was 67 and 87% of the AD for the thiazole- and butene-labels, respectively. Low total recovery could be attributed to conversion of radiolabelled material to $^{14}\text{CO}_2$ and the fact that the entire carcass was not analysed for radioactivity. Most of the radioactivity was recovered in urine (38–70% of the AD). The thiazole label excretion in urine was only 53% that of the butene label. Faeces and the gastrointestinal tracts, at sacrifice, contained 14–19% of the AD. Radioactivity in tissues and body fluids accounted for 11% (thiazole-radiolabel) and 3.5% (butene-radiolabel) of the administered dose (Table 1). For both radiolabel positions, residues appeared to plateau in skim milk and reach a steady state of excretion by Day 2 or Day 3 (Tables 2 and 3). It is unclear whether or not residues in milk fat reached a plateau during the treatment phase of the study.

The TRR levels were highest in the liver (0.87–1.6% of AD), followed by kidney (0.1–0.2% of AD). TRR levels in thiazole-labelled muscle samples were about 4 times those found in the butene-labelled muscle samples (ca. 0.22–0.24 mg fluensulfone eq/kg vs. ca. 0.04–0.05 mg fluensulfone eq/kg). Muscle contained 4.2% of the AD for the thiazole label and ca. 1% of the AD for the butene label. Fat had low levels of radioactivity (ca. 0.07–0.13 mg fluensulfone eq/kg (thiazole label) and 0.04–0.07 mg fluensulfone eq/kg (butene label)). Milk contained 1.7% (thiazole label) and 1.1% (butene label) of the administered dose with the thiazole label being excreted at a higher rate than the butene label.

Fluensulfone and the known plant metabolites (i.e. methyl sulfone, thiazole sulfonic acid and butene sulfonic acid) were not identified in any of the goat milk or tissue samples. Thiazole methyl sulfone (25% TRR) and butene sulfinic acid (66% TRR) were identified in urine as major metabolites. No other fluensulfone-related ^{14}C -residues could be identified in any other matrix. Major radiolabelled residues were extensively broken down and appeared to be incorporated into natural products.

Lactose and glucose accounted for the majority of the radioactive residues in liver (ca. 8–9% of the TRR). The majority of the radioactivity, extractable by strong alkaline treatment (24% KOH), was assumed to be composed of a range of other sugars and natural products. Lactose was also the

major residue in skim milk (ca. 46–63% of the TRR). The majority of the remaining radioactivity (31–38% of the TRR) in both skim milk and liver was associated with proteins and amino acids. Radiolabelled glucose was also seen in kidney (13–17% of the TRR). Radioactivity associated with proteins in kidney accounted for 25–36% of the TRR.

Incorporation of radiolabelled residues into triglycerides was apparent in all fat matrices. In milk fat, radioactivity associated with fatty acids accounted for 8 and 31% of the TRR for the butene and thiazole labels, respectively. Fatty acid-radiolabel association in the remaining matrices was for subcutaneous fat (15 and 52% of the TRR), renal fat (24 and 21% of the TRR) and omental fat (13 and 43% of the TRR) for the thiazole and butene labels, respectively. Association of thiazole and butene labels with proteins was 5 and 34% of the TRR in milk fat and 5 and 15% of the TRR in subcutaneous fat.

Radiolabelled residues were also examined in blood with relation to bovine haemoglobin. It was apparent that radioactivity was associated with the globin-protein in haemoglobin in blood.

^a Flank muscle: thiazole = six unknowns, 3.2–12.4% TRR; butene = five unknowns, 3.7–13.0% TRR. Loin muscle:

thiazole = six unknowns, 1.7–20.1% TRR; butene = eight unknowns, 2.5–40.0% TRR. Further work indicates that these were likely to be natural components.

^b Flank muscle: thiazole = six unknowns, 1.8–23.0% TRR. Loin muscle: thiazole = six unknowns, 2.5–20.1% TRR.

In summary, fluensulfone was not a significant residue in goat tissues or milk. Initially the parent compound is cleaved, displacing butene sulfinic acid which is readily excreted in the urine. However, excretion of the butene half of the molecule is not fully effective and the butene moiety is likely broken down to carbon dioxide and enters the normal metabolic pathways. The thiazole half of the molecule is converted to the thiazole methyl sulfone for excretion, but is not excreted as quickly. Therefore, a much larger portion of the thiazole moiety is incorporated into natural products much in the same way as the butene label. Incorporation of radiolabelled residues into glucose and eventually into lactose takes place mainly in the liver, but is also seen in the kidneys. Lactose is then exported to be excreted in milk. Through the citric acid cycle (i.e. oxaloacetate) radiolabelled residues can also be converted and incorporated into fatty acids and a variety of amino acids (e.g. aspartate) then eventually into triglycerides and proteins.

Figure 3 Proposed metabolic pathway of fluensulfone in lactating goat

Laying hens

The metabolism of fluensulfone in laying hens was investigated by LaMar and Quistad (2010, Study R-25454). For each radiolabel position, a group of ten hens was dosed for seven consecutive days at ca. 1.3 mg/bird/day (equivalent to 9.8 ppm in the diet). Eggs were collected twice daily and excreta were collected once daily throughout the study. Hens were sacrificed 20–22 hours after the final dosing, at which point tissues and GI tract (with contents) were collected for analysis.

Tissues, including GI tract with contents, were each homogenized in the presence of dry ice. Total radioactive residues were determined by LSC of solubilized tissues (liver, muscle, and fat) or following combustion (faeces, GI tract). Samples of liver, eggs, and muscle were extracted with twice with ACN:H₂O (1:1, v/v) and once by ACN (neat) for extraction of residues for characterization and identification. Samples of fat were extracted twice with hexane:acetone (4:1, v/v) followed by acetone (neat). Following the extraction procedures, all samples underwent alkaline treatment (KOH in MeOH/H₂O) of the post-extraction solids (PES). Residue analysis for the various extracts was by high-performance liquid chromatography (HPLC) and/or thin-layer chromatography (TLC). Numerous HPLC systems with varying stationary and mobile phases were investigated to achieve satisfactory separation of the radiolabelled components, with detection by UV absorption or refractive index. Identification of metabolites was by co-chromatography with known standards.

In the treated laying hens, 80% (thiazole label) and 79% (butene label) of the AD were recovered. Most of the administered dose was recovered in the excreta and gastrointestinal tracts (76–80%; Table 13). Butene radiolabelled matrices contained consistently higher ¹⁴C-residues when compared to the thiazole radiolabel. For example, only 0.15% of the AD for the thiazole radiolabel was excreted in eggs compared to 1.7% for the butene radiolabel. Differences in the amount of total

radioactive residues between the two radiolabels can be attributed to increased incorporation into natural products for the butene label. Thiazole methyl sulfone and butene sulfonic acid were both identified in the excreta. For both radiolabel positions, residues in eggs steadily increased from Day 1 to Day 8 and did not plateau within the dosing period (Table 14).

In fat samples, solvent extraction (acetone:hexane) released 81–95% of the TRR. Solvent extraction in liver, egg, and muscle was not as efficient, releasing approximately 13–34% of the total radioactivity from the matrix of interest. Use of basic and/or acidic conditions was required to accomplish more quantitative extraction (Table 15).

The TRRs were highest for liver (thiazole label: 0.64 mg eq/kg; butene label: 1.4 mg eq/kg) and egg (thiazole label: 0.29 mg eq/kg; butene label: 4.06 mg eq/kg). Thiazole-labelled omental and subcutaneous fats (0.04 mg eq/kg and 0.08 mg eq/kg, respectively), contained substantially lower radioactivity compared to butene radiolabelled fat (both 0.31 mg eq/kg). Breast and thigh muscle had the lowest amount of radiolabel in comparison to other tissues; however, butene radiolabelled muscle contained significantly higher residues (0.13 mg eq/kg for both thigh and breast muscles), compared to thiazole radiolabelled muscle (both 0.04 mg eq/kg). No tissues other than liver accounted for more than 0.1% of the AD.

Fluensulfone was detected in omental and subcutaneous fat, (0.009 mg/kg and 0.04 mg/kg for thiazole label, 0.02 mg/kg and 0.04 mg/kg for butene label). Trace amounts of fluensulfone may have been present in other matrices but could not be confirmed due to low levels. With the exception of thiazole sulfonic acid in liver (0.02 mg/kg), no other metabolites of fluensulfone were identified in eggs or tissues. Thiazole methyl sulfone and butene sulfonic acid were identified in faeces. The majority of the radioactivity appeared to be incorporated into natural products such as natural sugars (in liver) fatty acids (in eggs, fat and liver) and in proteins. Comparison of extraction of radioactivity from liver samples treated with and without protease enzyme indicates that ca. 0.16 mg/kg (24% TRR) is associated with proteins and/or amino acids. Incorporation of the radioactivity into triglycerides was noted in both fat matrices and in eggs, and accounted for 7% and 27% of the TRR for the thiazole and butene labels, respectively, in eggs and for 7–12% and 79–87% of the TRR for the thiazole and butene labels, respectively, in the fat matrices. In excreta, the identified residues were the methyl sulfone and BSA metabolites; parent fluensulfone was not observed. The tables below summarize the results of the poultry metabolism study.

^a For the thiazole labelled thigh muscle, there were at least six unknowns with one having a retention time in the region of MCW-2. Each unknown accounted for 2.4–7.3% of the TRR. For the butene labelled thigh muscle, there were at least three unknowns which accounted each for 5.0–5.8% of the TRR. For the thiazole labelled breast muscle, there were at least six unknowns with one having a retention time in the region of MCW-2. Each unknown accounted for 0–11.1% of the TRR. For the butene labelled breast muscle, there were at least three unknowns which each accounted for 1.8–8.1% of the TRR.

^b Combined extracts are the 0.1 M KOH and 24% KOH extracts.

^c For the thiazole labelled thigh muscle, there was only one peak in the fraction.

^d For the thiazole labelled thigh muscle, there were at least four unknowns which each accounted for 2.4–9.8% of the TRR. For the thiazole labelled breast muscle, there were two unknowns each accounting for 19.4% of the TRR.

In summary, the poultry metabolism study indicates that the parent compound is cleaved displacing butene sulfinic acid, while the thiazole moiety is converted to the thiazole methyl sulfone and thiazole sulfonic acid. Both are eliminated in the excreta. Fluensulfone is broken down to carbon dioxide and subsequently enters normal metabolic pathways. Through the citric acid cycle, radiolabelled residues are converted and incorporated into fatty acids and a variety of amino acids, then eventually into triglycerides and proteins (as seen in fat and liver). The thiazole portion of fluensulfone is excreted at a slightly higher rate. The higher levels of butene radiolabel incorporation

into natural products can be mostly attributed to association with fatty acids, which is not as apparent with thiazole radiolabelled tissues.

Figure 4 Proposed metabolic pathway of fluensulfone in laying hens

Plant metabolism

The Meeting received studies depicting the metabolism of fluensulfone in tomato, lettuce and potato. All of the studies were conducted with fluensulfone which was radiolabelled, separately, in the thiazole ring and the ethane bridge between the sulfonyl and trifluorobutene moieties.

Fluensulfone was extensively metabolised in all of the studies, with the only major residues being the BSA and TSA metabolites. A few chromatographic fractions had radioactivity in excess of 10% TRR. Investigation of these fractions indicated that the residues were associated with the BSA or TSA metabolites, as salts or other forms of the compounds.

Tomato

The metabolism of fluensulfone was investigated in tomato by Quistad and Bautista (2011, Report OR-25456). For each radiolabel position, an application of fluensulfone, formulated as an emulsifiable concentrate (48% ai), was made to soil at a rate of 4.1 kg ai/ha. Later that same day, tomato seedlings were planted into the treated soil.

Mature tomato fruits were harvested 87 days after treatment. Total radioactive residues were determined by combustion and LSC. Samples were extracted with ACN and ACN:H₂O followed by strong basic hydrolysis for residue characterization and analysis by TLC and/or HPLC. Residue identification was by co-chromatography of the available reference standards. Presence of the known metabolites BSA, MeS, and TSA was confirmed by HPLC-UV, HPLC-MS, and TLC. For unknown

metabolites, the extracts were cleaned up by solid-phase extraction (SPE) with silica-gel columns followed by analytical and semi-preparative HPLC followed by HPLC-MS. No storage stability determination was required as storage time after harvest did not exceed 18 days. Nevertheless a tomato sample containing thiazole labelled residues was reanalysed after 178 days of frozen storage. Fruit was extracted with ACN:H₂O in the same way as the initial fruit sample. HPLC analysis of the combined ACN:H₂O extracts confirmed the stability of the extracts under storage conditions.

Total radioactive residues were higher in samples from the [Bu-¹⁴C]fluensulfone treatment than from the [Th-¹⁴C]fluensulfone treatment (Table 21). Residues were < 0.001 mg eq/kg in the control sample. There was good agreement between total residues based on the sum of extracted fractions and total residues based on the combustion analysis.

Residues were readily extracted with ACN + ACN:H₂O (Table 22), with the follow-up alkaline extraction releasing only an additional 7–8% of the TRR. No fluensulfone was detected in the tomato samples. The identified residues were predominantly the BSA (42% TRR) and TSA (45% TRR) metabolites from the [Bu-¹⁴C] and [Th-¹⁴C] treatments, respectively (Table 23). From the [Th-¹⁴C] treatment, M3, the most abundant unknown metabolite, was considered to be due to the non-retention of TSA, which is a known phenomenon for sulfonic acids. This was confirmed by analysis with and without the presence of matrix which had an effect on peak shape and also by assessing the effects of column loading. Some inter-conversion between M1 and M3 was also noted during these experiments. Further investigation of M1 and M2 suggests that these compounds were salts of TSA. Unresolved radioactivity accounted for 22% of the TRR. From the [Bu-¹⁴C] treatment, Fraction F1-F2 in the combined ACN:H₂O extracts accounted for 27% of the TRR and was found to be mainly due to unretained BSA. Fractions F4 and F5 (2–5% of the TRR) were salts of BSA or related compounds. Unresolved radioactivity accounted for 14% of the TRR.

Lettuce

The metabolism of fluensulfone was investigated in lettuce by Quistad and Bautista (2011, Report R-25455). For each radiolabel position, an application of fluensulfone, formulated as an emulsifiable concentrate (48% ai), was made to soil at a rate of 4.1 kg ai/ha. Lettuce seeds were planted prior to application.

Samples of lettuce foliage were collected 49 days (immature) and 64 days (mature) after treatment. Within 23 days of harvest, the harvested lettuce samples were homogenized and the TRRs in each sample were determined by combustion analysis and LSC. Samples were extracted with ACN:H₂O and ACN, followed by strong basic hydrolysis. For thiazole-labelled samples, the extract was analysed by HPLC and TLC. For butene-labelled samples, the extract was filtered and the individual residues were then purified by two different HPLC methods. Purified metabolite (butene sulfonic acid) was then analysed via TLC and LC-MS.

Total radioactive residues were higher in samples from the [Th- ^{14}C]fluensulfone treatment than from the [Bu- ^{14}C]fluensulfone treatment (Table 24). Residues were < 0.001 mg eq/kg in the control sample. There was good agreement between total residues based on the sum of extracted fractions and total residues based on the combustion analysis, although the total by sum of fractions was consistently ca. 87% of that determined by combustion.

Residues were readily extracted with ACN + ACN:H₂O (Table 25), with the follow-up alkaline extraction releasing an additional 5–20% of the TRR. Trace levels of fluensulfone were found in the immature lettuce samples from both radiolabel positions. Major residues were the BSA (24%

TRR/38% TRR, immature/mature) and TSA (68% TRR/71% TRR, immature/mature) metabolites from the [Bu-¹⁴C] and [Th-¹⁴C] treatments, respectively (Table 26). From the [Th-¹⁴C] treatment, the sum of all other fractions (including unresolved) accounted for 24% of the TRR. Further analysis showed that the separated fractions were salts of TSA and/or other forms of TSA. M3 was found to be polar and due to unretained TSA. M1 was found to be a TSA salt or artifact due to chromatography. Metabolites M4, M5 and M6 were also chromatographic artefacts. Unresolved radioactivity accounted for 6–17% of the TRR. From the [Bu-¹⁴C] treatment, the sum of all other fractions (including unresolved) accounted for 46–52% of the TRR. Unresolved radioactivity accounted for 14–24% of the TRR. Further investigation of unidentified fractions showed that most of the fractions were salts or other forms of BSA and/or BSA bound to matrix compounds. Therefore, only BSA is present as a major metabolite with minor amounts of conjugated parent.

Potato

The metabolism of fluensulfone was investigated in potato by Quistad and Bautista (2011, Report R-25459). For each radiolabel position, an application of fluensulfone, formulated as an emulsifiable concentrate (48% ai), was made to soil at a rate of 4.0 kg ai/ha ([Th-¹⁴C]label) or 4.1 kg ai/ha ([Bu-¹⁴C]label). Potato seed pieces were planted prior to application.

Samples of potato tuber were collected 70 days (immature) and 106 days (mature) after treatment. Within 35 days of harvest, the harvested potato tuber samples were homogenized and the TRRs in each sample were determined by combustion analysis and LSC. Samples were extracted with ACN:H₂O and ACN, followed by strong basic hydrolysis ([Bu-¹⁴C] treatment only) and strong acid extraction (mature samples only). The initial organic extract was analysed by HPLC and TLC.

Total radioactive residues were higher in samples from the [Th-¹⁴C]fluensulfone treatment than from the [Bu-¹⁴C]fluensulfone treatment (Table 27). Residues were < 0.001 mg eq/kg in the control sample. There was good agreement between total residues based on the sum of extracted fractions and total residues based on the combustion analysis.

Residues were readily extracted with ACN + ACN:H₂O (Table 28), with the follow-up alkaline extraction releasing an additional 12–22% of the TRR from the [Bu-¹⁴C] treated samples. For the mature [Bu-¹⁴C] treated sample, the acid extraction released ca. 8% of the TRR. Trace levels of fluensulfone were found in the mature tuber samples from both radiolabel positions (however, this was not confirmed by TLC analysis). Major residues were the BSA (31% TRR/26% TRR, immature/mature) and TSA (63% TRR/65% TRR, immature/mature) metabolites from the [Bu-¹⁴C] and [Th-¹⁴C] treatments, respectively (Table 29). From the [Th-¹⁴C] treatment, the sum of all other fractions (including unresolved) accounted for 25–29% of the TRR. The most abundant unidentified fraction in the combined ACN:H₂O extracts was M3 and accounted for 3–7% of the TRR. Further examination showed this was a polar fraction which was considered to be an artifact resulting from the non-retention of TSA. A small amount of M1 was detected (< 2% of the TRR) which may be attributable to methyl sulfone, but this was not confirmed by TLC analysis. Unresolved radioactivity accounted for 20–21% of the TRR and was attributed to matrix-bound radioactivity causing smearing within the HPLC column or remaining in the pre-column. Further extraction of the PES (8% of the TRR) was not performed due to the low levels of radioactivity compared the amounts that had been

identified. From the [Bu-¹⁴C] treatment, the sum of all other fractions (including unresolved) accounted for 46–50% of the TRR. The most abundant unidentified fraction was the composed fraction F1-F2 in the combined ACN:H₂O extracts which accounted for 16–18% of the TRR. It was found to be mainly due to unretained BSA. Unresolved radioactivity (due to chromatographic artefacts) accounted for 28% of the TRR. Three other fractions F4, F5 and F9, containing < 1% of the TRR, were also resolved but no identification work was carried out due to the very low levels of radioactivity.

Overall, the metabolism of fluensulfone in tomato, lettuce, and potato is similar and corresponds well with that observed in rotational crop (see below). An overall summary of the metabolic residue profile from the target crops studies is shown in Table 30, followed by the proposed pathway in Figure 5.

Table 30 Summary of results from metabolism studies with fluensulfone in tomato, lettuce, and potato

Figure 5 Proposed metabolic pathway of fluensulfone in target and rotational crops

Environmental fate in soil

The Meeting received studies depicting the photodegradation of fluensulfone on soil; aerobic soil metabolism of fluensulfone, TSA, and MeS; and a confined rotational crop study with radish, lettuce, and wheat.

Photolysis

Photolysis of fluensulfone on the surface of soil was investigated by Ponte (2012, Report R-23320) in a study consisting of a preliminary test phase and a definitive test phase. In both phases, [Bu-¹⁴C] or [Th-¹⁴C] labelled fluensulfone was applied to a medium textured sandy loam soil (Table 31) at a rate of 4 kg/ha. The soil was irradiated with artificial sunlight, continuously, for 14 days, corresponding to 32 days of natural sunlight at 38°N. Soils were maintained at 75% of field moisture capacity (at 1/3 bar) and sampled at various time points throughout the irradiation period. The experimental design included a trapping system to capture volatile organic compounds as well as CO₂. Volatilized radiocarbon was released from foam trap plugs by extraction with ACN. Soils were extracted with acetone:water (4:1, v/v). For each sample matrix, TRRs were determined by LSC of trap solution or extract. For determination of residues, soil extracts were analysed by HPLC-UV and co-chromatographed with known standards; confirmation of metabolites was by TLC.

Table 31 Characteristics of the Soil (Northwood, US) Used

Parameter (units)	Value
Source	Northwood, North Dakota, USA
pH in water	6.8
Cation Exchange Capacity (CEC, meq/100 g)	17
Organic Carbon (%)	2
% Moisture at 1/3 bar	21.9
% Moisture at 15 bar	14
% Moisture at 1/10 bar (pF 2.0)	29.3
Bulk Density (disturbed) (gm/cc)	1.02
Sand (%)	63
Silt (%)	16
Clay (%)	21
USDA Textural Classification	Sandy Loam
FAO Textural Class	Medium
Olsen Phosphorus (ppm)	11
Total Nitrogen (Analyser) (%)	0.16
Soluble Salts (mmhos/cm)	0.17
Base Saturation Data	
Cation	Percent / ppm
Calcium	63.2 / 2152
Magnesium	20.4 / 417
Sodium	0.3 / 13
Potassium	3.8 / 253
Hydrogen	12.2 / 21

In irradiated samples, fluensulfone levels decreased from their initial levels to 52% ([Bu-¹⁴C]) or 34% ([Bu-¹⁴C]) of the AR (Tables 32-34).
